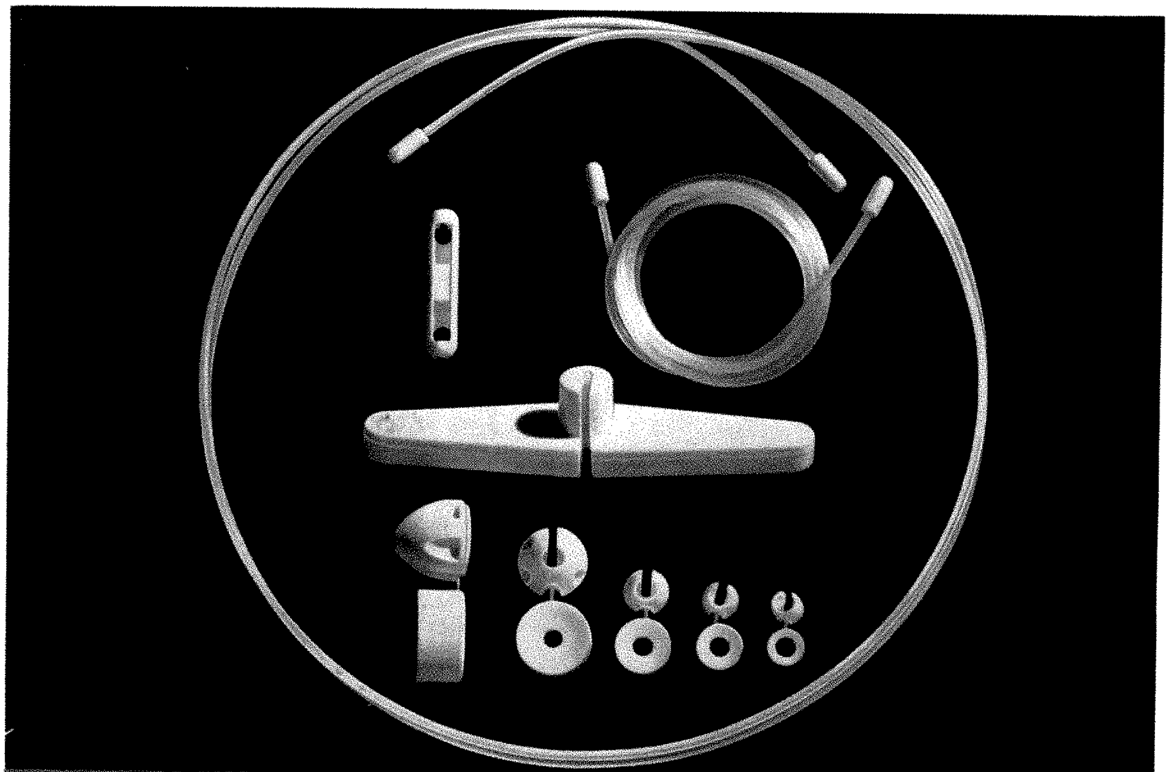
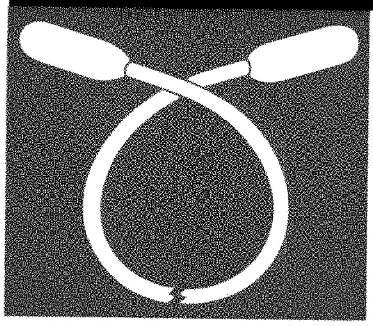
Armour Vein Stripper

Sterile, disposable, non-toxic and pyrogen-free

Eliminates time-consuming preparation and cleaning

Sterilised by irradiation



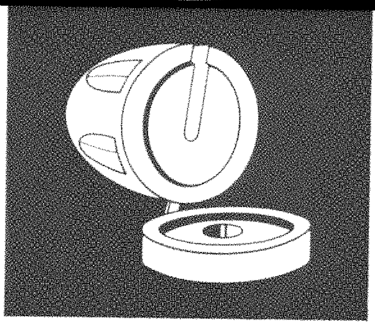


Nylon Cable

Has optimum handling quality.

Every end stop individually tested for firmness of attachment.

Breaking load of cable in excess of 150 lb.

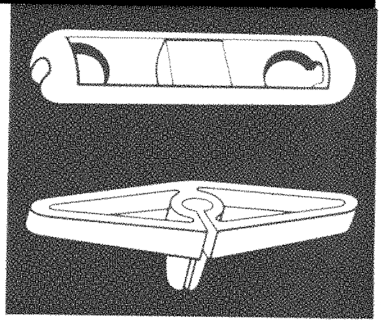


Nylon Olives

Snap fit for convenience of assembly.

Clean, well-defined cutting edge.

Hole without edge access prevents cable detachment.



Nylon Coupler and Draw Handle

Smooth, compact, coupling, ensures security of union.

Light, strong, well shaped.

UBRETID®
distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of **UBRETID** ampoules and tablets are available upon request.

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·83	£3·70	£4·27	£5·70	£5·69	£6·32	£7·74	£8·99

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 58. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St Martin's House, 159 Clapham High Street, London, SW4 7SU* (telephone 01 622 9225).

INSTRUCTIONS TO AUTHORS

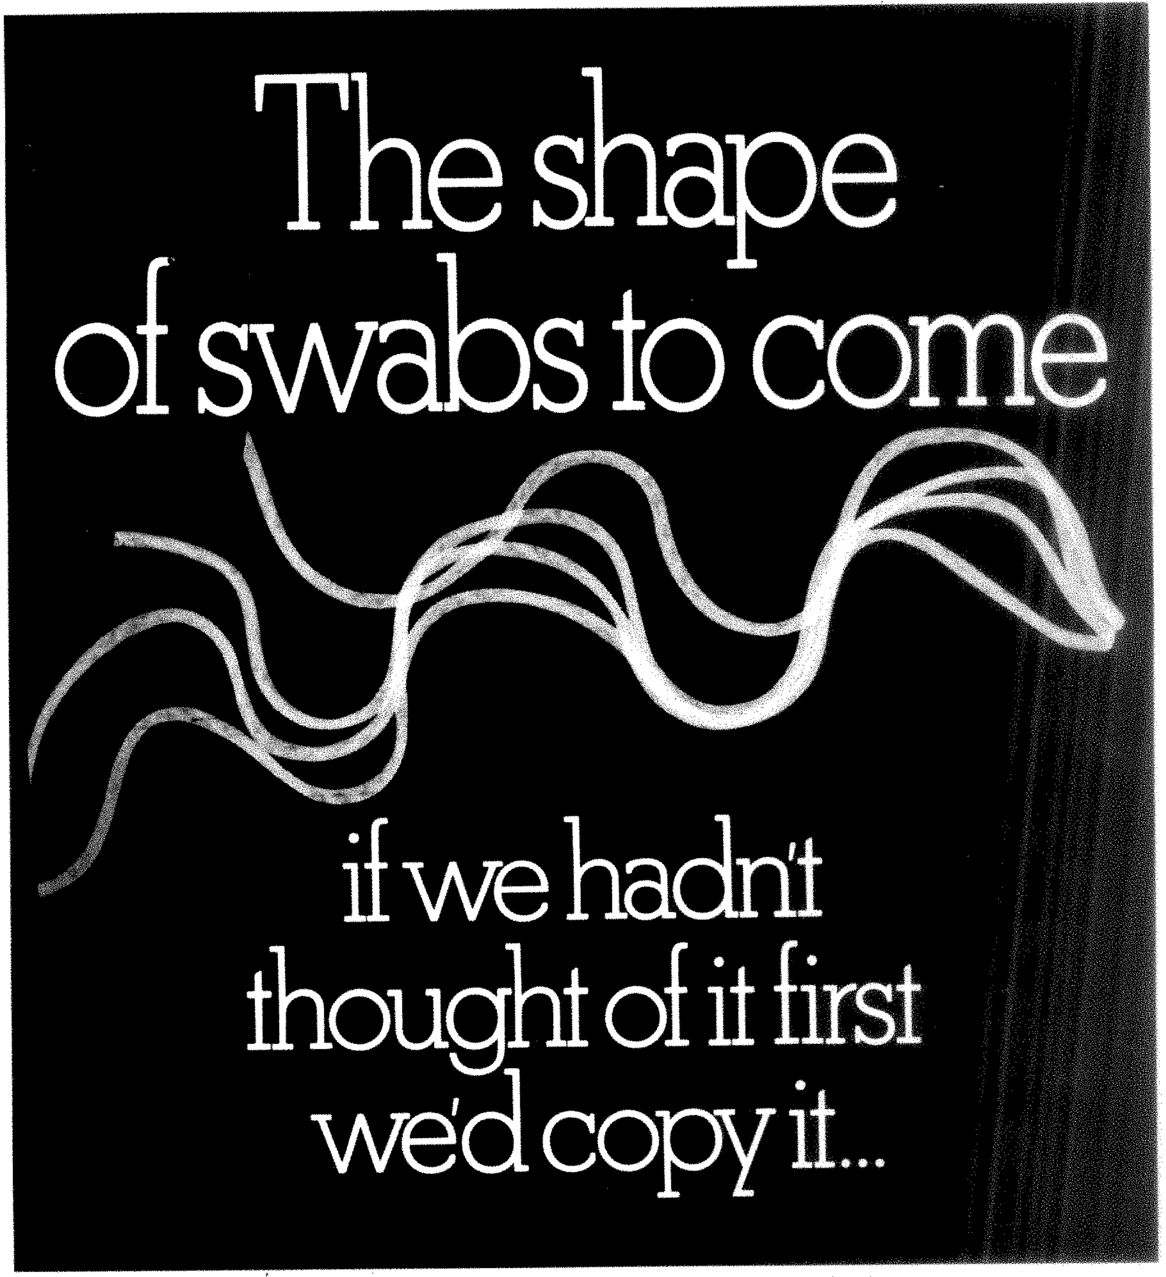
PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may than be inserted in the text without interrupting it with a list of names.



The new X-Ray images of RAY-TEC* X-Ray Detectable Swabs
are more distinctive, and more difficult to confuse on an X-Ray plate with any
natural structure in the body.

Now you can immediately distinguish RAY-TEC* X-Ray Detectable Swabs,
the only X-Ray Detectable Swabs backed by over 20 years of manufacturing know how
and Johnson & Johnson's stringent quality control.

At Johnson & Johnson Limited we would be the first
to admit that if we had not thought of such a good idea
first . . . we'd copy it.

The most important pipe cleaner in the world...

Eschmann Embolectomy Catheter

- ✳ Pure latex balloon—soft when inflated to conform to arterial irregularities
- ✳ X-ray opaque — so you can see what it's doing
- ✳ Graduated along the shaft — so you can see where it is
- ✳ Colour coded — to help find the right size quickly
- ✳ Sterile—in rigid protective pack
- ✳ Made with care and tested with concern

It all adds up to the most important pipe cleaner in the world.

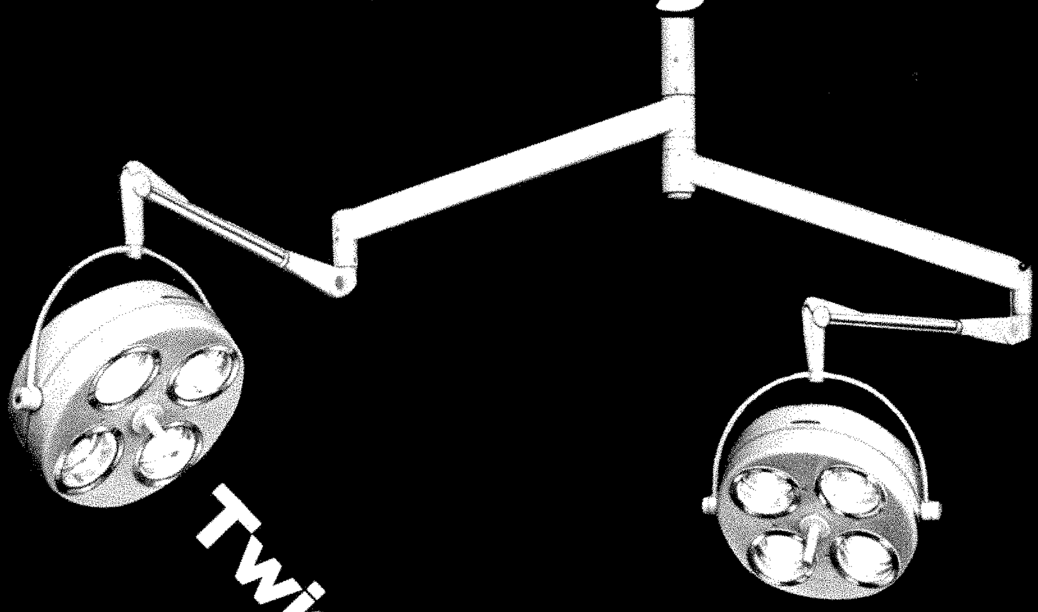
Manufactured by

ESCHMANN

Shoreham-by-Sea, Sussex

Available from established surgical dealers.

Twice the light!



Twice the manoeuvrability!

The Hamburg lamp is well known for its powerful light source and great manoeuvrability.
Now just think what two can do!
The Double Hamburg doubles everything..... twice the light.... twice the manoeuvrability.
Each lamp can be adjusted seperately by any member of the operating team, by its sterilisable handle. Now the field of light can be placed where its needed.... concentrated and intense, yet cool.

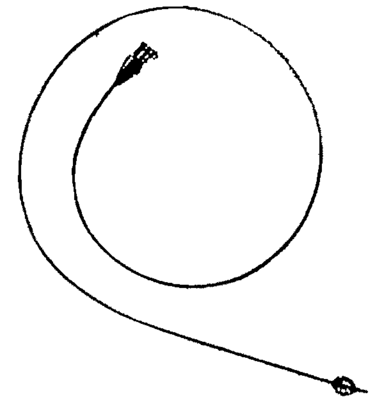
FOGARTY CATHETERS FOR ACUTE VASCULAR OCCLUSION



FOR. Venous Thrombectomy
- Occlusion/Emergency Tamponade
- Arterial Embolectomy
- Dilation/Creation of Atrial Septal Defects in Infants
- Double Lumen Balloon Catheter/Creation of Atrial Septal Defects in Infants
- Biliary Balloon Probe/Exploration and Removal of Debris and Stones
- Irrigation
- Rugged Universal Hub Fits All Luer-Lok Type Syringes

BALLOON CATHETER CONCEPT

Each catheter has a specially constructed balloon at the distal tip (except Irrigation Catheter). In thrombectomy and embolectomy, when the catheter is introduced into a vein or artery, the instrument follows the path of least resistance and the tip threads itself past the thrombus or plaque. The balloon is then inflated with sterile fluid and the catheter withdrawn, bringing the clot with it. As an emergency tamponade, for dilation, or as a biliary probe, the balloon is similarly inflated.

GENERAL DESIGN FEATURES

1. Tips on the various types are specially designed for the particular procedure, all are soft and atraumatic
2. Controlled symmetrical balloon geometry
3. Secure balloon attachment by spaced suture.
4. Length marked catheter bodies.

ALL FOGARTY CATHETERS

KEEPING THE STERILE FIELD STERILE

—that is the objective of patient drapes in theatre

BARRIER* Theatre Drapes — unlike absorbent cotton drapes — are treated to resist strike-through of fluids — thus reducing the risk of bacterial transfer to the open wound.

BARRIER* Theatre Drapes also provide a number of other advantages:—

✱ Drapes are folded, cuffed and marked for convenient, aseptic handling.

✱ A full range of both composite and single item drape sets are available for the majority procedures.

✱ Presented in both sterile form and for inclusion in hospital prepared packs.

✱ Complemented by an advanced and unique drape system of absorbent/repellent adhesive towels.

✱ Completely disposable, reducing the work load in service departments and eliminating associated laundry problems.

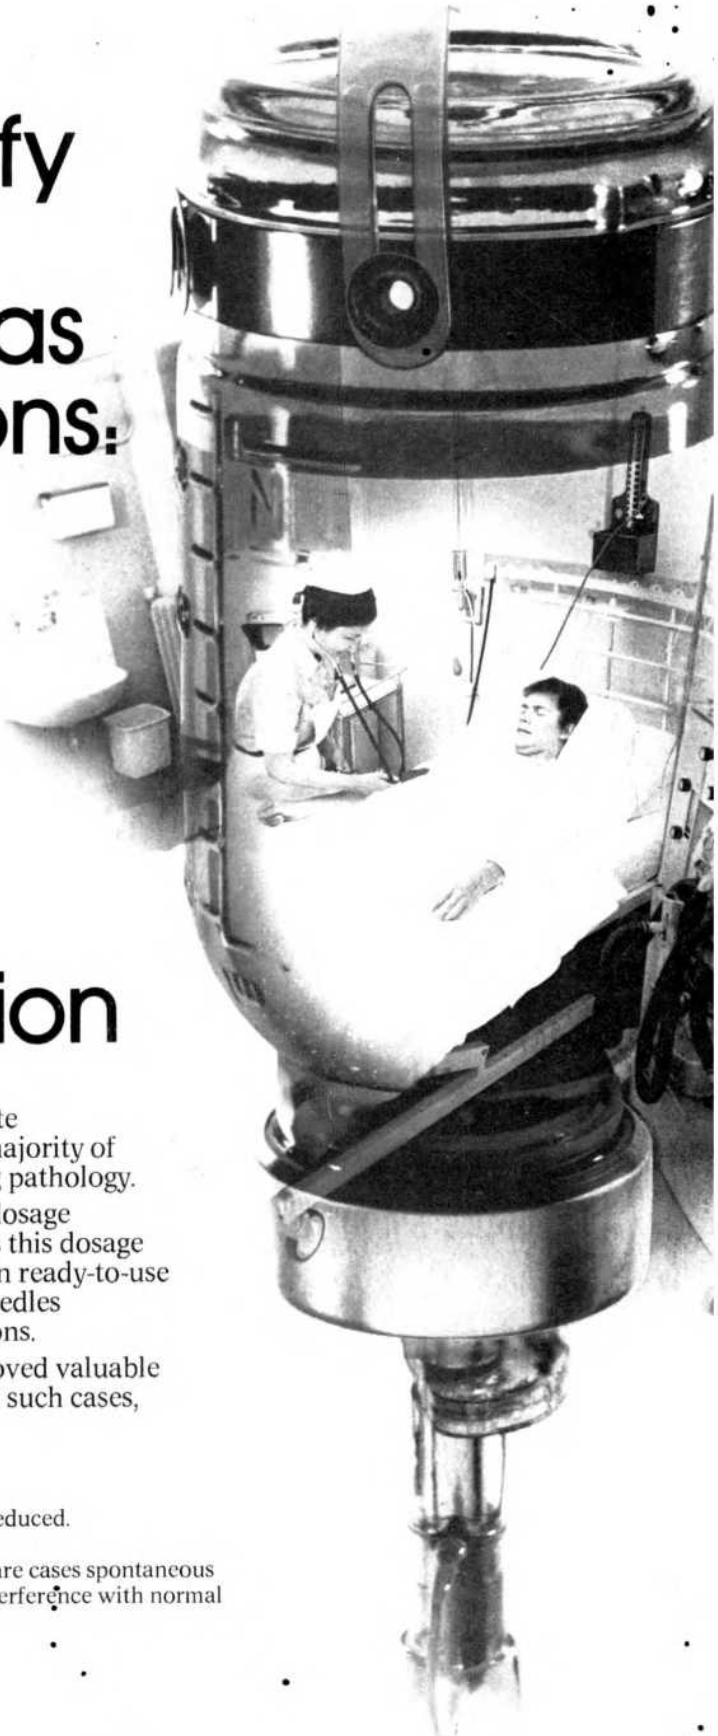
Now, to simplify treatment of pseudomonas chest infections:



Pyopen infusion

In the published papers, Pyopen's success rate in chest infections is 65% even though the majority of the patients described had severe underlying pathology.

The best results have been achieved with a dosage of 20-30G. I.V. daily. Pyopen infusion makes this dosage simpler to administer by providing Pyopen in ready-to-use infusion bottles with diluent and transfer needles for the easier preparation of infusion solutions.

Pyopen is, of course, a penicillin, and has proved valuable in patients with known renal impairment: in such cases, however, dosage should be reduced.

Adult dosage: 20-30G. I.V. daily.
In patients with renal impairment dosage should be reduced.
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by

ORIGINAL PAPERS

A REVIEW OF 460 PATIENTS ADMITTED TO THE INTENSIVE-THERAPY UNIT OF A GENERAL HOSPITAL BETWEEN 1965 AND 1969

By F. D. SKIDMORE*
RESIDENT SURGICAL OFFICER, BARNET GENERAL HOSPITAL, BARNET, HERTS.

SUMMARY

Four hundred and sixty patients with various severe disease processes were admitted to the intensive-therapy unit of a general hospital under the care of the anaesthetic and surgical staff in the 5-year period 1965–9 inclusive. The problems presented by these cases, their prognosis, and the lessons learnt in their management are reported, and the implications for similar units in the future are discussed.

THIS paper is concerned with the surgical patients admitted to a 5-bed intensive-therapy unit in a 450-bed hospital on the northern outskirts of London. The area served by this hospital, which has a total of 100 general surgical beds and 50 orthopaedic beds, is predominantly urban and is traversed by several major roads, including the beginning of the A1 London-to-Scotland trunk road. The total resident population served is of the order of half a million.

HISTORY OF THE INTENSIVE-THERAPY UNIT

The interest of the anaesthetic department of this hospital in respiratory problems has culminated in the design of a series of highly successful 'Barnet' ventilators (Rochford, Welch, and Winks, 1958). In 1960 a recovery ward was opened as an extension to a twin-theatre unit. This annexe to the operating theatres was intended to provide care for up to 8 hours after surgery. General advances in the understanding of the principles underlying the respiratory physiology of surgical patients during and after operation has resulted in the requirement of a specialized unit open for 24 hours a day in which personnel and equipment can be centred to provide a high standard of care for seriously ill patients. *Fig.* 1 shows the architect's plan of the unit which was built in communication with the operating theatres and recovery ward (Rochford, 1965); this was opened at the beginning of 1965. It is the intention of this paper to review the 460 patients who were primarily under the care of the surgeons and who were treated in the unit during the period from January, 1965, to December, 1969. It must be stressed that the unit is not restricted to surgical case care. *Fig.* 2 shows the relation of surgical admissions to the unit's overall intake.

A recently published comprehensive review from the University of Pittsburgh (Safar and Grenvick, 1971) considers the parallel development and organization of intensive care and therapy in North America over the past decade. The main author has been at the centre of development studies which have covered the emergent period of such units.

THE FUNCTION OF AN INTENSIVE-THERAPY UNIT

Lawson (1967) has categorized the types of surgical patient who benefit from intensive therapy. These are:—

1. Elective admissions for:—
   a. Major vascular surgery.
   b. Replacement surgery.
   c. Endocrine surgery.
2. Elective admissions of poor-risk cases.
3. Emergency admissions.

In the paper by Lawson (1967) dealing with an intensive-therapy unit in a major teaching hospital the close proximity of a major accident centre resulted in the absence of trauma cases in the series. In our series of nearly 500 admissions Lawson's first and third categories will be retained, but it has been our experience that the poor-risk cases in a general hospital are virtually all emergency rather than elective admissions. These cases require operative procedures of varying degrees of seriousness, the degree of difficulty of the operation being raised by ancillary problems of age and concomitant medical conditions. Our fourth group is concerned with cases of multiple trauma. The figures in *Table I* show the following proportion of cases: trauma, 29·8 per cent; postoperative, 13·04 per cent; poor-risk, 43·5 per cent; major surgery, 13·7 per cent.

---

* Present address: British Heart Foundation Research Fellow, Department of Anatomy, University of Cambridge.

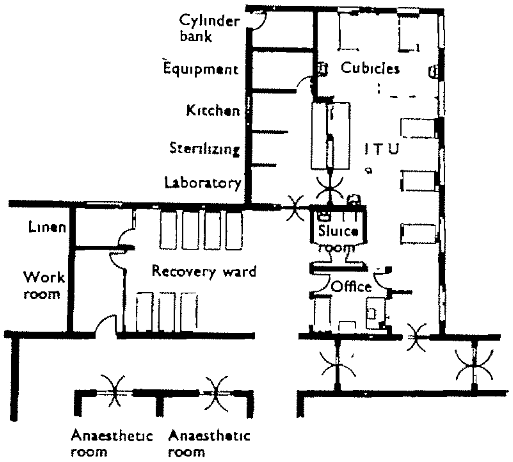

FIG. 1.—Architect's plan of the intensive-therapy unit and recovery ward.

The 5-bed unit takes patients referred for treatment from all specialities in the hospital and the administration of the admissions to the department is under the control of the duty anaesthetic registrar.

NURSING STAFF

The unit has 3 full-time sisters and there are normally 4 staff nurses who have been through the 6-month course organized by the unit to train nurses in intensive care. At any one time there will be upwards of 6 staff nurses on the course. The high standard of training has been reflected in the publication of a volume concerned with nursing procedures in such a unit (Gardner and Sheldon, 1967). The whole pattern of intensive therapy emerging from experience in various centres throughout the country is that trained nursing staff will carry out more and more of the emergency steps required in resuscitative procedures. There is no reason why after an adequate period of training emergency intubation and the initiation of respirator ventilation should not be within the capabilities of an intensive-therapy unit sister.

The unit staff are progressive in their regular reassessment of the patients in the unit to determine whether the needs of the patient require his treatment in the intensive-therapy complex. We have been most anxious to avoid falling into the trap of nursing all seriously ill patients in a specialized unit, thereby depriving student nurses in training on the general wards of the experience of nursing such patients under the supervision of the surgical ward sisters. It is our contention that the intensive-therapy unit empty of patients does not indicate that the unit is not taking on enough work but that, in fact, since some of the work carried on in the intensive-therapy unit is more akin to that of an operating theatre than of a normal ward there should be times when the unit can stand down.

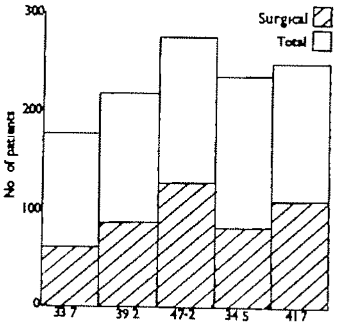

FIG. 2.—Total number of patients in the intensive-therapy unit in each of the 5 years under review. The figures at the bottom of the graph refer to the percentage of surgical patients for each year.

RATIONALE OF ADMISSION TO THE INTENSIVE-THERAPY UNIT

Examination of the general pattern of surgical patient care shows that four basic phases can be discerned in the medical staff responsibility. These are: (1) referral and examination, (2) diagnosis, (3) definitive treatment (operative or conservative), and (4) recovery. As the severity of any given illness increases so more of these stages have to be carried out on an in-patient basis. In the case of patients with serious conditions where the specific illness frequently has shock as a major component two further stages must be interposed into this scheme. These are (2*a*) resuscitation, and (3*a*) post-treatment monitoring of vital functions.

In the case of the most seriously ill, e.g., patients with major trauma or vascular catastrophes, it is often necessary to carry out emergency treatment or support respiration and cardiac function before any diagnostic evaluation can take place.

Units which look after patients who manifest major patho/physiological states require reserves of manpower, materials, and space that are not available on the general wards because of cost/utilization requirements. The concentration of personnel and equipment on a 24-hour availability basis with sufficient space around the patient to give access to the resuscitation team is of prime importance in such units. Vourch (1967) describes similar conclusions from a large French unit. Safar and Grenvick (1971) recognize these factors of importance in the evolution of American intensive-therapy units.

Route of Admission to Intensive-therapy Units.—Patients in the different groups, as already outlined, show obvious variations in their hospital treatment before reaching the intensive-therapy unit.

1. Immediate admission to the intensive-therapy unit:—

a. Major trauma cases who on assessment in the casualty department show severe dysfunction of several systems are transferred immediately to the intensive-therapy unit for management.

b. Patients manifesting shock because of gastro-intestinal tract bleeding or peritonitis and those with septicaemia are similarly managed, and it has been our experience that the proximity of the operating theatre means that the problems of moving an ill patient around the hospital are minimized when it is apparent that the time for operation is correct.

Table I.—Admissions to the Intensive-therapy Unit over the 5 Years 1965–9

Reason for Admission	No of Patients admitted					Total No. of Patients	Percentage of 460 Patients
	1965	1966	1967	1968	1969		
Trauma	20	30	29	28	30	137	29·8

Deaths	24	30	32	27	25	138 deaths	
Total No. of patients (medical and surgical)	178	219	275	238	253	1162	
Percentage of surgical patients	33·7	39 2	46 2	34·4	41·7		

Total admissions, average per month, 19 36, surgical admissions, average per month, 8 66. Overall mortality, 28·7 per cent of patients 29·8 per cent of admissions.

c. Certain specialized cases, essentially requiring respiratory care, are transferred to the unit from other centres. These include patients with tetanus, respiratory insufficiency, fat emboli, and neonatal problems. Patients with tetanus have been separately considered (Rochford, 1969).

2. Patients undergoing major surgery of various types and those in whom problems develop during the course of operation are admitted to the unit from the operating theatre, having spent the preoperative period in a general ward.

3. An intermediate class of patient exists, many of whom are also categorized as 'poor-risk'. These patients are transferred to the unit from the general wards, either medical or surgical, prior to operation to enable evaluation of their cardiac and respiratory states. They return to the unit after operation for monitoring and continuation of resuscitative therapy and are later discharged back to their ward of origin.

4. Late admissions. Chest conditions such as atelectasis and embolization are the most common postoperative complications, followed by cardiac problems such as infarction and dysrhythmias. Delayed ileus, wound dehiscence, and fistulae are the major conditions in the abdomen which merit admission to the unit at this stage.

The intensive-therapy unit has obvious connotations of crisis both to the patient and relatives in so far as they recognize the high degree of individual care that the incumbent is receiving. Hewitt (1970) has reviewed the subjective responses of patients who have been treated in such units and found that although about half the patients were worried by various facets of their time in the intensive-therapy unit, insight of their state of illness was not mentioned as being a particular cause of concern. We have in all cases tried to play down the 'crisis aspect' to the patient, particularly since, with a 5 per cent re-admission rate, one is anxious to avoid a precipitate drop in morale when a patient realizes he or she has to be returned to the unit. The mean time spent in the unit was less for the patients who survived than for those who died, and this can be taken as evidence of the fact that the patients whose recovery was progressing satisfactorily were returned to the general ward, whereas those whose condition was unsatisfactory were kept for further treatment. A corollary of this is that resources of nursing and medical staff can be fully directed to those with the greatest need.

Recordings.—A specially designed, large, single-sheet chart is available for each patient on a day-to-day basis; changeover takes place at 12 noon, by which time it has been our experience that the morning's laboratory results are to hand for assessment, prior to ordering the treatment for the following 24 hours. The patient's ward notes are kept at hand in the unit, but it is stressed that all the information relating to the patient's course in the intensive-therapy unit should be on the special charts. These can be filed after the patient has been discharged from the unit and are subsequently available for perusal.

STATISTICAL CONSIDERATIONS OF UNIT UTILIZATION

The two major factors expected to affect the use of intensive-care beds are the arrival patterns of patients and their length of stay in the unit. *Fig.* 3 A shows the Poisson distribution of the variation in the number of patients arriving each day from various sources at the intensive-therapy unit. *Fig.* 3 B shows the exponential graph of the type of length-of-stay distribution found for all cases. From these findings we can construct a simple theoretical model to predict the bed occupancy of the unit. The model is as follows:—

1. Patients who arrive when the unit is full do not form a queue but are treated elsewhere. This is likely to be an oversimplification of what happens in practice. For instance, an extra bed may be put up or other patients may be discharged to make room.

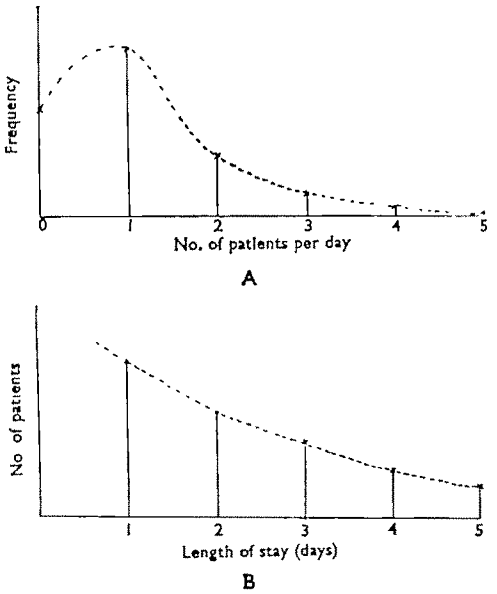

FIG. 3.—A, Frequency distribution of the number of admissions per day to an intensive-therapy unit. B, Length-of-stay distribution in an intensive-therapy unit.

2. The operational policies are constant.

3. The arrival of patients is completely random with a mean arrival rate of *a*.

4. The length of stay of patients is exponentially distributed with a mean *b*.

Then, the occupancy (*p*) of *n* beds in an *m*-bed intensive-therapy unit is:—

$$Pn-\frac{sn}{R\times n!},$$

where $m>n$, $s = ab$, and

$$R = \sum_{n=1}^{m}\frac{sn}{n!}.$$

This model can be further refined to take account of any admission or discharge policies associated with the number of patients in the unit, e.g., the admission policy may be to restrict admissions to particular types of patient if the unit is nearly full. To do this we calculate the arrival rates and discharge rates of patients for each bed state, i.e., when there is 1 patient in the unit, when there are 2 patients in the unit, and so on. So instead of means *a* and *b* we have, for example, for a 3-bed unit:—

a_0, Arrival rate when unit unoccupied,
a_1, Arrival rate when 1 bed is occupied,
a_2, Arrival rate when 2 beds are occupied,

and

c_1, Discharge rate when 1 bed is occupied,
c_1, Discharge rate when 2 beds are occupied,
c_2, Discharge rate when 3 beds are occupied.

Then, as a refined model, the occupancy of *n* beds (in an *m*-bed unit) is given by:—

$$Pn = \frac{1}{p}\frac{a_0 a_1 \dots a_n{}^{-1}}{c_1 c_2 \dots c_m},$$

where

$$p = 1+\frac{a_0}{c_1}+\frac{a_0 a_1}{c_1 c_2}+\dots\frac{a_0 \dots a}{c_1 \dots}$$

and $P_0 = 1/p$.

The results show that as the model for an intensive-therapy unit we can us with confidence the effects of any chang or discharge policies. *Table II* shows b time for our own unit for a typical peri

Table II.—BED-OCCUPANCY TIME FOR T THERAPY UNIT FROM OCTOBER, 1967, TO D

These figures refer to all admissions.

ANALYSIS OF OVERALL FI

Fig. 2 and *Table I* show the gener surgical admissions to be between 80 year over the 5 years 1965–9, but with in 1967. It was decided to different winter and summer admissions to the u purpose 'winter' is the 6 months fro March inclusive and 'summer' is fr September inclusive (*Table III*). The m stay of patients undergoing care in t therapy unit during winter and summ shown in *Fig*. 7.

Readmissions.—Twenty-one pati be readmitted to the unit during the 5-year period. Of these, 18 patients major-surgery and poor-risk groups. readmission in order of frequency were breakdown, 8; chest complications, dehiscence, 2; re-exploration of the c duct, 1; gastrectomy after gastrotomy, thorax after oesophagogastrectomy, 1; 1; post-pancreatectomy, 1.

Mortality.—*Table I* shows the mo for the groups under consideration. mortality was 28·7 per cent, with the showing a most encouraging drop in co the first year for which the unit was in particular it will be seen from *Fig*. 4 that the mortality in trauma cases has 54·5 to 20·0 per cent and in the poor- figures have dropped from 73·3 to 2 (winter figures).

ANALYSIS OF INDIVIDUAL

1. POOR-RISK CASES

The total number of patients admitt course of the 5 years who were consid under this heading was 200. There w among these patients and *Table V* sho disease-process groups with figures fo and mortality in each subgroup. T discussed later.

The predominance of gastro-intestinal tract disorders in this group is immediately obvious.

The total mortality for the poor-risk group was 80 patients (40 per cent). Considered in isolation this might seem a high figure, but against this must be set the improvement which has been manifest over the 5 years of the study, and also the fact that 80 per cent of the patients were more than 50 years of age and 47 per cent were over 60 years old. *Fig.* 5 shows the age distribution of the patients and the associated mortality. The largest number of patients occurred in the 70–80-year age-group. The average age of the poor-risk patients during the 5 years under review was 62·8 years.

There were approximately 2 men to every woman in the poor-risk series, and this is shown graphically in *Fig.* 6. This, to some extent, is the result of chronic pulmonary disease occurring more frequently in males. *Table VI* compares the number of incidents of chronic cardiopulmonary disease and acute chest infections recorded in the two sexes in the 200 poor-risk patients.

Length of Stay in Hospital prior to Admission to the Intensive-therapy Unit.—The disease categories seen cover a range of conditions whose time scale in terms of speed of progression varies enormously. Thus, the patient with an aortic dissection is seriously ill within minutes of the onset of the disease process and will be admitted to hospital and the intensive-therapy unit for resuscitation and an attempt at surgical corrective treatment. At the other end of the scale, patients with chronic peptic ulcer disease aggravated by chronic bronchitis, or arising because of steroid therapy in a patient with an ulcer diathesis, may well be in hospital for a considerable period of time on a medical régime before the referring physician asks for a surgical consultation.

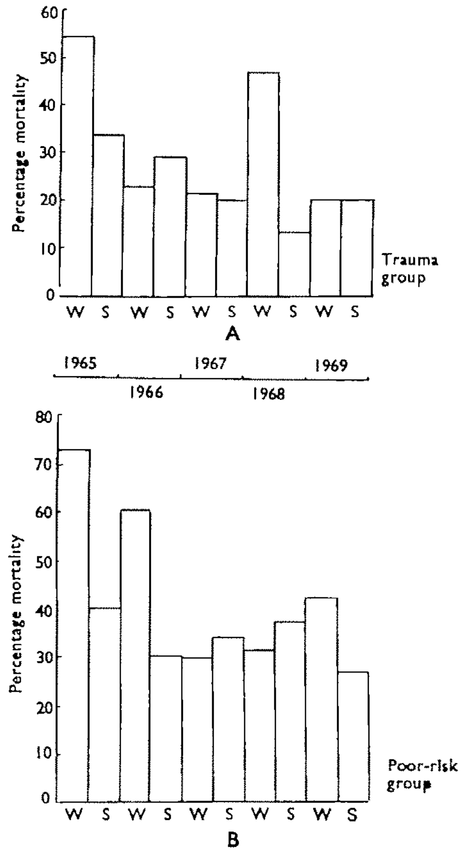

FIG. 4.—Patient mortality expressed as a percentage of the admissions in the trauma group (A) and in the poor-risk group (B).

Table III.—PERCENTAGE OF TOTAL SURGICAL ADMISSIONS PER ANNUM IN EACH GROUP SUBDIVIDED INTO WINTER (W) AND SUMMER (S) 6-MONTH PERIODS

REASON FOR ADMISSION	1965		1966		1967		1968		1969	
	W	S	W	S	W	S	W	S	W	S

	W	S	W	S	W	S	W	S	W	S
Trauma	54·5	33·3	23·0	29·2	22·0	20·0	46·2	13·3	20·0	20·0
Poor risk	73·3	40·0	60·0	30·8	30·2	33·2	31·3	36·8	42·9	26·4

Alternatively, such a 'chronic' ulcer patient may suffer a disastrous bleed or perforation which makes urgent surgical treatment imperative.

Another group of patients can be identified, namely those in hospital receiving medical treatment for a non-surgical condition and who develop an associated complication which requires surgical correction or who present with a surgical disease as a separate condition while they are in hospital. *Fig.* 8 shows the distribution of the patients according to the number of days that they were in hospital prior to admission to the intensive-therapy unit. The majority is admitted to the unit within 24 hours of attending the hospital, but there can be seen to be a separate population which is referred late to the surgeon. The commonest problems in this category were 11 cases where patients on a medical régime for peptic ulcer required surgery and 14 cases who developed obstruction while already in hospital. Investigation of the deaths in this subgroup revealed a mortality of 16 per cent.

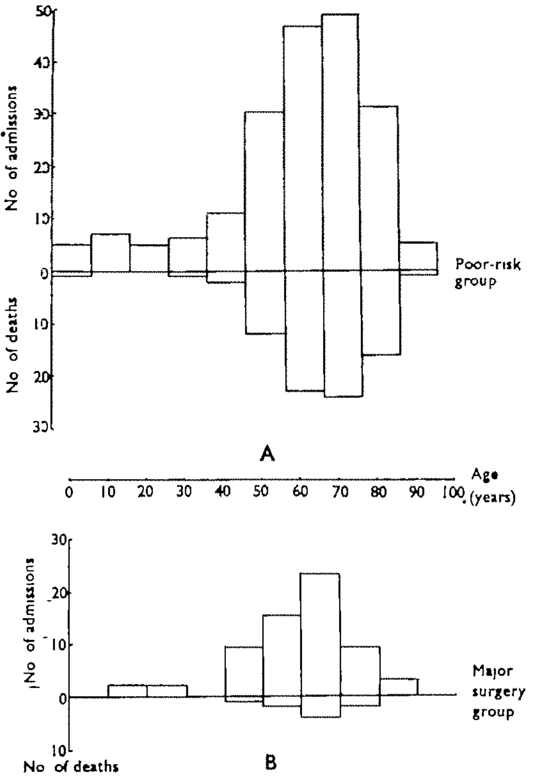

FIG. 5.—Age distribution and mortality for patients in the poor-risk group (A) and in the major surgery group (B).

Table V.—MAJOR DISEASE PROCESSES COMPARED WITH THE NUMBER OF ADMISSIONS, READMISSIONS, AND DEATHS IN THE POOR-RISK GROUP

DISEASE PROCESS	NO. OF ADMISSIONS	NO. OF READMISSIONS	NO. OF DEATHS
Peptic ulcer	46	5	19
Obstruction	48	3	28
Peritonitis	32	0	9
Prostatic enlargement	15	0	1

Obstetric/gynaecological cases	4	0	0
Primary respiratory disease	5	0	1
Others	2	0	0

Fig. 9 compares the age range and mortality in the patients with ulcer disease, obstruction, and peritonitis, which together made up 63 per cent of the total patients in this group.

Patients with Peptic Ulcer Disease.—The 46 patients in this group included 37 males, of whom 15 died, and 9 females, of whom 4 died. There were three main reasons for the admission of these patients to the unit.

1. Age. *Fig.* 9 A shows that a large percentage of the patients in the category were over 65 years. Peptic ulcer is a chronic disease which normally manifests itself in early middle age. The low national mortality figures for the various vagotomy and drainage procedures have resulted in general practitioners and physicians referring a large number of their patients with recurrent ulcer disease for surgery to forestall serious problems and also to avoid committing the patients to a life of severe dietary restriction. In a large series McLeod and Carter (1971) showed that the maximum age incidence was in the 50–59 age-group for male patients and in the 40–49 age-group for female patients. Thus the age distribution showed an almost normal curve with loading obviously on the younger side. These authors

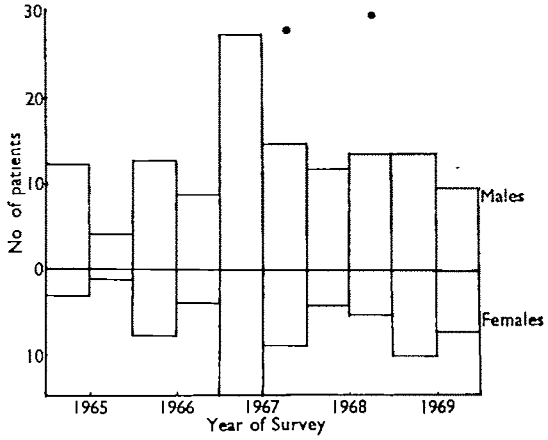

FIG. 6.—Male : female ratio in the poor-risk group.

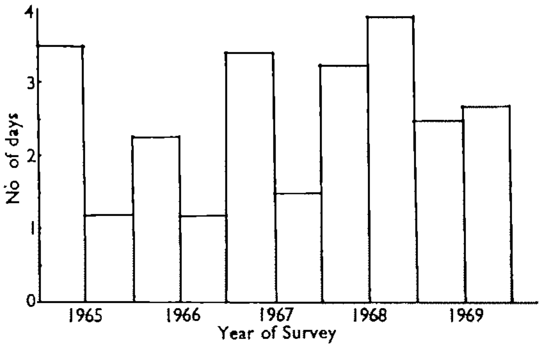

FIG. 7.—Average length of stay of all surgical patients in the intensive-therapy unit for successive winter and summer periods, 1965–9.

Table VI.—DISTRIBUTION OF CARDIOPULMONARY DISEASE AND CHEST INFECTIONS IN MALES AND FEMALES

DISEASE	NO OF PATIENTS	
	Males	Females
Chronic bronchitis	22	2
Asthma	3	1
Acute chest disease	19	11
Congestive cardiac failure	16	5

suggested that about 70 per cent of the cases in their series represented chronic ulcers. It is therefore to be expected that in patients presenting at a later age the ulcers will tend to be extremely indurated and often fixed to neighbouring intra-abdominal structures. Perforation to major vessels is common and resection difficult.

Table VII.—OPERATIONS PERFORMED IN 46 CASES OF PEPTIC ULCER

OPERATION	NO. OF PATIENTS	NO OF DEATHS
Perforation oversewn	13	5

Rheumatic heart disease	2
Asthma	1
Hypertension	1

2. The patient may present with one of two major complications of the primary lesion, namely haemorrhage or peritonitis. In our series of 46 cases, 23 patients presented with haemorrhage and 20 patients with peritonitis, while 14 out of the total number had severe shock from either of these causes.

3. The presence of other related or non-related medical conditions may weigh the balance in deciding to temporize on a medical régime in a patient with an ulcer which in a more fit patient would be worthy of surgery. In this series the following associated problems were seen. Seventeen patients had respiratory-tract disorders ranging from chronic bronchitis to previous pulmonary resection. There were 8 patients with cardiac disorders and 5 on steroid therapy. *Table VII* lists the operations that were performed on these 46 patients and the right-hand column shows the mortality for each procedure.

The primary causes of death in these patients were evaluated as being due to chest infection in 6 cases and cardiovascular disease in 6. There were also 6 deaths referable to intra-abdominal infection. (For comparison of the mortality figures *see* Schiller, Truelove, and Gwyn Williams, 1970).

Patients with Intestinal Obstruction.—There were 51 admissions in this series comprising 48 patients. Their ages ranged from 6 weeks to 94 years, the average being 69·1 years. *Fig.* 9 B shows that 40 of the 48 patients under consideration were over the age of 60 years at the time of operation. The male to female ratio was 28 : 20 and the 27 deaths that occurred were distributed equally between the sexes in the ratio of 17 males to 10 females. The causes of obstruction which was diagnosed or confirmed at laparotomy were as shown in *Table VIII*.

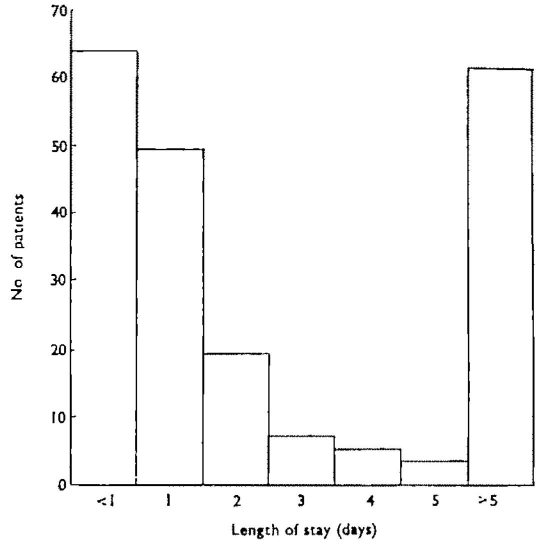

FIG. 8.—Number of days that poor-risk patients were in the hospital prior to admission to the intensive-therapy unit.

Table X.—CAUSES OF PERITONITIS

Cause of Peritonitis	*No. of Cases*
Late perforated appendix	10
Colon perforation	6
Pancreatitis	5
Bowel infarction from mesenteric vascular disease	5
Adhesions and bowel necrosis	2
Anastomotic leak	1
Reduplication cyst perforation	1
Jejunal necrosis, cause unknown	1
No peritonitis at operation	1

The high instance of diseases of the cardiorespiratory systems occurring in these patients cannot be over-emphasized. The relevant figures are shown in *Table IX*. Many of the conditions in this group coexisted. Other complicating factors were shock, anaemia, and metabolic imbalance secondary to fluid loss.

The major causes of death were cardiopulmonary failure (12 cases) and peritonitis (10 cases). The progress of malignant disease accounted for 4 deaths, bleeding from oesophageal varices 1, and renal failure 1.

Patients with Peritonitis.—*Fig.* 9 C shows the age range of the patients, and it is noticeable that a greater proportion of young people occurred in this group compared with the peptic ulcer and obstruction cases. Twenty males and 12 females were admitted to the intensive-therapy unit with peritonitis; of these, 4 males and 5 females died.

Operation was carried out in all except 2 of the patients, in whom acute pancreatitis was diagnosed from the history and confirmed by laboratory and clinical findings and thus immediate operation was deemed not necessary.

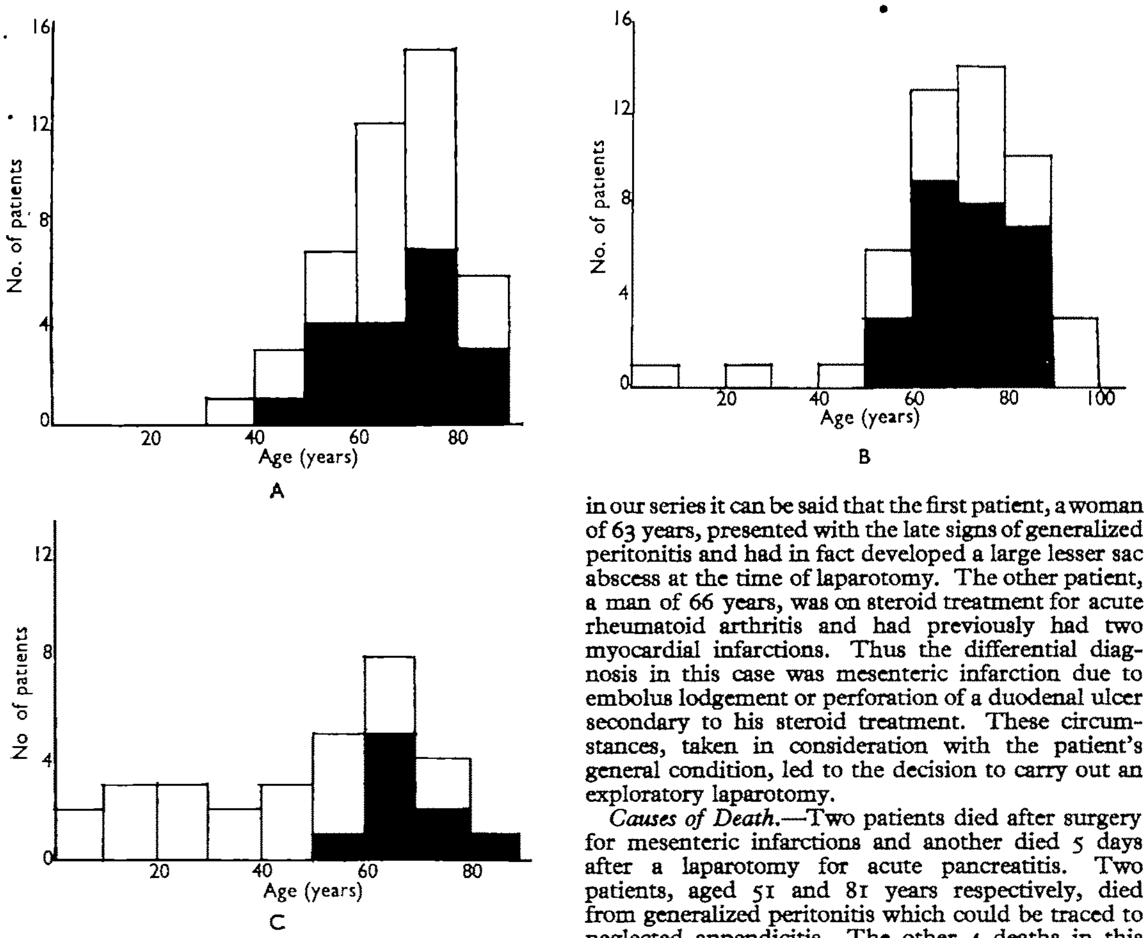

FIG 9.—Mortality and age-range in patients with (A) ulcer disease, (B) obstruction; (C) peritonitis. ■, No. of deaths.

The causes of peritonitis as established at operation (except in the 2 cases not submitted to operation) were as shown in *Table X*.

One case, a child of 6 years in whom no peritonitis was found at operation, was diagnosed as a high retrocaecal appendix with marked dehydration, air hunger, guarding, and rebound. Re-evaluation after a negative laparotomy revealed a right basal pneumonia.

The common general complications were mainly pulmonary in nature. Local complications included 10 abscesses and 2 wound dehiscences.

Patients with Pancreatitis.—Five patients with pancreatitis are included in the peritonitis group, and 2 of these underwent laparotomy shortly after their admission. Although general surgeons are increasingly aware of this condition and the advantages of instituting a conservative régime of therapy, it is nevertheless a common experience that a high proportion of these patients undergo laparotomy (Diaco, Miller, and Copeland, 1969). In 'defence' of the fact that early operation was performed on 2 patients in our series it can be said that the first patient, a woman of 63 years, presented with the late signs of generalized peritonitis and had in fact developed a large lesser sac abscess at the time of laparotomy. The other patient, a man of 66 years, was on steroid treatment for acute rheumatoid arthritis and had previously had two myocardial infarctions. Thus the differential diagnosis in this case was mesenteric infarction due to embolus lodgement or perforation of a duodenal ulcer secondary to his steroid treatment. These circumstances, taken in consideration with the patient's general condition, led to the decision to carry out an exploratory laparotomy.

Causes of Death.—Two patients died after surgery for mesenteric infarctions and another died 5 days after a laparotomy for acute pancreatitis. Two patients, aged 51 and 81 years respectively, died from generalized peritonitis which could be traced to neglected appendicitis. The other 4 deaths in this group were due to generalized peritonitis caused by perforation of a colon neoplasm, perforation of a diverticulum mass, and perforation of a colon in a patient with distal proctocolitis, and haemorrhage into hepatic secondaries respectively. *Fig*. 9 C shows that only 1 of the 9 deaths occurred in patients less than 60 years of age.

Prostatic Hypertrophy.—Over the 5-year period approximately 600 prostatectomies were performed in the hospital and the ones that merited intensive-therapy care under the poor-risk heading totalled 15. The age range of these patients was 57–92 years with a mean of 75·2 years. Complications could be divided into two groups.

General problems were mainly cardiopulmonary in origin (13 cases), while local difficulties usually related to bleeding from the enlarged gland (4 cases) and the hypotensive effects of the bleeding on the elderly patients' circulation. It is interesting to record that of these 15 poor-risk patients, only 1 succumbed and he was found at post-mortem examination to have an occult carcinoma of the bronchus.

Comparison of these patients with those in comparable series of poor operative risk patients who underwent cryoprostatectomy shows that the mortality in our series was less than that in patients who were submitted to cryoprobe instrumentation (Gill and Fraser, 1970).

Other cases of prostatic hypertrophy who were admitted to the unit are considered in the postoperative series (*vide infra*).

Vascular Disease.—In no group of emergency admissions is the surgeon faced with greater problems than those in this category. The generalized nature of the arteriosclerotic degeneration of the arterial tree with its risks to cerebral, coronary, and renal parenchyma not infrequently manifests itself by dissection, leakage, or blockage of major trunks with the attendant, rapidly advancing problems of severe pain and poor distal perfusion. *Fig.* 10 shows the age and mortality distribution of the patients in this group and *Table XI* gives a breakdown of the lesions.

Table XI.—REASON FOR EMERGENCY ADMISSION AND NUMBER OF DEATHS IN PATIENTS WITH VASCULAR DISEASE

Lesion	*No. of Cases*	*No of Deaths*
Aortic disease		
Leak	12	9
Dissection	2	
Emboli		
Iliac	1	3
Femoral	4	
Endarterectomy	3	1
Amputation	1	0

Oesophageal Varices.—Two patients died after direct surgery on the bleeding vessels at the oesophagogastric junction.

The high mortality-rate of 62 per cent in this small group of vascular emergencies, i.e., 15 out of 24 patients died, compares unfavourably with a mortality of 14 per cent (3 out of 22 patients) in the elective major vascular disease cases considered under the major surgery heading (*vide infra*). From these limited figures, therefore, there would appear to be a fourfold risk attendant upon emergency procedures.

Biliary-tract Disease.—Six patients were admitted to the unit at the time of biliary-tract surgery because of attendant complications. Two patients had previously sustained myocardial infarction and 1 patient was on mono-amine oxidase inhibitors for depression. A woman of 52 years was admitted to the unit from the preoperative ward having sustained a subarachnoid haemorrhage while awaiting cholecystectomy. Operation was not performed and she died of the cerebrovascular accident. The other admissions in this group were a male of 53 years, who sustained a large pulmonary embolus after cholecystectomy, and a patient with carcinoma of the pancreas who died after a cholecystojejunostomy had been performed.

Orthopaedic Diseases.—Nine cases were admitted after elective orthopaedic surgery; 6 of these were women who had required surgery for a fractured neck of the femur. The age range of these patients was 70–95 years, with a mean of 83 years. Complicating factors included acute and chronic chest infections, congestive cardiac failure, diabetes, and postoperative hypotension. One of the 6 patients had to be readmitted because of her diabetes going out of control in the postoperative period, but she was eventually fit enough to return to the general ward. The other admissions in this group were a man of 68 years with an acutely prolapsed vertebral disk who died of coexistent cardiac failure, and a man of 31 years who had a skin-graft following an infected spinal fusion scar. The final case was a youth of 19 with a fractured shaft of the femur who had a major fat embolus and was admitted with extreme hypoxia. This case has been reported elsewhere (Ross, 1970).

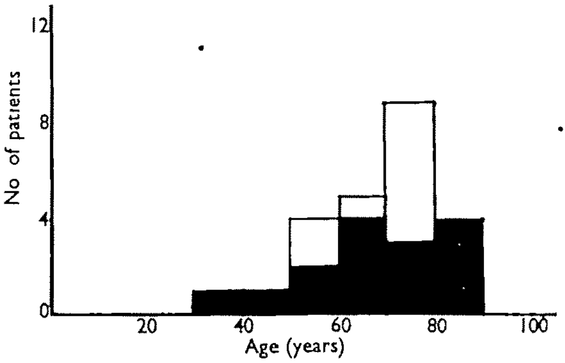

FIG. 10.—Mortality and age-range in patients with emergency vascular disease.

General Considerations of Other Minor Groups.—

1. *Wound Dehiscence.*—Three patients were admitted because of wound dehiscence. Two of the patients had acute or chronic chest conditions and 1 was a diabetic. One of these patients had to be readmitted with a further dehiscence 10 days after his second suture. This event should always be considered in a very serious light. The patient survived both these setbacks and was eventually discharged home. In a large series of cases of wound dehiscence the mortality associated with the incident is given as 11 per cent (Wolf, 1950) and 20 per cent (Mann, Spinazzola, Lindemith, LeVine, and Kuczerepa, 1962).

2. *Obstetric and Gynaecological Cases.*—Our colleagues in this speciality only found it necessary to admit 4 patients to the unit during the 5 years under review. These cases were:—

1. Therapeutic abortion for uraemia (blood-urea 380 mg. per cent).
2. Shock consequent upon secondary uterine haemorrhage.
3. Severe pre-eclamptic toxaemia at 34 weeks' gestation.
4. A patient who had undergone hysterectomy and suffered a severe exacerbation of asthma while in the recovery unit.

Comment.—From the description of the variety of cases which make up the acute admissions considered under the heading of poor-risk cases it can be seen that the challenge to the unit is ever present. Of the 200 patients reviewed, only 19 (9·5 per cent) had malignant disease. Thus, despite their age and multiple system failure either because of, or coexistent with, their primary disease, the majority of poor-risk patients who are taken care of in the intensive-therapy unit can look forward to an eventual return to a normal way of life.

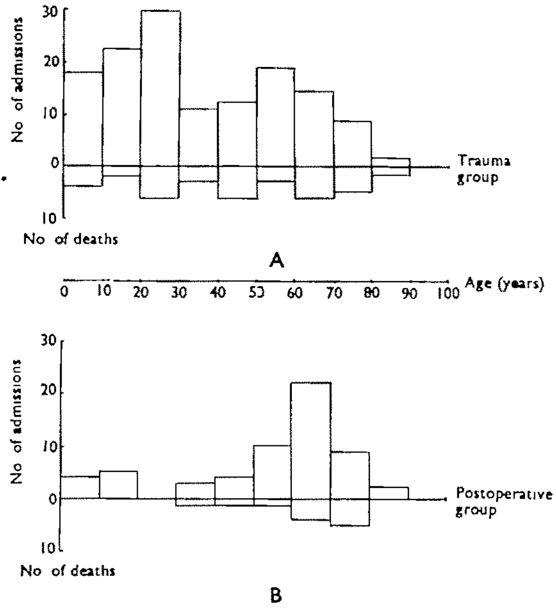

FIG 11.—Mortality and age-range in patients in (A) the trauma group and (B) the postoperative group

We have learnt the benefits of transferring patients early to the unit if their general condition is poor prior to intended or essential surgery. The presence of equipment and personnel and the position of the unit at the hub of the hospital allow rapid and frequent checking of the patient by the duty surgical registrar during a period of resuscitation before timed surgery. The practitioner on duty in a busy hospital should never be worried by the occasional case which after full assessment in the unit is clearly not in need of intensive therapy. Rather he should aim never to miss bringing to the unit those whose disease potentialities are such that they may suddenly be in dire need of many of the services which are only available in the intensive-therapy unit/operating theatre complex.

ANALYSIS OF INDIVIDUAL GROUPS

2. PROBLEMS OCCURRING DURING THE COURSE OF OPERATION

Table I shows that 13·04 per cent of all the patients admitted to the unit came in the category of operative problems. There were 12 deaths among the 60 patients and *Fig.* 11 shows these mortalities in relation to the age distribution. The major cause of death in these patients was myocardial disease (6 patients).

Discussion of General Figures.—The patients in this group all suffered some unexpected incident in the period during which they were in the theatre suite. As a result they were admitted for observation and treatment. In the 26 patients under the age of 60 years there were 3 deaths. Among 22 patients in their sixth decade there were 4 deaths, but in the 11 patients over the age of 70 there were 5 deaths, which indicates that the older patient faces the risk of degenerative cardiac disease giving rise to complications during surgery and, with their physiological resilience lessened because of increased age, recovery after the unexpected incident is less certain. Of the 8 young people (i.e., less than 20 years) admitted in this category, 4 were referred from ear, nose, and throat surgeons. Considering the extremely large volume of routine ear, nose, and throat surgery in this age-group this is an acceptably low operative complication rate. However, the problems that occur, namely haemorrhage, respiratory obstruction, and clot inhalation, are serious (Roberts, 1965). It is common experience that haemorrhage after tonsillectomy, either of a primary or secondary nature, is notoriously difficult to quantify. It is only when the melaena is observed in the days following operation that the surgeon is made aware of the concealed component of the haemorrhage in the child who he has been observing.

Table XII.—REASON FOR ADMISSION TO THE INTENSIVE-THERAPY UNIT IN PATIENTS UNDERGOING HEAD AND NECK SURGERY

TYPE OF SURGERY	REASON FOR ADMISSION TO THE INTENSIVE-THERAPY UNIT	NO. OF CASES
Ear, nose, and throat	Haemorrhage	3
	Inhalation of clot	1
	Congenital heart disease	1
	Epiglottis biopsy	1
Thyroidectomy	Haemorrhage	2
	Respiratory distress (1 tracheostomy)	3
	Observation following total thyroidectomy	2

Table XIII.—RESPIRATORY PROBLEMS DURING OPERATION CAUSING ADMISSION TO THE INTENSIVE-THERAPY UNIT

Respiratory Problem	*No. of Incidents*
Slow reversal after curarization	7
Probable/certain inhalation of gastric contents	4
Stridor	3
Postoperative cyanosis	3
Hypotension	2
Bronchospasm	1
Congestive cardiac failure and pneumonia	1
Bilateral pneumothorax	1

Two deaths in the younger age-group occurred. One, a 30-year-old woman, died 4 days after an appendicectomy during the course of which she suffered a cardiac arrest because of a fault in the anaesthetic machine. The other, a 44-year-old diabetic grand multipara (para 12) with a known deep-vein thrombosis, died of a pulmonary embolus on the tenth day after a Caesarean section. She had been on Warfarin for 6 days at the time of her death.

Specific Analysis of Patients.—Five major groups of patients could be discerned and these are grouped as follows:—

1. *Head and Neck Surgery.*—The details of this group are shown in *Table XII*. There were no deaths in this group.

2. *Respiratory Problems.*—There were 15 patients in this category, of whom 1 had to be readmitted.

They were undergoing a wide range of surgical procedures and in most cases were admitted to the unit at the request of the anaesthetist who was taking the case for the reasons given in *Table XIII*.

The only death in this group was that of a 78-year-old woman whose respiration was never adequate after an oesophagogastrectomy.

3. *Cardiovascular System Problems*.—There were 26 patients in this group. Of these, 14 were undergoing various general and orthopaedic procedures and 12 were undergoing prostatectomy. It has been our policy to use epidural anaesthesia whenever it is technically feasible for this operation. With well-trained anaesthetic staff who are alert to the problems which may arise in these cases the morbidity is negligible and the mortality acceptable.

In the 12 prostatectomy cases under review, 5 showed cardiovascular malfunctions and there were 7 cases of postoperative bleeding. There were 2 deaths; both patients had cardiac arrest during surgery and died shortly afterwards. Post-mortem examination revealed that both patients had suffered large myocardial infarctions.

In the remainder of patients in this group there were 7 episodes of cardiac arrest and 6 patients showed prolonged hypotension, 1 of these suffering gross arrhythmias. Five of the patients who suffered cardiac arrest on the operating table died; 2 immediately and 3 after a period of gradual deterioration in the unit following operation.

4. *Problems relating to the Central Nervous System*.—One patient died in status epilepticus because of advanced cerebral secondaries from carcinoma of the breast. Two patients were shown to have hypothermia (32·3° C.) after operation. One of these cases had unfortunately been on chlorpromazine for a long time prior to surgery, and it is thought that the effect of this drug on her heat-regulating mechanism contributed to her hypothermia and eventual death from bronchopneumonia.

5. *Bacteriaemic Shock*.—Two patients were admitted to the unit with hypotension and rigors after urethral instrumentation. Both recovered satisfactorily and they were discharged back to the ward on the following day after antibiotic therapy.

Comments.—The close liaison established in the recovery ward/intensive-therapy unit complex by virtue of admission control by the anaesthetic department and the fact that the intensive-therapy unit nurses spend a considerable proportion of their time in the operating theatre with the anaesthetist have resulted in good teamwork and easy transfer of patients who have had anaesthetic problems from one part of the complex to another. It is important that the same people should continue to watch over and manage a patient during the critical hours following an unforeseen incident. The relatively high concentration of medical staff in the operating-theatre complex during routine lists means that advice is immediately available for the nurses should the condition of one of these patients deteriorate.

ANALYSIS OF INDIVIDUAL CASES

3. MAJOR ELECTIVE SURGERY

Sixty-three patients out of the total series were admitted to the intensive-therapy unit after major elective surgery. In most cases they were admitted for routine monitoring during the immediate postoperative phase to ensure adequacy of respiration and stabilization of the haemodynamic state. In the case of patients who had undergone vascular procedures maintenance of a satisfactory peripheral flow as evidenced by skin colour and temperature, palpation of distal pulses, and good urinary output is most important. Seven patients (11 per cent) had to be readmitted during their postoperative course; virtually all of these admissions were occasioned by the development of sputum retention, atelectasis, and pulmonary consolidation following major upper gastro-intestinal procedures. In an excellent monograph published in 1957 Anscombe showed the relationship between various abdominal incisions and ventilatory capacity of patients expressed as a percentage of their preoperative capacity. It is to be expected that in a group of patients undergoing procedures which require upper abdominal incisions there should be marked interference with respiratory excursion and capacity and unwillingness to utilize the respiratory reserves available because of pain.

The close co-operation between the physiotherapy staff and the intensive-therapy unit is of great value. The physiotherapists can become more involved with the management of the patients than is common in the general wards, and with the greater frequency of their visits to the unit all the patients receive more physiotherapy treatment than would be possible in the general wards. The nursing staff also have time to watch, and subsequently emulate the physiotherapy staff, and are able to give remedial treatment at hours when the physiotherapists are not normally available. This is particularly important during the night immediately following operation.

The age distribution and mortality are shown in *Fig*. 5 B. There were 9 deaths in the series, 6 of these being due to chest infections and 2 the result of colon infarction after major aortic grafting. One patient with advanced metastatic tumour from a breast primary died 2 days after adrenalectomy.

Specific Analysis of Patients.—

1. *Vascular Disorders*.—Twenty patients underwent major elective vascular surgery; 11 operations involved aortic replacement for an aneurysm and 9 were aortodistal grafts. Two patients died; both patients appeared to be unable to maintain the circulation to their mid-descending and sigmoid colon without the inferior mesenteric contribution. One other patient died of chest infection after aortic replacement; tracheostomy was performed when it became apparent that his postoperative respiratory requirements could not be maintained without prolonged artificial ventilation, but despite this his condition rapidly deteriorated.

It is important to compare and contrast the mortality in this series of patients with those patients in whom it was necessary to perform emergency vascular surgery, who have been considered in the poor-risk category (*see Fig*. 10).

2. *Upper Gastro-intestinal Tract Surgery*.—The operations performed are shown in *Table XIV*.

A mortality of 4 out of 21 patients is acceptable where such major operations are concerned, and the morbidity in terms of postoperative complications was extremely low. Thus, 5 patients had radiological and clinical evidence of chest infection, 1 patient suffered a pneumothorax, and 1 patient had an anastomotic leak after an oesophagogastrectomy. This latter patient subsequently died of bronchopneumonia.

Table XIV.—OPERATIONS PERFORMED IN PATIENTS UNDERGOING GASTRO-INTESTINAL TRACT SURGERY

Operation	*No. of Cases*	*No of Deaths*
Oesophagectomy	7	1
Oesophagogastrectomy	2	—
Total gastrectomy	5	1
Whipple operation	6	2
Thoraco-laparotomy	1	—

3. *Lower Gastro-intestinal Tract Surgery*.—Fourteen patients were accepted into the unit after major surgery of the lower gastro-intestinal tract. There were 9 cases of carcinoma of the rectum necessitating abdominoperineal resection. Panproctocolectomy was performed in 4 cases with ulcerative colitis. The remaining case underwent laparotomy and small-bowel resection for Crohn's disease.

Two patients in this group died; 1 of bronchopneumonia following panproctocolectomy for ulcerative colitis at the age of 58 years. This patient had a tracheostomy in an attempt to control his severe respiratory infection but he eventually succumbed. A man of 70 years died of uraemia and pneumonia 6 days after an abdominoperineal resection. Morbidity and complications were otherwise minimal, and the average period of stay in the unit of the surviving cases was 1 day.

4. *Major Endocrine Surgery*.—Six patients (all women) in this category were admitted. All underwent bilateral adrenalectomy. Five patients had metastatic breast neoplasms and 1 had Cushing's disease. The 5 patients with primary breast lesions also underwent oophorectomy at the same time. Mortality was limited to 1 woman of 44 who was accepted for operation with full realization of her desperate condition. She had massive pulmonary metastases and haemoptysis and severe pain from hypertrophic pulmonary osteo-arthropathy. Operation was attempted in an effort to effect some regression in the size of the pulmonary deposits which were causing extreme discomfort. The attempt failed and she died 4 days after operation.

5. *Major Ear, Nose, and Throat Surgery*.—The intensive-therapy unit was asked to provide facilities for monitoring a youth of 19 after the closure of a tracheal fistula which was the end-result of a tracheostomy performed while he was deeply unconscious following a major road-traffic accident. There was also a male of 60 years who was observed following a resection of an arytenoid neoplasm. Both these patients were returned to the ear, nose, and throat unit without incident.

Comments.—It will be apparent from the remarks made concerning low morbidity and short period of stay in the unit that many of the patients who underwent major surgery had an uneventful postoperative course. It may therefore be argued that these patients could well have been returned to the general ward for routine postoperative supervision. It is, however, our view that one of the essentials of surveillance after major surgery is that the patient should be in the full view of the nursing staff. This statement has two facets:—

1. The nurse in charge of such patients should not have to leave them except for the briefest intervals. The continuity of observation by a trained nurse is most valuable, both to the patient in ensuring his continued progress and to the nurse in allowing her to take full responsibility over a period of time when the patient's condition may show marked variations.

2. It is virtually impossible in a general ward to provide an arrangement whereby the seriously ill patient can be constantly observed under satisfactory illumination without causing a marked disturbance to other sleeping patients.

We feel that scrupulous attention to detail during the immediate postoperative period can result in a haemodynamically stable and mentally alert patient being returned to the general wards within 24 hours. In a hospital such as the one in which this survey has been carried out where night staff on the postoperative wards are frequently looking after 8 or 10 patients returning from operation per day the retention of the most major cases in the recovery ward/intensive-therapy unit complex ensures that the other postoperative patients are adequately and equally supervised.

ANALYSIS OF INDIVIDUAL CASES

4. TRAUMA

Fig. 2 shows the absolute numbers and relative percentages of patients admitted in this category. As has been explained at the outset of this paper, the hospital's catchment area includes several fast urban motorways approaching London from the north, and many of the patients admitted in this category received their injuries as a result of high-velocity accidents on these roads.

Table XV.—POSITION OF INJURY IN 137 CASES OF MAJOR TRAUMA

Position of Injury	*No. of Cases*
Face/head	82
Chest	28
Multiple rib	30
Abdomen	31
Spine/pelvis	27
Major arm/leg	65
Total	263

Injury index = 1·927.

The epidemiology of road accidents has recently been reviewed (Bull, 1970). The quantification of the degree of severity of one accident compared with another is extremely difficult and involves the assessment of many independent variables. *Table XV* shows that, on average, each casualty admitted to the intensive-therapy unit for care had sustained two distinct major injuries either of which alone would constitute severe trauma. This figure is comparable with an injury index of 2·266, cited by Brooks, Nahum, and Siegel (1970).

The age distribution (*Figs.* 11 A, 12) shows the high incidence of injury in the first three decades suffered by the adventurous and impetuous male. There is a second peak in the fifth decade which probably corresponds to accidents occurring to pedestrians, and readers are referred to Bull's (1970) graph. *Table XVI* shows the marked male/female difference both in overall number of trauma cases and in the associated mortality.

The mortality figure for this group is high, the overall death-rate being 37 out of 137 patients. *Fig.* 13 shows that by far the largest number of deaths occurred within 24 hours of admission, i.e., 23 out of the 37 deaths.

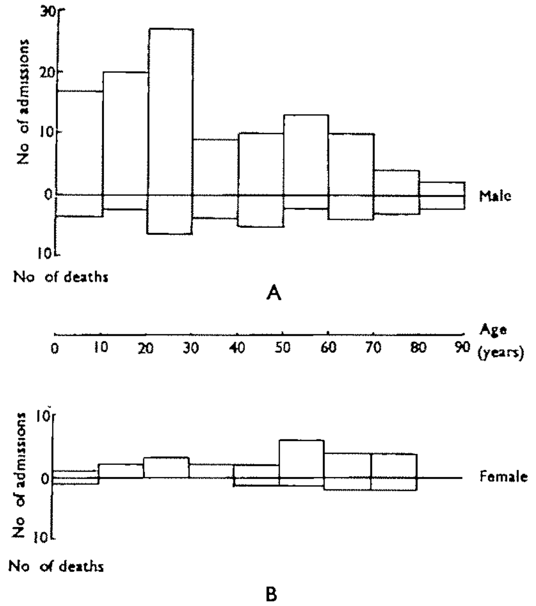

FIG. 12.—Age distribution for male (A) and female (B) trauma admissions, with the associated mortality.

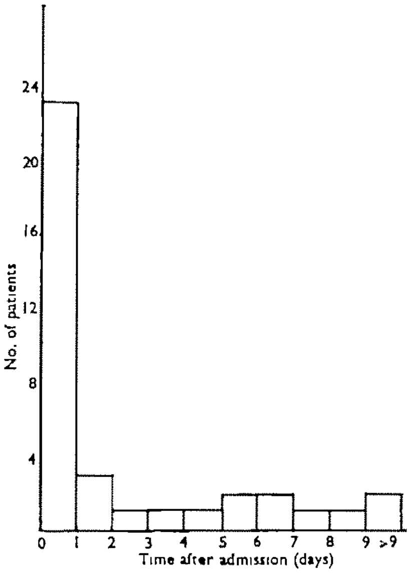

FIG. 13.—Day of death of 37 major trauma patients admitted to the unit.

Table XVI.—AGE AND SEX COMPARED WITH MORTALITY IN THE TRAUMA GROUP

SEX	AGE (years)								
	0–9	10–19	20–29	30–39	40–49	50–59	60–69	70–79	80+
No. of males No. of deaths	17 3	20 2	27 6	9 3	10 5	13 2	10 4	4 3	2 2
No. of females No. of deaths	1 1	2 —	3 —	2 —	2 1	6 1	4 2	4 2	— —

Totals: males: 113, deaths 30; females: 24, deaths 7.

Analysis of Mortality Figures.—In many cases the cause of death given at the post-mortem examination was 'multiple injuries'. However, analysis of the clinical course of the patients taken in conjunction with the post-mortem diagnosis has enabled a reasonable assessment to be made of the major cause of death. *Table XVII* reviews the 37 deaths in this series.

Specific Analysis of Patients.—

Head Injuries.—Lewin (1966) quotes a figure of 60 per cent of road-traffic accident deaths being associated with head injuries. The present series shows that a head injury was a major factor in the death of 23 of the 37 patients who succumbed (62·7 per cent). In the overall group of patients with major trauma 80 out of 137 patients (58·4 per cent) had head injuries. Major head injury, i.e., skull fracture, with or without extra- or subdural haematoma and localizing signs, occurred in 48 cases. There were 26 patients with concussion of a moderate to minor degree, 4 mandibular fractures, and 2 patients with severe facial lacerations.

Chest Injuries.—There were 10 cases in which there was evidence of trauma to the heart or mediastinum, 11 patients who manifested pulmonary injury, 6 patients with flail chests, and 31 patients with multiple rib fractures. The average number of rib fractures was 6, the range being 2–18.

The amount of blood-loss into the soft tissues of the chest wall when many ribs are fractured is rarely appreciated. Abrams (1961) has stated that a litre of blood can be present between the chest-wall muscles before there is any external sign of swelling. Taken in conjunction with the fact that rib fractures may cause pleural rupture and an associated haemothorax, it can be seen that there is ample reason for the post-traumatic fall in haemoglobin level which is common in patients who have suffered chest-wall injuries. If the bruising to the chest has been severe there may be associated interstitial pulmonary haematoma, and Abrams (1961) has described the summation of (1) oligaemia, (2) pulmonary damage, and (3) decreased respiratory excursion as giving rise to a serious interference with normal pulmonary function. If the patient has pre-existing lung disease or poor respiratory excursion due to age or obesity only a minor chest-wall injury may be necessary to create a serious situation.

Table XVII.—CAUSE OF DEATH IN 37 CASES OF MAJOR TRAUMA

Cause of Death	*No. of Cases*
Head injuries:	
Head injury alone	14
Head injury and chest lesion	5
Head injury and orthopaedic lesion	2
Head injury and abdominal lesion	2
Total	23
Chest conditions:	
Fat embolus	1
Bronchopneumonia	1
Rib fracture and torn diaphragm	1
Heart rupture	1
Major rib fractures with instability	2
Total	6
Orthopaedic injuries:	
Major pelvic fractures	2
Extensive leg fractures	1
Bilateral traumatic amputation of legs	1
Total	4
Abdominal vascular injuries:	
Ruptured inferior vena cava	2
Ruptured aorta	1
Major hepatic lacerations	1
Total	4

Tracheostomy: Fifteen tracheostomies were performed during the 5-year period. Of these, 7 were performed for primary chest conditions, of which 2 patients eventually died. Seven tracheostomies were performed on patients with prolonged unconsciousness following head injury and 3 of these succumbed. One patient required a tracheostomy for a neck stab wound.

Table XVIII.—FRACTURES IN 67 CASES OF MAJOR TRAUMA

Position of Fracture	*No of Cases*
Femur	35
Tibia and fibula	25
Pelvis	21
Arm	13
Lumbar spine	7
Thoracic spine	1
Cervical spine	1
Total	103

Abdominal Injuries.—There were 13 cases of rupture or lacerations of solid viscera; spleen 5, kidney 6, and liver 2. In 5 patients major venous tears occurred. Jejunal rupture was seen once, and there were 3 cases of abdominal lacerations and stabbing. Two patients who had rupture of the inferior vena cava failed to survive. Post-mortem examination of these patients revealed lacerations of the vena cava at the point of insertion of the hepatic vein just below the diaphragm.

Musculo-skeletal Injuries.—It has already been noted that the quantification of the degree of trauma is extremely difficult where so many variables exist. In *Table XVIII* the number of fractures sustained by different bony structures is itemized, but this can in itself give little indication of the degree of associated soft-tissue trauma.

There was a total of 103 incidents of fracture in 67 patients. Seventeen of the 67 patients had only peripheral injury, i.e., there was no associated head, chest, or abdominal trauma. Of these patients, 5 died. Ten patients out of the 50 who had a peripheral, i.e., musculoskeletal, and a central system injury died. Of the factors listed in *Table XVIII*, only the arm-bone fractures cannot be considered as constituting major orthopaedic trauma. Despite this, the total of 103 incidents of fracture in 67 patients indicates that systemic injury and falling circulating blood-volume combined to give a potentially dangerous shock state in all the patients under consideration in this category.

Comments.—Many of the patients admitted after trauma had sustained injuries to the upper body which were nearly mortal, and *Fig.* 13 should be considered in the light of this fact. The majority of these patients had severe head injuries and were deeply unconscious from the outset. Their associated lesions usually required transfusion and support, but with vital centres in the midbrain not functioning the pattern of falling temperature, unstable blood-pressure, and the necessity for an increasing amount of respiratory support was commonly seen. This pattern culminated in the absence of spontaneous respiration and eventual circulatory arrest.

Those patients whose injuries are most severe but not mortal form a group which provides one of the greatest challenges in current surgery. In addition to the urgent need for circulatory support there is the essential forward planning to counteract possible renal shutdown, and, as unforeseen variations in the patient's clinical course appear, it is necessary to give thought to major complications such as fat embolization, traumatic aortic aneurysm, late manifestations of head injury, and unrevealed spinal fractures in an effort to explain symptoms and signs which may arise.

DISCUSSION

The challenge of work in an intensive-therapy unit in a general hospital is seen to arise from several factors. On the one hand, there is a group of young people arriving as a result of trauma incidents who are acutely ill and who require urgent care if they are to survive. Another major group of patients consists of the elderly with diseases of the gastro-intestinal tract who often present late with their symptoms. The overall incidence of malignant disease in all the patients in this series is of the order of 15 per cent; thus there can be a reasonable expectation of return to normality in a high proportion of our patients if treatment is successful. There is, however, often little time to spare in instituting diagnosis, resuscitation, and definitive treatment. It is therefore important for the medical staff to establish the priorities, particularly with regard to biochemical analysis and radiology which will enable them to confirm their diagnosis and so institute effective treatment.

The high mortality in certain poor-risk cases has already been alluded to. Thus, in the obstruction series 28 out of 48 patients succumbed; 19 out of 46 peptic ulcer patients died; in the emergency vascular series there were 15 deaths out of 24 patients. In most cases the patients with peptic ulcer and the vascular diseases had been known sufferers from their complaint, although with varying degrees of seriousness, for some time. Surgical treatment for these conditions may well be extensive and in some cases is precluded by age or other associated disease factors. However, it must be the impression that more positive evaluation of patient symptomatology at the level of primary medical care might result in more of these patients being admitted for elective surgery (with the demonstrated lower mortality) than has hitherto been the case.

The greatest problem is often one of interdepartmental management in so far as there may be the requirement to arrange neurosurgical investigation or dialysis support at another hospital within 24 hours of a major accident. There is a natural reluctance to move a patient who has just achieved haemodynamic stability and thus the difficulty will not be solved until there are more centralized major accident centres with all such specialities represented so that interhospital transfer can be avoided. We may see in the future such centres equipped with fast transport of an advanced nature for the collection of patients from outlying units, but at present the benefit of specific required care, e.g., haemodialysis, has to be balanced against the difficulties of transporting the severely injured patient to the specialized centre and the effect of such moves on the patient's general condition.

The concomitant progression of cardiac and pulmonary disease with age in patients living in a primarily urban area in Britain is another factor which would seem to point patients to earlier surgical treatment. In the peptic ulcer series 13 of the 19 deaths were attributed to cardiopulmonary causes, and in the obstruction series 12 of the 28 deaths were similarly itemized. It is difficult to speculate as to the numbers of these patients who would have survived operation with prior and more leisurely cardiopulmonary investigation and treatment, but comparison of the mortality in emergency vascular cases with the death-rate in the elective series described under Major Surgical Procedures is illuminating and probably points the way to the type of mortality figures expected.

Over the course of a 5-year period the results achieved by the unit have primarily been due to the more rapid evaluation of the clinical state of the patient and interpretation of the physiological and biochemical deficits associated therewith. This has in turn enabled corrections to be applied to achieve haemodynamic stability. It is in this general way that more rapid recovery can be achieved and morbidity and mortality figures consequently fall.

CONCLUSIONS

1. The importance of a stand-by medical and nursing organization ready within minutes to receive a seriously ill patient from home, accident site, or another ward in the hospital has been demonstrated. This system benefits the patient and is the most effective way of utilizing equipment which would otherwise have to be duplicated throughout a general hospital.

2. Clear access to the patient for several medical and ancillary personnel simultaneously is essential if urgent procedures are to be carried out on the seriously ill patient in the minimum time. This facet of care can best be managed in an intensive-therapy unit.

3. Proximity of the intensive-therapy unit and the operating theatre is a great advantage both in terms of primary surgery and any subsequent procedure which may be deemed necessary because of complications which arise (e.g., sputum retention) or when a staged surgical operative régime has been planned.

4. The instruction of new medical resident staff and nursing personnel can best be carried out on an informal and continuous basis in a small unit where patients are being observed and equipment is constantly in use.

5. A well-run unit rapidly develops a high morale which carries it through times when the results in terms of patient salvage are poor. The teamwork which is essential in providing a comprehensive 24-hour staffing requires continuous exchange of ideas and teaching at all levels in the unit, and frequent reviews of the methods by which results are achieved are essential.

6. The identification of the physiopathological changes seen in shock and the pharmacological management of these variations from normal represent a major field of surgical research. The careful observations of trained nursing staff in an intensive-therapy unit thus act as a firm base on which clinical evaluation and research can be founded.

Acknowledgements.—I wish to thank the consultant surgeons at Barnet General Hospital for their help and encouragement during my 2-year tenure of the post of Resident Surgical Officer. Mr. Alan Small, Mr. V. J. Downie, Mr. D. A. Bailey, and Mr. B. D. Stutter were most kind in allowing me to study their patients. Dr. Eric Gardner gave much encouragement at the inception of this project and I am indebted to Miss Angela Gardner for the statistical model.

The senior intensive-therapy unit sisters, Miss Rosemary Pope and Miss Mary Healey, are cordially thanked for their help in the unit at all times and for their willingness to assist in checking details from the intensive-therapy unit records.

THE CALCIUM PALMITATE GALL-STONE

BY A. G. A. COWIE, D. JUNE SUTOR, SUSAN E. WOOLEY, AND C. G. CLARK
DEPARTMENT OF SURGERY, UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL, AND DEPARTMENT OF CHEMISTRY, UNIVERSITY COLLEGE, LONDON

SUMMARY

Crystallographic studies have recently shown that calcium palmitate is the fourth most abundant crystalline constituent of gall-stones. In a study of the gall-stones from 31 consecutive patients undergoing operation at University College Hospital, London, in 1970, 2 patients were found whose stones contained calcium palmitate as the sole crystalline constituent, and a stone from a third patient had this compound as the major component. Three other patients had small beads of calcium palmitate in stones consisting predominantly of cholesterol. Some points of interest concerning these stone-formers are reported.

IN a recent statistical study of the characteristics of a collection of 331 gall-stones from 8 countries (Sutor and Wooley, 1971) the crystalline composition of the stones was determined by the X-ray powder method. Calcium palmitate was present in 36 per cent of the stones and accounted for 6 per cent of all the crystalline material in the series. Five stones consisted entirely of this compound. In 18 others it was present as a major component and in 16 as a minor one.

Prior to the work of Sutor in 1970 calcium palmitate had not been reported as a constituent of gall-stones from any country except Japan. Palmitic acid together with oleic and linoleic acids comprise 80 per cent of the fatty acids present in human bile, but 90 per cent of these acids are conjugated to lecithin (Blomstrand and Ekdahl, 1960) and therefore are unlikely to precipitate.

Little if any information is available concerning the conditions giving rise to calcium palmitate gall-stones, and we therefore present here preliminary data on a few such stone-formers found in a survey of the composition of bile and gall-stones from patients undergoing surgery for gall-stone disease at University College Hospital, London, in 1970.

MATERIALS AND METHODS

Thirty-one consecutive unselected patients formed the group in which the calcium palmitate stone-formers occurred. The gall-stones obtained at operation were washed, blotted dry, weighed, placed in formalin solution in distilled water for 24 hours, then washed, and air dried. The stones were analysed by the X-ray powder method, as described by Sutor and Wooley (1969), using a Nonius Guinier-type camera and filtered copper radiation. To determine the approximate amounts of crystalline material present the X-ray diffraction patterns obtained were matched against standard ones for known constituents of gall-stones. Bile was obtained at operation both from the gall-bladder and from the common bile-duct, taking care as far as possible to avoid contamination of the common bile-duct bile by the gall-bladder bile. The bile samples were analysed chemically. Total cholate concentration was determined by the method of Irvin, Johnson, and Kopala (1944), phospholipid concentration by a modification of the method of Fiske and Subbarrow (1925), and cholesterol concentration by a method derived from that of Babson, Shapiro, and Phillips (1962) and Leffler and McDougald (1963). Total bile-salt was estimated by assuming a relatively constant total cholate to bile-salt ratio in human bile of 1 : 2·7 (Sjövall, 1960).

Table I.—DATA FOR THE PATIENTS IN THE PRESENT SERIES

PATIENT	AGE AND SEX	PARITY	GALL-BLADDER FUNCTION	TIME SINCE ONSET OF SYMPTOMS (mth.)
1	73 F.	1	Normal	12
2	79 F.	0	Non-functioning	6
3	74 M.	—	Non-functioning	$\frac{1}{2}$
4	64 F.	0	Normal	4
5	67 F.	0	Non-functioning	5
6	47 F.	7	Non-functioning	6

Patients 1–3, gall-stones of 95–100 per cent calcium palmitate.
Patients 4–6, gall-stones of 1–3 per cent calcium palmitate.

RESULTS

Two of the patients had stones in which the only crystalline material present was calcium palmitate (Patients 1 and 2 in *Tables I–III*). Another patient (No. 3) had a stone in which calcium palmitate was the major component, the minor one being vaterite (a form of calcium carbonate). Three patients (Nos. 4–6) had small beads of calcium palmitate (Sutor, 1970) in stones otherwise consisting of cholesterol, except for 1 stone which probably contained a small amount of calcite (another form of calcium carbonate). The calcium palmitate beads accounted for only 1–3 per cent of the crystalline material of these stones.

The age, sex, and parity of the patients, the time since the onset of their symptoms, and their gall-bladder functions are given in *Table I*. Data for the gall-stones are presented in *Table II*. The results of the bile analyses, expressed in mmol per litre, are shown in *Table III*. These values were converted to percentages of the total molar concentration of the three constituents, phospholipid, cholesterol, and bile-salt, and plotted on a phase diagram in *Fig.* 1 (Hofmann and Small, 1967). This diagram shows in the lower left-hand corner the micellar area where cholesterol is soluble, and biles outside this region are supersaturated with respect to cholesterol and have the potential to crystallize.

Table II.—DATA FOR THE GALL-STONES FOUND IN PATIENTS IN THE PRESENT SERIES

PATIENT	NO. OF STONES	WEIGHT OF STONES (g)	SITE OF STONES
1	1	1·3	Common bile-duct
2	1	7·2	Common bile-duct
3	1	3·3	Gall-bladder
4	103	6·6	Gall-bladder
5	3	55·0	Gall-bladder
6	7	7·5	Gall-bladder

Table III.—COMPOSITION OF BILE (mmol/litre) FROM PATIENTS IN THE PRESENT SERIES

PATIENT	GALL-BLADDER BILE			COMMON BILE-DUCT BILE		
	Phospholipid	Cholesterol	Total Bile-salt	Phospholipid	Cholesterol	Total Bile-salt
1	7·36	1·84	26·01	2·09	1·34	9·57
2	8·01	1·89	33·47	7·99	1·86	31·66
3	13·81	4·57	40·93	8·50	3·15	22·18
4	12·05	6·98	42·70	—	—	—
5	No bile in gall-bladder			—	6·46	19·29
6	7·23	5·97	13·40	7·05	3·59	11·04

—, Insufficient bile to make measurement.

DISCUSSION

The patients having stones consisting almost entirely of calcium palmitate tend to be older than the other types of stone-formers, but the numbers are too small for the differences to be significant. These patients produced only single stones, which in 2 instances were found in the common bile-duct. At operation in these 2 cases the surgeon noted particularly that the gall-bladder appeared remarkably normal macroscopically, being free from overt signs of inflammatory change. Histologically, however, there was plentiful evidence of chronic inflammation. There were only 2 other common bile-duct stones in the series; these were in patients with cholesterol stones, both of whom had previously undergone cholecystectomy for cholelithiasis. It is rare to find stones in the common duct without stones in the gall-bladder, and the possibility that palmitate stones nucleate and grow in the bile-duct should be considered.

The composition of both the common bile-duct bile and gall-bladder bile from the patients with calcium palmitate stones is within the micellar zone of cholesterol solubility in bile. However, bile from patients having only a small trace of calcium palmitate in the form of beads in their stones had a composition outside this micellar region (*Fig.* 1). In the gall-bladder bile from a calcium palmitate stone-former there is less cholesterol than in the corresponding common bile-duct bile (*Fig.* 1). By contrast, in gall-bladder bile from cholesterol stone-formers the mean concentration of cholesterol is greater than that for common bile-duct bile (Sutor, Cowie, and Clark, 1973).

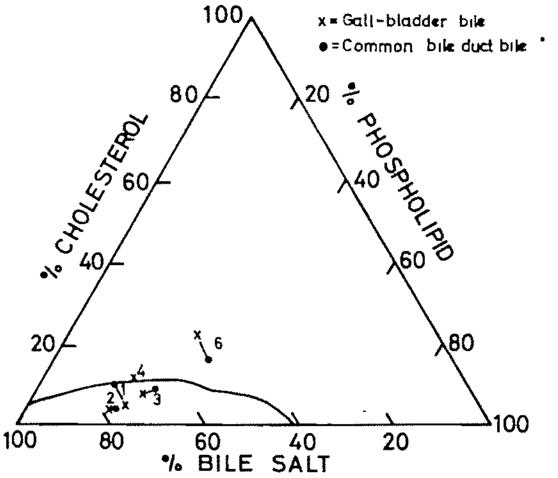

FIG. 1.—Phase diagram for bile from patients with calcium palmitate in their gall-stones. Patients 1–3, gall-stones of 95–100 per cent calcium palmitate. Patients 4–6, gall-stones of 1–3 per cent calcium palmitate.

From these data a picture emerges of the type of patient who has been found to develop calcium palmitate stones. Bearing in mind that so far too few of such patients have been found for statistically significant evaluations to be made, it is interesting to speculate whether future findings will be similar to those reported in this preliminary study. In particular we will be suspicious that the elderly patient, of low parity in the case of a female, who at operation is found to have a single, soft, pultaceous stone in the common bile-duct (especially if the gall-bladder is macroscopically normal) and whose gall-bladder bile and common bile-duct bile show no abnormality with respect to cholesterol solubility, may have a calcium palmitate stone.

In the study of the composition of gall-stones from different countries, Sutor and Wooley (1971) found several stones consisting entirely or predominantly of calcium palmitate. Unfortunately, detailed clinical information was not available, only the age and sex of the patients being known. There were 5 stones consisting entirely of calcium palmitate and of these, 2 came from males aged 74 and 78 and 2 from females aged 52 and 37. The age and sex of the fifth patient were unknown. Six other stones containing a major amount of calcium palmitate and one other (minor) constituent came from 5 males aged 63, 63, 63, 68, and 74 respectively, and 1 female aged 28. These data substantiate that calcium palmitate stones are more common amongst elderly patients.

Acknowledgements.—We thank the surgeons at University College Hospital for allowing material from their patients to be studied and Miss J. Fowler and Miss G. S. Dines for making the bile analyses. We are grateful to the Medical Research Council and the Nuffield Foundation for financial assistance.

ABDOMINAL ACTINOMYCOSIS

BY M. DAVIES AND N. C. KEDDIE
THE ROYAL INFIRMARY, MANCHESTER

SUMMARY

A case of sigmoid actinomycosis is described and the cases of abdominal actinomycosis presenting at the Manchester Royal Infirmary over the past 20 years are reviewed. The whole problem of abdominal actinomycosis is discussed, with special reference to the sites of infection and mode of treatment. The relevant literature is reviewed.

THE first clinical description of actinomycosis has been attributed to Von Langenbeck (1845). In 1877 Bollinger demonstrated that a fungus was the infective agent in producing the hard masses that occurred in the jaw bones of cattle. The following year Harz (1878) suggested the name *Actinomyces bovis* for this fungus. At the same time Israel (1878) was studying material obtained from a patient with suppuration in the neck. He noted granules which contained the same mycelia as those described by Bollinger (1877) in cattle. Israel, who remained active in the study of actinomycosis, considered that it is an endogenous anaerobic infection and despite suggestions that it is an exogenous aerobic infection by such workers as Bostroem (1890) this theory has been upheld ever since. About 20 per cent of cases of actinomycosis have the primary site of infection in the abdomen (Cope, 1938), the majority originating in the region of the caecum. Other less common sites are the stomach, duodenum, genito-urinary tract, and colon. The sigmoid colon is a very rare site of infection, and this is why we decided to report the present case.

REVIEW OF CASES

During the past 20 years 7 cases of abdominal actinomycosis have been treated at Manchester Royal Infirmary. The total number of cases of actinomycosis treated at the same hospital during this period was 13. This represents an unusually high proportion with the primary site of infection in the abdomen, which is probably explained by the fact that the cervical cases would most probably have been referred to a dental hospital. Of the 7 cases, 5 originated in the appendix, 1 in the sigmoid colon, and 1 in either the gall-bladder or the duodenum. In all these cases the diagnosis was confirmed by growth of the actinomyces on culture or by the discovery of the typical colonies in histological sections. Suspected cases not confirmed by either histology or bacteriology have not been included.

CASE REPORTS

Case 1.—A 29-year-old housewife was admitted to Manchester Royal Infirmary in September, 1970, complaining of pain in her left iliac fossa which had persisted for 4 months. She had lost about 3 kg. in weight but there was no change in bowel habit. Her only other complaint was of mild frequency of micturition. On examination she was very pale with a temperature of 38° C. Palpation of her abdomen revealed a firm tender mass, 10 cm. in diameter, in her left iliac fossa. The mass was fixed to the left side of her pelvis and rectal examination revealed a tender swelling in the pouch of Douglas on the left side. The haemoglobin was 10·3 g. per cent and the white-cell count was 12,000 c.mm. with a normal differential. A midstream specimen of urine showed no pus cells.

A laparotomy was performed on 14 Sept. through a left lower paramedian incision. A fixed mass was found in the left iliac fossa adherent to the side-wall of the pelvis and involving the sigmoid colon. The left Fallopian tube and ovary were not involved, but the transverse colon and omentum were tethered to the upper margin of the mass. The mass itself was composed of dense fibrous tissue and contained multiple abscesses. The nature of the pathology was not clear from the macroscopic appearance. The abscesses were drained and specimens of the pus were sent for culture. Portions of the walls of the abscesses were sent for histological examination by frozen and paraffin sections. The frozen sections were reported as showing non-specific acute inflammation. The wound was closed and the area drained through a separate stab incision. No 'sulphur granules' were seen at this time. Bacteriological studies showed Gram-positive cocci which failed to grow on culture. The biopsies revealed acute abscesses with surrounding granulation tissue and mature fibrous tissue. No specific granulomata were seen.

Postoperatively the patient was given 2 pints of blood and started on penicillin, 1 MU. 6-hourly, and streptomycin, 0·5 g. twice daily intramuscularly. As bacterial cultures were sterile antibiotics were discontinued after

5 days, by which time her temperature was normal. The wound healed well and she was allowed home 10 days later on no specific treatment. She was seen for follow-up on 6 Nov., when she still complained of a dull ache in her left iliac fossa. Her haemoglobin and white-cell count were normal at this stage and a barium-enema examination, although showing no specific abnormality, revealed some rigidity and atypical irregularity in the sigmoid colon. The radiologist suggested that she might have Crohn's disease. She attended again on 11 Dec., when she complained of a recurrence of the swelling in her left iliac fossa with a discharge from the site of her previous drain. She was started on ampicillin, 250 mg. four times a day orally, and was seen a week later when her condition was unchanged. One month later the mass was larger and she was admitted to hospital for the second time. She was again pyrexial with a temperature of 37·8° C., but her white-cell count was only 10,300 c.mm. Her haemoglobin had dropped to 12·1 g. per cent. Her erythrocyte sedimentation rate was 95 mm. in the first hour. A colonoscopy was carried out and no abnormality was seen to the limit of the examination. The instrument could not, however, be passed beyond the distal sigmoid colon owing to the rigidity of this part of the bowel.

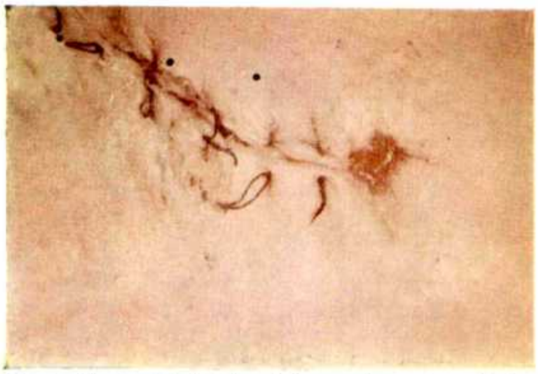

FIG. 1.—*Case* 1. The incision of the second operation with the sinus and granulations.

A second operation was performed on 28 Jan., 1971, when the sinus at the previous drain site was excised and an abscess involving the full thickness of the abdominal wall was opened. Yellow granules were noted in the pus and a clinical diagnosis of actinomycosis was made. The abscess was drained and after multiple biopsies had been taken the wound was closed around a corrugated drain (*Fig.* 1). The clinical diagnosis was confirmed both on culture and histological examination (*Figs.* 2, 3). The organism was found to be sensitive to penicillin, tetracycline, and erythromycin. She was therefore started on long-term penicillin therapy, 1 MU. 6-hourly intramuscularly for the first week, 1 MU. 12-hourly intramuscularly for 1 week, followed by 1 MU. daily intramuscularly as an out-patient for 1 month. This was supplemented by oral penicillin 'V', 250 mg. four times a day for 2 months. Her erythrocyte sedimentation rate, which was 111 mm. per hour at the time of the second operation, returned to normal limits after 2 weeks of treatment and after 2 months of treatment all traces of the mass had disappeared and the sinus had not recurred. Her liver-function tests at the height of the infection had shown a reversal of the albumin/globulin ratio (albumin, 2·8 g. per cent; globulin, 5·1 g. per cent), suggesting involvement of the liver by the fungal infection. At the end of the course of treatment her liver-function tests had returned to normal.

Case 2.—A female, aged 21 years, presented with a 2-month history of pain in her right groin preceded by 3 months' general malaise. Three weeks before admission she had developed a swelling in her right iliac fossa which had started to discharge after a week. On examination she was found to have a mass, 8 cm. in diameter, in her right groin which was discharging yellow pus. No granules were found in the pus which on first culture failed to reveal *Actinomyces*. Her haemoglobin was 7 g. per cent and her white-cell count was 15,000 c.mm. with 89 per cent of polymorphs. At operation the abscess was drained and culture of the pus revealed actinomycosis. She was given a 2-month course of soluble penicillin, 2 MU. daily, following which the sinus healed.

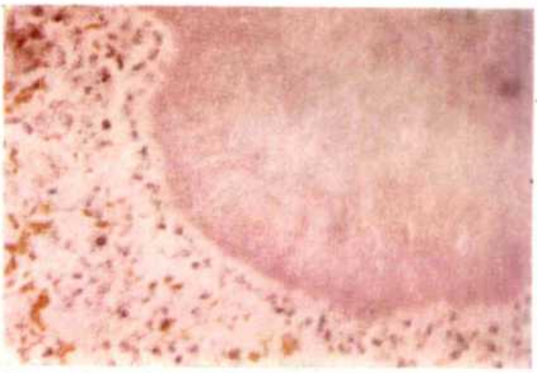

FIG. 2.—*Case* 1. Section of the sulphur granule, demonstrating how the name 'ray fungus' arose.

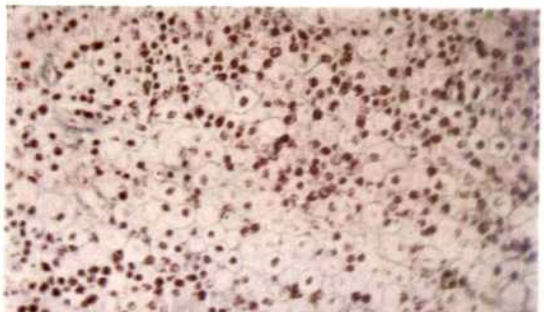

FIG. 3.—*Case* 1. Section showing the typical foamy macrophages seen around the lesions.

Case 3.—A female, aged 27 years, gave a long history of recurrent attacks of small-bowel obstruction for which she had had three operations prior to her presentation in May, 1951. Examination of her abdomen at this time revealed abdominal distension with a palpable mass in her right iliac fossa. At laparotomy there was a mass in the caecum. Biopsies were taken and an ileotransverse anastomosis was performed. The biopsies revealed no specific abnormality and a provisional diagnosis of either Crohn's disease, or carcinoma, or tuberculosis was made. In November of the same year she returned with a discharging sinus in her right iliac fossa and at this time 'sulphur granules' were seen in the pus. A diagnosis of actinomycosis was made. She was therefore started on soluble penicillin, 1 MU. daily intramuscularly. Unfortunately, she died shortly afterwards.

Case 4.—A female, aged 30 years, presented with a 6-week history of general malaise and pain in the right iliac fossa. On examination there was a palpable mass in her right iliac fossa. At laparotomy the appendix was found to enter a mass which contained a moderate amount of pus. The abscess was simply drained and she was started on 1 MU. of penicillin twice daily intramuscularly which was continued for 2 months. Culture of the pus confirmed the diagnosis of actinomycosis. The sinus cleared up permanently after 3 months.

Case 5.—A male, aged 41 years, presented in 1953 with history of pain in his right hypochondrium and dyspnoea. His temperature was 38·5°C. and a diagnosis of acute cholecystitis was made. Subsequently, however, the gall-bladder was found to function normally on radiography. Whilst in hospital he developed a fluctuant swelling in his right flank which was thought to be a perinephric abscess. This was drained and culture of the pus grew a non-haemolytic streptococcus. He was put on streptomycin intramuscularly. In 1957 he developed a recurrence of the pain in his right hypochondrium and was put on the waiting list for cholecystectomy. Before this could be done he was admitted as an emergency with an area of cellulitis over his right costal margin. He was put on penicillin therapy and the area was aspirated on three occasions with negative culture. Following this, the area was explored and the abscess drained. Culture on this occasion grew only a non-haemolytic streptococcus. In 1959 the abscess recurred. It was explored more thoroughly and was found to track subdiaphragmatically. Culture of the pus on this occasion revealed *Actinomyces*. He was put on repeated courses of penicillin intramuscularly. After three further flare-ups of the infection the condition subsided.

Case 6.—A male, aged 17 years, had an appendix abscess drained in November, 1953, at which time it was impossible to remove the appendix. In January, 1954, an operation was performed to remove the appendix which was adherent to the bladder. The appendix was successfully removed but the wound discharged yellow pus post-operatively. The discharge persisted until May, 1954, when another abscess developed in his left lumbar region. This was drained and revealed thick yellow pus which grew *Escherichia coli*, non-haemolytic streptococcus, and *Staphylococcus aureus*. Without antibiotic therapy the discharge from his appendix wound and the lumbar abscess subsided. In July, 1954, he developed an abscess in his sacral region. This abscess was aspirated and revealed *Actinomyces*. He was started on penicillin, 1 MU. intramuscularly twice daily. After 1 month of treatment the sinus finally healed.

Case 7.—A male, aged 13 years, gave a 2-week history of diarrhoea following which he had developed an abscess in his right groin. A diagnosis of inguinal lymphadenitis was made and he was started on penicillin 600,000 U. daily. The abscess failed to subside and 1 month later was drained, revealing *Actinomyces*. Streptomycin was added to the penicillin therapy and the abscess cleared up. Three years later he was admitted with acute appendicitis. At operation the appendix was found to be adherent to the scar of the previous drainage wound in the groin. Following the removal of the appendix he made a good recovery.

DISCUSSION

Pathogenesis of Abdominal Actinomycosis.—The organism responsible for abdominal actinomycosis is an anaerobic, Gram-positive, branching filamentous fungus which is related in many respects to bacteria. *Actinomyces israeli* is a common saprophyte in the mouth and gastro-intestinal tract, the endogenous nature of the infection being virtually beyond doubt. Slack (1942), who examined 100 pairs of tonsils from routine tonsillectomies, found colonies of anaerobic actinomycetes in 14 per cent of cases. The organism enters the abdominal cavity from the alimentary tract in the majority of cases and infection from the genital tract, diaphragm, or blood-stream is extremely rare (Cope, 1938). The actinomycetes cannot penetrate healthy mucosa and damage to the mucosa by trauma, disease, or surgery is an essential prerequisite to infection. Having penetrated the bowel, the organism proliferates, leading to the production of a mass of dense, almost woody, fibrous tissue. Areas of this mass usually undergo softening with the production of abscesses, which may rupture through the abdominal wall producing sinuses, penetrate into adjacent viscera causing fistulae, or rupture through the diaphragm leading to pulmonary actinomycosis. Lymphatic spread in actinomycosis does not occur, presumably because of the large size of the filaments; lymphadenitis is due to the secondary infection which is very common. Blood spread, however, is quite common and hepatic involvement via the portal vein leads to the typical 'honeycomb' liver.

Actinomycotic pus consists of a dense infiltration of mainly polymorphs, in the centre of which are colonies of actinomycetes forming the 'sulphur granule'. This sulphur granule or mycelium tends to be surrounded by club-shaped excrescences which radiate outwards, giving rise to the alternative name of 'ray fungus'. These clubs are not formed in artificial culture and are produced by deposition of host lipid on to the mycelium (Walter and Israel, 1963).

Abdominal Localization.—Apart from the neck, the abdomen is the commonest site for actinomycosis, accounting for one-fifth of the cases (Cope, 1938). The ileocaecal region is the usual site as a result of a perforated appendix, but no site is immune.

Stomach and Duodenum.—Perigastric actinomycosis occurs only when the gastric mucosa is diseased or after gastric surgery. The actinomycetes cannot survive in a healthy stomach (Cope, 1938). Nathan (1929) reviewed gastric actinomycosis and described a fatal case which was found to have a large callous ulcer penetrating into the liver and pancreas. He attributed the rarity of the infection in this site not to gastric acidity but to vigorous motility preventing the fungus from settling. Cope (1938) believed that perforation of the mucosa was essential. Perigastric actinomycosis occurs in two circumstances: either associated with a perforated ulcer or following gastric surgery. A common feature in all the cases described is a latent period before the onset. Till (1946) described a case presenting 4 months after a perforated gastric ulcer. More recently Pheils, Reid, and Ross (1964) and Ashton and Slaney (1963) have described cases following gastric surgery. The infection in Ashton and Slaney's case complicated a leaking duodenal stump. Again a long latent period was noted. A rare complication of gastric actinomycosis was reported by Wilson (1961), who described pyloric stenosis following infection in the antrum. The stenosis responded dramatically to parenteral penicillin and sulphadiazine.

Gall-bladder and Pancreas.—Invasion of the pancreas and biliary tree by the fungus is extremely rare. The pancreas most probably becomes infected by direct spread from the stomach or duodenum owing to penetration by a peptic ulcer. Fontan, Serrano-Rios, Navarro, Oliva, and Ramirez (1969) described a fatal case in a 62-year-old man who had multiple actinomycotic abscesses in the pancreas and liver. The present *Case* 5 probably represents a case of actinomycotic cholecystitis and we have found only

2 other established cases in the literature (Mayo-Robson, 1905; Rewerts, 1964). The mode of infection of the gall-bladder by the fungus is less well understood. Mayo-Robson (1905) felt that infection did not occur via the skin, blood-stream, or lymphatics or by direct spread from the gut as no other lesion was present in his case. He believed that the infection reached the gall-bladder by retrograde spread up the bile-duct from the duodenum. Cope (1938) pointed out that once the organism has penetrated the bowel the mucosa heals and may show no sign of the initial infection, so that this is the most likely route of infection in actinomycotic cholecystitis.

Jejunum and Ileum.—The extreme rarity of actinomycosis in these regions has been explained by the rapid passage of the small-bowel contents. A more important reason may be the infrequency of penetrating lesions of the mucosa. A feature of the infection is the relatively normal appearance of the bowel at operation, the bulk of the inflammation occurring in the mesentery. Rigler (1964) described a case occurring in the ileum following perforation by a fish bone, and stressed the importance of complete excision where possible.

Ileocaecal Region.—This was the commonest site in the present series, as was also found in other reports (Cope, 1938). The source of infection in virtually all the cases is the appendix, 'periappendicular actinomycosis' being a more accurate name. The most interesting feature is the differing modes of presentation, which explain why this well-recognized condition is so often misdiagnosed. Cope (1938) classified pericaecal actinomycosis into two clinical types: (1) those which start with an attack of acute, usually perforated appendicitis; (2) those which start insidiously and first reveal themselves by the presence of a lump. He considered the former to be the commonest mode of presentation and certainly most of the cases described in the literature have come to light following an acute appendicitis (Wilson, 1961; Duncan, 1965). It is interesting that none of the cases in our series was of this type. Four presented as a mass in the right iliac fossa and 1 as recurrent attacks of small-bowel obstruction. After the disease has become established in this region, unless it is treated, it progresses in a classic way irrespective of its mode of presentation, with the formation of a hard craggy mass with associated sinuses or fistulae.

Colon.—Apart from the caecal region colonic actinomycosis occurs most frequently in the transverse and sigmoid regions. Because of the rarity of the disease in these sites the diagnosis is usually made late, a presumptive diagnosis of carcinoma, diverticular mass, or Crohn's disease usually being made. Palmisano and Russin (1969) and Salmo, Rudolf, and Makki (1969) both described cases occurring in the transverse colon. In the latter case a preoperative diagnosis of carcinoma of the stomach was made; it was only after resection of the affected colon that the diagnosis came to light. Actinomycosis of the sigmoid colon is even rarer, but previous cases have been described by Cope (1938) and Piper, Stoner, Mitra, and Talerman (1969). The rarity in this region is difficult to understand as perforation of the bowel secondary to diverticular disease and carcinoma occurs most commonly in the sigmoid colon. An even more difficult fact to explain is the rarity of the infection following perforation of diverticula anywhere in the colon. We were unable to find any cases of actinomycosis following perforated diverticulitis. Although no cases of vesicocolic fistula have been recorded complicating actinomycosis, Piper and others (1969) described a case of ileovesical fistula which they attribute to actinomycosis arising in the sigmoid colon.

Anorectal Region.—Actinomycosis may arise primarily in the rectum and anal canal or may involve the perirectal tissues secondarily by downward spread from the iliac fossa. As would be expected, the infection tends to flourish in the loose tissues of the ischiorectal fossa, with a tendency to spread posteriorly rather than anteriorly (Morson, 1961). Perirectal actinomycosis may, therefore, come to light as an abscess in the buttock which recurs after drainage. A further progression of this local spread may explain the sacral abscess in the present *Case* 6 following actinomycosis in the right iliac fossa.

A special type of anorectal actinomycosis which took the form of an indurated ring at the anorectal junction was described by Morson (1961). He suggested that all rectal strictures should be biopsied to exclude this infection. Finally, a case of primary actinomycosis of the rectum was described by Fry, Martin, Dearing, and Culp (1965) in association with multiple perirectal and perianal fistulae, features which would lead most clinicians to suspect Crohn's disease.

Diagnosis.—Actinomycosis is one of the great imitators in clinical practice, particularly when it occurs in the abdominal cavity. Whilst reviewing cases presented by previous authors one is impressed by the length of time between the onset of symptoms and the final diagnosis. Our series is no exception to the rule as the average time to diagnosis was 18 months, ranging from 1 week to 6 years. Although the modes of presentation were varied there were certain features which, if borne in mind, may lead one to suspect the condition. The majority of cases demonstrates the 'latent' period referred to earlier, the symptoms following weeks or months after an abdominal catastrophe, which often involves perforation of the gut, or abdominal surgery. This may help to distinguish the condition from carcinoma, diverticular disease, and Crohn's disease.

A persistent discharging sinus, particularly following surgery for a perforated viscus, should always suggest the diagnosis, but unfortunately bacteriological study of the discharge may well be negative in the first instance. Even when specifically sought the classic colonies are difficult to culture, particularly as secondary infection of the abscess with such organisms as *E. coli* and staphylococci is so common. If visible macroscopically the 'sulphur granules' are pathognomonic but these are not always present, e.g., in only 5 of 13 cases at Manchester Royal Infirmary. Biopsy of the walls of sinuses or abscesses may also be fruitless, being reported on numerous occasions as showing 'non-specific' inflammation.

Constitutional disturbances, although non-specific as far as diagnosis is concerned, may be particularly severe in actinomycosis. Pyrexia is common in the early stages but is often masked by antibiotic therapy. Microcytic anaemia is a constant feature. Although

P 25 352.

the erythrocyte sedimentation rate is often raised above 100 mm. in the first hour, its value lies in monitoring the response to treatment rather than in diagnosis. Weight-loss usually occurs if the disease is widespread but again is not specific.

The diagnosis of actinomycosis rests almost entirely on the discovery of the typical colonies in pus obtained from the abscesses, but one must not scorn the pathologist for failing to see them initially if the possibility of their presence was not suggested by the clinician.

Treatment.—The first treatment for actinomycosis was surgical extirpation, and surgery still has a place today. Originally the aim was complete extirpation of the disease, which in most cases is impossible. Nowadays surgery is usually limited to incision and drainage with curettage of large abscesses. However, as recently as 1965 Duncan stressed the importance of an aggressive surgical approach in abdominal actinomycosis. Iodine was the first therapeutic agent to be used, and a palatable dosage of 5 minims in milk three times a day was suggested by Chitty (1926). It may still be a useful adjunct to the more usual therapy. The polyvalent actinomyces vaccine has been used as a specific therapeutic agent in the past. Placa, Proca, and Tomas (1966) revived its use in an abdominal case with success, following failure of antibiotic therapy. Its use nowadays lies in diagnosis in cases with negative biopsies. Following intracutaneous injection of 0·1 ml. of graded dilutions of the vaccine a local allergic reaction results in cases of actinomycosis (Bronner and Bronner, 1969). Radiotherapy has been used for its effect of softening fibrous tissue, but is not now used, mainly because of its effects on adjacent viscera.

With the advent of sulphonamides the prognosis of actinomycosis rapidly improved. Walker (1938) was one of the first to describe its use, suggesting a dosage of 1 g. three times a day. Since penicillin was first used no better treatment has been found. If penicillin is administered in the correct dosage it cures virtually every case. All the cases in our series were treated by penicillin with cures in all but 1. When first introduced, a daily dosage of up to 10 MU. intramuscularly was recommended. This was very painful, required prolonged hospitalization, and has recently been shown to be quite unnecessary. A reasonable dosage is 2 MU. daily by intramuscular injection continued for 1–2 months after all clinical evidence of the infection has settled. In fact, our *Case* 1 was treated successfully with a considerably lower dosage, converting to oral penicillin in the later stages of the treatment. A feature of treatment that cannot be overstated is the necessity to continue the therapy for long periods after clinical extirpation of the infection. The cases showing a recrudescence of the disease after short-term therapy are legion.

Recently writers have described the use of other antibiotics in the treatment of abdominal actinomycosis with equally good results (Martin, Nichols, Wellman, and Weed, 1956; Svane, 1966; Halter, 1967). The use of more expensive and more toxic antibiotics appears to be unnecessary unless there is an allergy to penicillin or, as very rarely occurs, a resistant strain of fungus is encountered.

UNABSORBABLE SUTURE MATERIAL—A RARE CAUSE OF RECURRENT STONES IN THE COMMON BILE-DUCT

By D. B. MACKIE,* STEPHEN HAYNES,
CENTRAL MIDDLESEX HOSPITAL, LONDON

AND ROY E. MAY
FRENCHAY HOSPITAL, BRISTOL

SUMMARY

Three cases are reported in which unabsorbable suture material used to ligate the cystic duct at cholecystectomy was subsequently found within the lumen of the extrahepatic bile-ducts. In 2 cases well-formed gall-stones having a central nucleus of either silk or nylon were removed from the common bile-duct. In the third case two braided nylon sutures were found within the stump of the cystic duct. The use of absorbable suture material for ligating the cystic duct is therefore recommended.

MOST authorities believe that the majority of gall-stones found in the common bile-duct was originally formed in the gall-bladder (Smith and Sherlock, 1964). Thus, following cholecystectomy any stone found within the common bile-duct usually represents either failure to explore the bile-duct or failure to remove all the stones from the bile-duct at the original operation. Such stones therefore are commonly referred to as residual rather than recurrent.

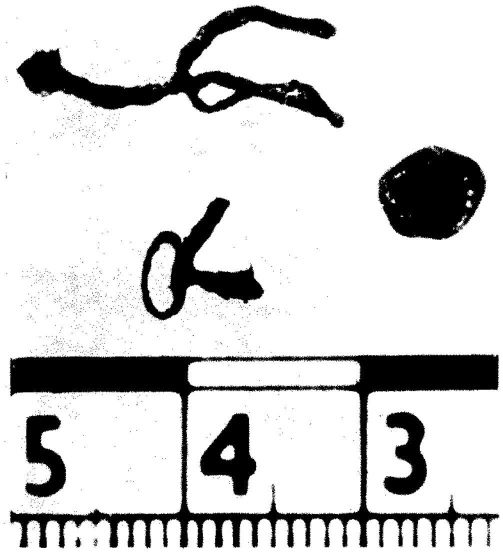

FIG. 1.—*Case* 1. Two braided nylon sutures and residual stone removed following re-exploration of the common bile-duct.

The purpose of this report is to record 3 instances in which unabsorbable suture material used to ligate the cystic duct at cholecystectomy was subsequently found within the lumen of the extrahepatic bile-ducts. In 2 cases a gall-stone formed *de novo* around a nucleus of either silk or nylon, whilst in the third case two nylon sutures encrusted with calcareous material were removed from the stump of the cystic duct.

CASE REPORTS

Case 1.—Mrs. M. J., aged 70 years, presented in 1969 with a 7-year history of recurrent epigastric pain radiating to the back. She had been jaundiced on one occasion and a cholecystogram confirmed the presence of gall-stones. At cholecystectomy numerous stones were palpated in the common bile-duct and a formal exploration was undertaken. The bile-duct was sutured with 000 catgut around a T-tube. The cystic duct, however, was ligated and transfixed with two braided nylon sutures. Her recovery was satisfactory and a postoperative T-tube choledochogram was normal.

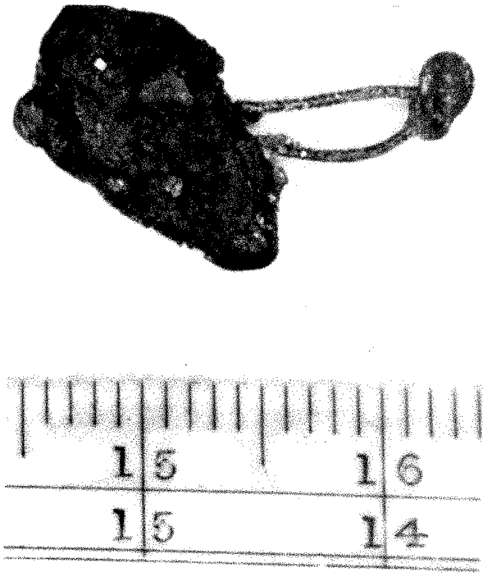

FIG. 2.—*Case* 3. Gall-stone having a central nucleus of monofilament nylon removed from the common bile-duct at the second exploration.

One year later the patient returned complaining of episodic epigastric pain during the preceding 3 months. No abnormality was found on examination and an intravenous cholangiogram demonstrated a dilated common bile-duct but no definite calculi were seen. Re-exploration of the bile-duct was performed and a residual stone was removed from the lower end. In addition, two braided nylon sutures were found within the lumen of the stump of the cystic duct and both were heavily encrusted with calcareous material (*Fig.* 1). A side-to-side choledochoduodenostomy was performed. Her postoperative recovery was smooth. The stone was examined and no suture material was found within it. The patient has remained well since.

---

* Present address: Salisbury General Infirmary, Salisbury.

Case 2.—Mrs. E. F., aged 54 years, was admitted to hospital for elective cholecystectomy in 1967 following recurrent bouts of biliary colic over a 10-year period. During one episode she had become jaundiced. At cholecystectomy numerous gall-stones were present in the gall-bladder but a peroperative choledochogram demonstrated a normal narrow segment, free flow of contrast into the duodenum, and no evidence of stone in the common bile-duct. The gall-bladder was removed and the cystic duct was tied with a silk ligature. Her postoperative recovery was satisfactory.

In 1969 the patient was investigated on account of further abdominal pain, and an intravenous cholangiogram demonstrated an enlarged common bile-duct with a suspicious filling defect in the distal portion of the duct. Exploration of the common bile-duct was advised and at operation one stone was removed. The stone was crushed and a silk ligature was found within it. Her postoperative recovery was uneventful and she has had no further symptoms.

Case 3.—Mrs. E. G., aged 73 years, was admitted to hospital as an emergency in December, 1970, with a history of recurrent episodes of epigastric pain radiating through to the back. Six years previously she had undergone cholecystectomy with exploration of the common bile-duct at a military hospital in Germany. Her postoperative recovery had been uneventful and the postoperative choledochogram had demonstrated a normal common bile-duct.

On examination the patient was both febrile and jaundiced but no abnormality could be found in the abdomen. Biochemical investigations confirmed the clinical impression of obstructive jaundice. Subsequently the jaundice resolved spontaneously and an intravenous cholangiogram demonstrated stones within the common bile-duct.

At operation the common bile-duct was enlarged and some monofilament nylon suture material was found adherent to the anterior surface of the duct. A transduodenal exploration of the common bile-duct was performed together with sphincteroplasty; two large and several smaller stones were removed. The two large stones were crushed and in the middle of one a monofilament nylon suture was found (*Fig.* 2). Her postoperative recovery was uneventful and she has remained well.

DISCUSSION

A residual stone in the common bile-duct following cholecystectomy is a distressing but potentially avoidable complication. The importance of operative cholangiography in detecting unsuspected stones in the common bile-duct is now well established (Ferris and Weber, 1956; Le Quesne, 1960), and when operative cholangiography is used routinely in all cases the incidence of residual stones is greatly reduced. Thus, Harvard (1970) reported residual stones in only 5 out of 300 consecutive operations for calculous biliary tract disease. In all 5 cases residual stones occurred in ducts which had previously been explored. This emphasizes the frequent difficulty experienced in interpreting postexploratory cholangiography. The stone removed from the common bile-duct in the present *Case* 1 was faceted (*Fig.* 1) and when crushed no suture material was found. We suggest that this stone was one of the many originally formed in the gall-bladder and that it was thus a residual gall-stone.

Although a previously inadequate operation is undoubtedly the main aetiological factor in residual choledocholithiasis there have been spasmodic reports of recurrent stones forming around unabsorbable suture material (Homans, 1897; Rains, 1961). Despite this there is no unanimity of opinion in surgical textbooks with respect to the most suitable material for ligating the cystic duct. Both Maingot (1969) and Rob and Smith (1969) recommend catgut whereas Gardham and Davies (1963), Rains (1964), and Farquharson (1969) advocate unabsorbable suture material.

The first case reported here was the only instance in which the cystic duct was both transfixed and ligated. Transfixion of necessity introduces the suture material into the lumen of the duct and this may have been a factor favouring the extrusion of the two braided nylon sutures into the cystic duct stump. Once within the bile-duct such material forms an ideal nucleus around which bile, pigment, and cholesterol may aggregate to form a recurrent stone (*Cases* 2 and 3). However, as judged by the scarcity of reports in the literature such stone formation is most unusual. Thus, if ligature extrusion occurs with any frequency it must be assumed that the majority passes harmlessly into the duodenum. Nevertheless the routine examination of recurrent gall-stones may demonstrate that this form of choledocholithiasis occurs more frequently than expected. We suggest that the use of an absorbable suture material for ligating the cystic duct would further reduce the incidence of this rare complication.

Acknowledgements.—We should like to thank Mr. J. W. P. Gummer and Mr. W. W. Slack for permission to publish details about cases who were under their care, and Professor L. P. Le Quesne for his helpful advice.

OPEN SKIN-GRAFTING IN DEVELOPING COUNTRIES

By EZZAT A. GIBRAIEL*

CHIEF OF PLASTIC SURGERY AND BURNS, ASHRAFIEH SURGICAL HOSPITAL, AMMAN, JORDAN

SUMMARY

Because of the poor condition of most granulating wounds and the unpredictable and frequently unsatisfactory results of closed skin-grafting, 160 open skin-grafting operations were performed and studied in Egypt and Jordan in order to develop a reliable procedure for use in developing countries. A simple, economical, and successful open grafting method was established. The results are given together with the details of 4 illustrative cases. Important technical points are mentioned. The necessity of the application of open grafts on patients in developing countries is stressed and the advantages of the author's method are discussed.

In some developing countries it is distressing to see many patients with chronic, ungrafted, granulating wounds following deep burns and other forms of traumatic skin-loss. These wounds are frequently associated with cachexia, anaemia, and toxaemia and are often complicated by troublesome deformities and disabling contractures. Such patients occupy hospital beds for months and act as reservoirs for cross-infection.

This unhappy state is mainly due to the poor condition of granulations produced under unfavourable conditions and the prevalence of sepsis. The results of closed grafting techniques are frequently unsatisfactory and, indeed, many patients are denied the benefits of grafting because of the lack of consistently successful grafting procedures under these circumstances.

For these reasons open skin-grafting has been practised by the author in two developing countries (Egypt and Jordan) in an attempt to perfect a reliable method that can be routinely applied even when conditions are unfavourable.

MATERIALS

One hundred and sixty open grafting operations were performed by the author in Egypt and Jordan. About 60 per cent of the cases were due to full-thickness burns; the rest were caused by other forms of traumatic skin-loss. This series includes wounds in all anatomical regions. The trunk was involved in 32 per cent of the cases, the head and face in 6 per cent, the neck in 13 per cent, the upper extremity in 34 per cent, the hand in 10 per cent, the lower extremity in 49 per cent, the scrotum in 1 case, the penis in 1 case, and the orbital socket after exenteration in 1 case. The age of the granulations ranged from 10 days to 3 years; in 37 per cent of the cases the granulations were more than 2 months old.

The patients were operated on in 4 different hospitals in Cairo and Amman. A large number of them were referred from other territories of Egypt and Jordan and therefore this group could be considered to be representative of these two countries.

Clinical infection in the form of purulent discharge was present to a variable extent in almost all the cases. Many patients were referred in poor condition; they had received very little local wound care and were potentially contaminated with many pathogenic organisms. Bacteriological studies were not carried out because facilities were not readily available in most instances, but based on circumstantial evidence and on clinical grounds mixed infection appeared to be prevalent, Gram-negative organisms, particularly *Pseudomonas pyocyaneus*, predominating.

Sepsis, unless obviously severe, was not considered a contra-indication to open grafting, especially when the granulation tissue possessed reasonable vascularity. Complete eradication of sepsis was not usually practical, but when considerable suppuration was present daily cleansing of the wounds and the application of wet Eusol absorptive dressings were carried out before operation to reduce the discharge. When Sulfamylon became available, it proved very helpful in preparing grossly septic cases for grafting. Antibiotics, mostly penicillin, streptomycin, tetracycline, or chloramphenicol, were given before and after operation to help minimize sepsis.

METHODS

Split-thickness skin-grafts were removed under general or local (ethyl chloride) anaesthesia according to the circumstances of each case. When local anaesthesia was used the whole operation was performed as a bedside procedure (Gibraiel, 1971). When general anaesthesia was employed only the process of removal of the grafts was carried out in the operating theatre and the granulating wounds were left undisturbed. The skin thus procured was kept until application in an ordinary refrigerator at above 0° C. After this short procedure of skin removal the patient was returned to his ward, and when he became fully conscious the grafts were applied to the granulating areas to avoid displacement of the grafts during recovery and transport and to gain the patient's co-operation and assistance during their application. This latter process was carried out by a 'clean' but not necessarily sterile technique. The skin was put directly on the raw areas without preparation, i.e., no shaving or curettage of the granulations was done. No sutures or any other devices were used to fix the grafts. The latter were left completely exposed. With simple and reasonable measures it was possible to achieve adequate exposure of almost any region of the body.

After operation the exposed grafts were managed in the usual way (Muir and Barclay, 1962; Blocker, 1964; Converse and Brauer, 1964; Cannon and Murray, 1966; Moncrief, 1966; Artz and Moncrief,

---

* Formerly Consultant Plastic Surgeon, Cairo Institute for Burns, Cairo, Egypt.

1969). Dressings were usually applied at about 4–7 days after operation, but in cases with excessive marginal discharge and/or encrustation, exposure was discontinued as early as the third postoperative day without detriment to the taking of the graft.

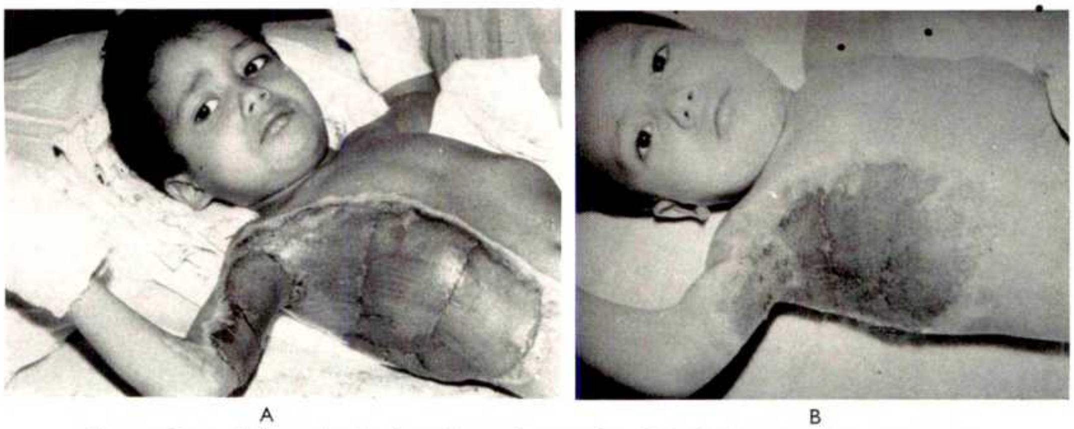

FIG. 1.—*Case* 1. A, Exposed grafts about 48 hours after operation. B, Result about 2 months after operation.

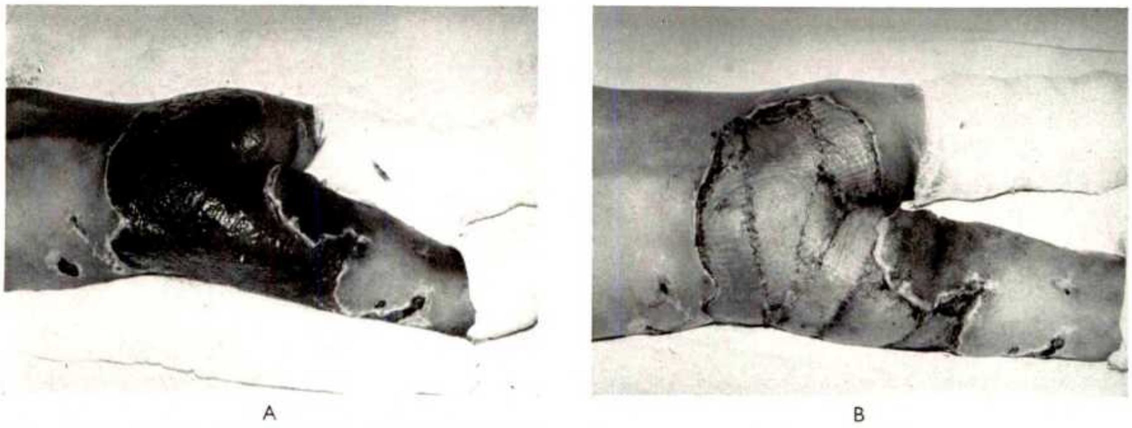

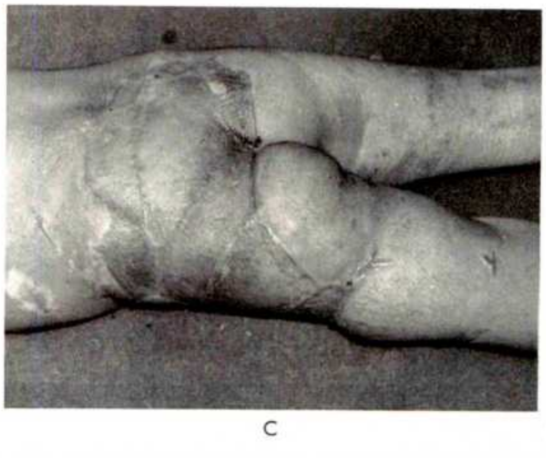

FIG. 2.—*Case* 2. A, Preoperative condition. B, Exposed grafts on the third postoperative day. C, Final result.

Very extensive as well as most circumferential granulating wounds were grafted in stages.

Patients were followed up for a period of 1–6 months after operation.

RESULTS

Grafting was successful in 150 cases (94 per cent). Excellent results (90–99 per cent take) were achieved in 132 cases (83 per cent). Failure occurred in 10 cases (6 per cent), most of these being amongst the early cases. Causes of grafts not taking were recognized in each case and were found to be avoidable with reasonable precautions so that an excellent take was achieved in the following 60 cases. Causes of failure were:—

1. Gross sepsis (5 cases). When the purulent discharge was fairly excessive, it was possible to achieve a good take by the frequent evacuation of the subgraft discharge in the first 48 hours after operation and by the administration of pre- and postoperative antibiotics.

2. Severely fibrotic ischaemic granulations (2 cases). Chronicity *per se* was not a cause of failure since an excellent take was achieved in many cases with chronic granulations of up to 3 years old. Failures due to this reason were later avoided by the application of the homograft test (Moncrief method) to the doubtful chronic cases, and in the event of failure of this test either the whole wounds were excised or the old granulations were pared off and

grafting was performed when young vascular granulations had developed.

3. Mechanical displacement of the grafts (2 cases). Further losses due to this reason were avoided by judicious restraining and proper positioning of patients and by good postoperative care.

4. Growth of numerous epithelial islands under the grafts was responsible for failure in 1 case of a deep partial-thickness burn which had been misdiagnosed as a full-thickness burn.

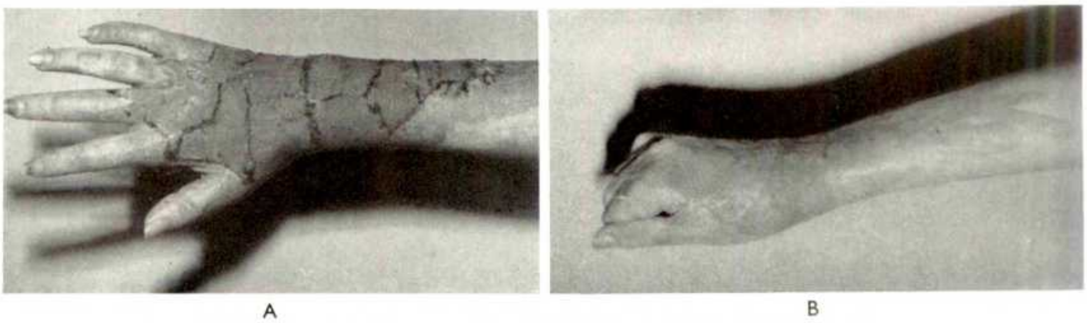

FIG. 3.—*Case* 3. A, Exposed grafts on the fifth postoperative day. B, Final result.

TECHNICAL CONSIDERATIONS

Certain technical points were found of importance for the successful application of open grafting in developing countries.

Vascularity of the granulations as assessed clinically by their colour was found to be the most important factor in determining the success of open grafting. The following methods proved to be very helpful in improving the vascularity of pale granulations before operation: (1) daily wet Eusol dressings, (2) Sulfamylon dressings, (3) improving the general condition of the patient with blood transfusions in particular, and (4), in difficult cases with very poor ischaemic granulations, removal of these granulations and waiting for the development of new vascular granulation tissue.

Because of the prevalence of sepsis the granulations should not be exposed in the operating theatre in order to avoid soiling theatre equipment and contaminating donor sites. Therefore the total surface area to be grafted should be roughly estimated in the ward 1–2 days before operation so that enough skin can be taken at operation. In general it is preferable to take an excess amount of skin-grafts to ensure complete coverage of all the granulating wounds; the rest can be stored in the refrigerator for possible use at a later date.

The grafts should be as thin as possible and in large sheets as these were found to be more suitable for exposure on granulating wounds.

Children and uncooperative patients should be adequately restrained in bed before the application of the grafts. Restraint should be continued as long as the grafts are exposed in order to prevent their displacement. However, if the grafts are dislodged they can be replaced with excellent chances of survival provided that the grafts remain supple and moist.

CASE REPORTS

Case 1.—M. A. K., a male child of 3½ years, was referred to the Cairo Institute for Burns on 14 June, 1970, because of an extensive septic granulating area of his trunk, right axilla, and right upper arm following a burn injury about 2 months previously. The granulations looked adequately vascular despite obvious suppuration. Thin split-skin grafts were removed from both thighs under general anaesthesia, were applied to the raw areas with the patient in bed, and were kept exposed for 1 week. About 48 hours after operation (*Fig.* 1 A) the grafts were well fixed and vascularized. Almost full take of the grafts was finally achieved. *Fig.* 1 B shows the result about 2 months after operation.

Case 2.—O. M. B., a male child of 8 years, was admitted to Ashrafieh Surgical Hospital on 3 May, 1971, following a car accident in which he had sustained a crush injury of his lower back, buttocks, anal and perianal regions, and left thigh with extensive destruction of the skin and soft tissues. The case was managed initially with repeated excisional and débridement procedures. Because of heavy faecal contamination due to partial anal incontinence severe sepsis developed with abundant suppuration. This was partly controlled by systemic non-specific polyvalent antibiotics and by changing the dressings once or twice daily. On 29 May the granulations looked fairly satisfactory (*Fig.* 2 A) in spite of residual sepsis and were grafted. On the third postoperative day the graft take was almost complete (*Fig.* 2 B). *Fig.* 2 C shows the excellent result about 2 months after operation, by which time the patient was also fully continent.

Case 3.—N. A. Gh., a 17-year-old girl, was referred to the Plastic Surgery Service of Ashrafieh Surgical Hospital on 13 May, 1971, because of a granulating area of her right hand and forearm following a burn injury about 1 month previously. As a result of inexpert and inefficient local treatment received elsewhere the granulations were unhealthy and septic and the fingers were stiff in extension. After 2 days' preparation with Sulfamylon application and elevation of the extremity the condition of the wound had improved and open grafting was performed. The patient was encouraged to move her fingers slightly from the first postoperative day. On the fifth postoperative day all the grafts were taking very well (*Fig.* 3 A). Excellent healing was rapidly and simply achieved and good function of the right hand was restored (*Fig.* 3 B).

Case 4.—B. Kh. M., a 15-year-old boy, was admitted to Ashrafieh Surgical Hospital on 3 May, 1971, because of major burn injury. This had resulted in an extensive granulating area involving the chest wall, neck, left axilla, and left upper extremity (*Fig.* 4 A). The whole area was resurfaced in one procedure. An excellent take of all the grafts was achieved. *Fig.* 4 B shows the result of exposure on the fifth postoperative day.

DISCUSSION

Although open grafting is a well-known procedure, it is not popular in Egypt and Jordan because there is an impression that this method is unsuitable when the local and general conditions are unfavourable. However, it is under these circumstances that open techniques are helpful. Exposure of grafts is recommended when there is a poor recipient site (Artz and Moncrief, 1969), in heavily infected cases (Muir and Barclay, 1962), and when the condition of the granulating wound is uncertain (Cannon and Murray, 1966). Therefore the prevalence of sepsis and the poor and uncertain condition of most granulating wounds make exposure of grafts a necessity in developing countries.

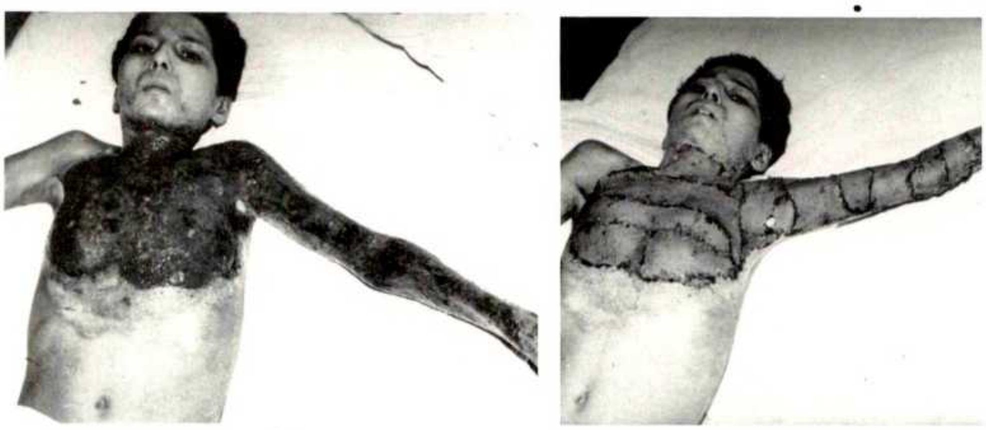

FIG. 4.—*Case* 4. A, Preoperative condition. B, Condition on the fifth postoperative day.

The validity of these statements has been confirmed by the present series. In the experience of the author the results of exposure were better when compared with closed grafting techniques which had been routinely performed before this work was undertaken. This could be attributed to the following reasons:—

1. Sepsis was checked by the open method which provided conditions of dryness, coolness, and exposure to light—factors which are unfavourable to bacterial growth.

2. Exposed grafts were easily observed and any harmful subgraft discharge was readily evacuated.

3. When closed grafting was employed it was necessary to curette or shave the septic granulations, the resultant ooze and possible haematoma formation being responsible for the loss of many grafts.

In general, open grafting is preferred by many authorities. In the experience of Artz and Moncrief (1969) most grafts take better when exposed than when put under a dressing. In describing the method of the United States Army Surgical Research Unit for the treatment of burns Moncrief (1966) states that grafting is better accomplished without covering dressings. Open grafting was mentioned as being used routinely by Blocker (1963). It is particularly indicated for the grafting of granulating wounds of the face, neck, trunk, shoulders, axilla, perineum, and buttocks in order to avoid the displacement of the grafts by the inevitable movement of these parts inside dressings (Muir and Barclay, 1962; Converse and Brauer, 1964).

The grafting method used by the a
following advantages:—

1. It is very well tolerated even b
burned patients and poor-risk indivi
very little anaesthesia is needed and
minimal since no curettage or shaving o
tions is done.

2. The method is very economical; it
time and medical supplies for other pati
them badly so that there is a more econ
hospital facilities which are often limite
ing countries.

3. Contamination of operating thea
equipment, and donor sites from septic
is almost completely avoided by this m
the granulating wounds are not exposed
ing theatre. Thus, cross-infection in th
sepsis in donor sites are reduced to a m

It is my belief that open grafting, part
performed by the method described
represent a revolutionary advance in the
of granulating wounds in developing
satisfactory take can be confidently
almost all cases even under unfavoura
with the minimum of expense.

VEIN-GRAFT BY-PASS IN AXILLARY AND BRACHIAL ARTERY OCCLUSIONS CAUSING CLAUDICATION

BY P. B. WOOD

ST. BARTHOLOMEW'S HOSPITAL, LONDON

SUMMARY

Four cases of axillary and brachial artery occlusions which caused claudication in the arm and hand are presented. They demonstrate that the effects of reduced arterial supply are equally disabling in the hand as in the leg. Axillary and brachial artery occlusions can be treated by vein-graft by-pass, in a similar way to arterial disease in the leg, with excellent results.

UPPER-LIMB ischaemia due to arterial disease is much less common than lower-limb ischaemia, but it presents in a similar way, either as rest pain in the hand or as a claudication-type pain on exercise which is felt in the forearm muscles as well as in the small muscles of the hand. There has been a very widely held view that arterial surgery in the upper arm is never or rarely indicated. Martin, Lynn, Dible, and Aird (1956) stated, when considering embolism in peripheral vessels, 'upper limb operation is virtually never required, spontaneous recovery is common even without any treatment at all, for preformed collaterals are more numerous in the upper limb than in the lower'.

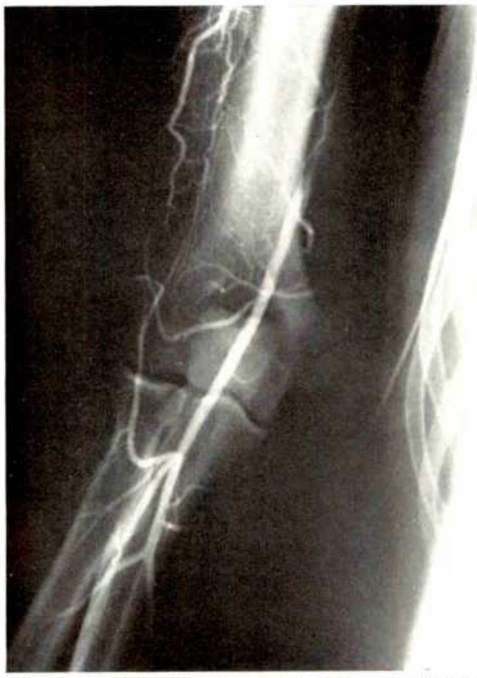

FIG. 1.—*Case* 1. Preoperative arteriogram, showing large collaterals filling the brachial artery distal to the block.

It has been our experience that although severe ischaemia (gangrene) rarely occurs following axillary and brachial occlusions, functional disability (claudication) is more common and can be very severe. It will interfere with work and may make such simple tasks as combing the hair or brushing the teeth extremely difficult. Eastcott (1969) stated, 'reconstructive arterial operation is seldom applicable in cases of upper limb occlusions'. This has not been our experience and we have recently had 4 cases of axillary and brachial occlusions with claudication which were all found to be suitable for a reconstructive arterial operation. They were considerably improved by autogenous vein-graft by-pass.

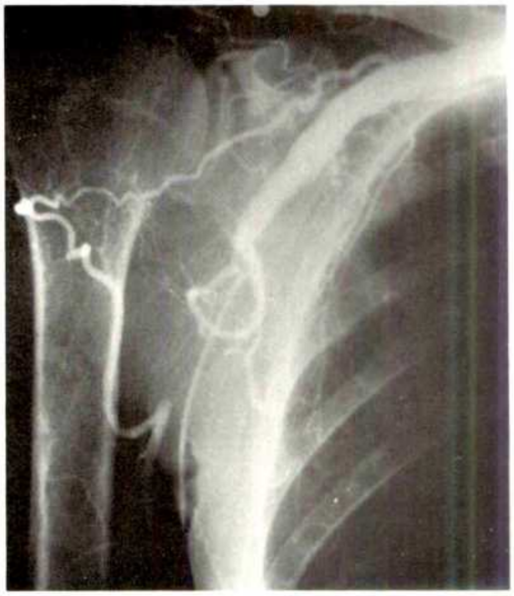

FIG. 2.—*Case* 3. Preoperative arteriogram, showing a block of the lower axillary artery with an excellent collateral circulation around the block.

CASE REPORTS

Case 1.—A 27-year-old man developed an occlusion of the right brachial artery in October, 1969, when his arm was crushed by a fork-lift truck. His work as a butcher was severely limited by claudication. A weak radial pulse was palpable on the right side but this disappeared on exercise. An arteriogram showed a brachial artery block with several large collaterals filling the artery distal to the block (*Fig*. 1). In February, 1970, he had a brachial artery vein-graft by-pass with complete relief of his symptoms.

Case 2.—A 62-year-old man injured the medial side of his right arm in an industrial accident in September, 1969. He developed intermittent claudication in the arm and hand which was sufficient to interfere with his work. Both radial pulses were palpable but the right one was reduced and disappeared on exercise, when the hand became pale. An arteriogram showed a stenosis of the right brachial artery and an irregularity stretching over 6 cm. In September, 1970, he had a brachial artery vein-graft by-pass with complete relief of his symptoms.

Case 3.—A 66-year-old man presented complaining of pain in his right arm on exercise. The pain in his right forearm and hand prevented such simple tasks as brushing his teeth and combing his hair. No pulsation was palpable in the right arm below the axilla. A subclavian arteriogram showed a 5-cm. block in the lower axillary artery with a good collateral circulation around the block (*Fig.* 2). An axillobrachial vein-graft by-pass 3 weeks later resulted in complete relief of his symptoms and the radial pulse was restored.

Case 4.—A 70-year-old man presented with a history of polio affecting both legs at the age of 2½ years. He had used crutches since then. Three months prior to admission he had noticed a pain in the left arm on use, associated with coldness and pallor of the limb. At the time of admission he found it difficult to use his crutches because of the pain. No pulsation was palpable in the left arm below the axilla. A subclavian arteriogram showed a block in the third part of the axillary artery. A left axillobrachial vein-graft by-pass was performed with return of the radial pulse and relief of symptoms. He was discharged on elbow crutches.

OPERATIVE TECHNIQUE

This is essentially similar to that used for saphenous vein-graft by-pass in the lower limb (Taylor, 1962). The brachial and axillary arteries are exposed through a longitudinal incision over the basilic vein. For adequate exposure the insertion of the pectoralis major, and occasionally the pectoralis minor, may have to be divided. A 3-mm. strip of muscle and tendon is left on the humerus for repair of the pectoralis major at the end of the operation. A length of basilic and antecubital vein is freed of its branches. The vein usually empties into several venae comitantes in the upper arm; it is divided immediately below this point. The vein is reversed and anastomosed end to side above and below the occlusion. Arterial spasm during surgery is more of a problem in the brachial artery than in lower-limb arteries; it can be reversed with local papaverine and/or lignocaine. Mechanical dilatation of the artery is sometimes necessary.

DISCUSSION

Upper-limb ischaemia is caused by a wider variety of pathological processes than is found in the lower limb. Of all peripheral arterial emboli, 17 per cent pass to the upper limb and 77 per cent to the lower (Billig, Hallman, and Cooley, 1967). Atherosclerotic occlusions are probably also less common in the upper limb although 1 of our cases would seem to have been a spontaneous thrombosis in an atherosclerotic vessel. Trauma is a major cause of upper-limb ischaemia and 3 of our cases fall into this group. Crutch thrombosis has been a well-recognized entity for some time (Ryle, 1922). Cervical rib can cause claudication, or more commonly rest pain and gangrene, owing to distal embolization. Encroachment of the artery by malignant disease can occur (Knox, Nay, and Blumenthal, 1966). A fibromuscular stenosis of the axillary artery has been recorded (Garrett, Morris, Howell, and DeBakey, 1965). Iatrogenic causes are due to injury secondary either to thoracic and cervical operations or to retrograde brachial artery catheterization. The latter cause is likely to be seen with greater frequency as left-heart catheterization becomes a routine investigation.

Claudication in the arm can be severe even when an excellent collateral circulation is demonstrable by arteriography. The radial pulse may be palpable but the patient could still have claudication. There is a tendency for symptoms to subside as collaterals enlarge but even up to 1 year after occlusion, symptoms may still be severe. It would seem to us that symptoms in the arm are potentially more disabling than similar symptoms in the leg, since active function of the hand is impaired. Right-arm claudication would seem, in general, to be more disabling than left since most people are right-handed. Brachial artery catheterization should not, therefore, be attempted through the dominant arm.

The only other report of revascularization of the upper limb by use of vein-grafts comes from Houston (Garrett and others, 1965). Here an autogenous long saphenous vein was used. The basilic and cephalic veins are readily accessible, however, and their use does not seem to cause any chronic venous insufficiency. All our patients had some minor oedema of the hand in the first few weeks postoperatively but this was never a problem. The long-term results of vein-grafting in the arm have not been recorded, but there seems no reason to suspect they will be different from the excellent results at present being obtained in the leg.

Acknowledgements.—I would like to thank Professor G. W. Taylor and Mr. M. A. Birnstingl for permission to publish details of the patients under their care.

THE INFLUENCE OF ELECTRICAL STIMULATION OF THE LEG DURING SURGICAL OPERATIONS ON THE SUBSEQUENT DEVELOPMENT OF DEEP-VEIN THROMBOSIS

By L. R. DEJODE, M. KHURSHID, and W. W. WALTHER

WHIPPS CROSS HOSPITAL, LONDON

Summary

The effect of galvanic stimulation of the calf muscles during surgical operations on the development of postoperative deep-vein thrombosis was assessed using ^{125}I fibrinogen in 64 patients over 40 years of age undergoing major surgery. Alternate legs were stimulated in alternate patients using the opposite leg as a control. No significant difference in the incidence of deep-vein thrombosis was observed either in the immediate postoperative period or later.

The use of ^{125}I fibrinogen in the detection of deep-vein thrombosis is now a well-recognized method (Atkins and Hawkins, 1965; Flanc, Kakkar, and Clarke, 1968). In a clinical study Doran, White, and Drury (1970) stated that the incidence of post-operative deep-vein thrombosis can be reduced by electrical stimulation of the legs during operation. Browse and Negus (1970), using the ^{125}I-fibrinogen method, came to a similar conclusion. Since the incidence of deep-vein thrombosis is likely to be high in elderly, debilitated, and relatively immobile patients we decided to monitor such cases by the ^{125}I-fibrinogen method to test the contention of Doran and others (1970).

MATERIALS AND METHODS

Patients of both sexes aged 40 years or over undergoing major operations were studied. There were 22 female and 42 male patients and the mean age was 62 years. The operation was a major upper abdominal or thoraco-abdominal procedure in 40 patients, a major lower abdominal or pelvic in 20, and 4 operations fell into neither category.

The method of stimulation of the calf was similar to that used by Browse and Negus (1970) and Doran and others (1970), employing brief intermittent galvanic stimulation every 2 seconds to produce forcible contraction of the calf muscles.

Each patient had one leg stimulated during his operation, the other leg serving as an unstimulated control. Alternate patients had alternate legs stimulated; 33 had their right leg stimulated and 31 the left.

^{125}I fibrinogen, 100 m.c., was given intravenously either just before the operation or at its completion. Thyroid uptake was blocked by 100 mg. of potassium iodide orally 24 hours before operation and continued daily for 1 month. The use of the Pitman 235 Ratemeter (Kakkar, Nicolaides, Renney, Friend, and Clarke, 1970) allowed both legs to be scanned in about 10 minutes.

RESULTS

The total number of thrombosed legs found was 36 in 25 patients, being 39 per cent of the total number of cases.

Table I shows the distribution of deep-vein thrombosis in this study.

Table I.—Occurrence of Deep-vein Thrombosis in the Present Series

Total number of patients	64
Number of patients forming thrombi in legs	25 (39 per cent)
Total number of thrombosed legs	36
Patients with thrombi on unstimulated side only	8
Patients with thrombi on stimulated side only	6
Patients with thrombi on both sides	11
Total number of legs thrombosed on unstimulated side	19 (15 per cent)
Total number of legs thrombosed on stimulated side	17 (13 per cent)

Table II.—Time of First Appearance of Deep-vein Thrombosis

Time of Appearance of Thrombosis	*No. of Patients*
At operation	3
Up to 24 hr. after operation	10
Up to 72 hr. after operation	7
Up to 9 d. after operation	5
Total	25

Table III.—Incidence of Deep-vein Thrombosis in Stimulated and Unstimulated Legs in Relation to the Time of Onset after Operation

Time after Operation		*No. of Patients*
Within first 24 hr.:	Unstimulated	10
	Stimulated	8
Second to ninth days:	Unstimulated	9
	Stimulated	9

Initial evidence of deep-vein thrombosis appeared during the first 9 days following operation. *Table II* shows the distribution in time of the occurrence of deep-vein thrombosis in patients.

Since the possible beneficial effect of leg stimulation during the operation is likely to decrease rapidly with the passage of time we have particularly noted those cases where the deep-vein thrombosis was diagnosed within 24 hours of operation. *Table III* shows the distribution of thrombosis between stimulated and unstimulated legs in relation to the length of time after the operation.

DISCUSSION

The possibility of reduction of postoperative deep-vein thrombosis by the use of calf stimulation is based on the view that thrombosis begins during operation in the majority of cases (Doran and White, 1967).

Our results show that thrombosis was detected in 13 patients in the period between operation and up to 24 hours afterwards whereas in 12 patients this occurred between the second and ninth days. In the latter group the later onset of deep-vein thrombosis would not be expected to be prevented by the use of calf stimulation and is presumably due to factors acting in the postoperative period. It is perhaps significant that our series included a high proportion of elderly, frail patients undergoing very extensive surgery, and in these cases early mobilization was obviously limited or impossible.

These are, however, the very patients most at risk from deep-vein thrombosis and this accords with our overall incidence of deep-vein thrombosis of 39 per cent. Browse and Negus (1970), on the other hand, report a lower incidence of 23 per cent, but no patient in their series had any serious blood-loss or hypotension during or after surgery and most were active within 2 or 3 days.

The evidence for the efficacy of calf stimulation in preventing deep-vein thrombosis should be looked for in the group of patients who developed deep-vein thrombosis during operation or in the first 24 hours after operation. In the 3 patients in our series who developed deep-vein thrombosis during operation this occurred in the stimulated leg in the first, in the unstimulated leg in the second, and in both legs in the third. The distribution of thrombosis between stimulated and unstimulated legs in the first 24 hours after operation does not confirm the value of stimulation; as expected, there is no difference between the groups in the period after 24 hours.

The explanation of the conflict between our failing to demonstrate the protective effect of calf stimulation and the beneficial effect observed by Browse and Negus (1970) may be due to our agreed deliberate selection of cases in whom the likelihood of deep-vein thrombosis was very great. Thus, it may be that in the 10 patients who developed deep-vein thrombosis in the first 24 hours after operation any protective effect of calf stimulation was obscured by the early onset of deep-vein thrombosis in the immediate postoperative period when calf stimulation had ceased and the venous return was still slowed after the long operation and anaesthetic.

On the basis of our results we cannot conclude that stimulation of one leg during operation substantially reduces postoperative deep-vein thrombosis on the stimulated side in elderly patients undergoing major surgery. It remains possible that calf stimulation reduces the risk of deep-vein thrombosis when used in routine operations in elderly patients. In such patients the increased venous return during operation may be sufficient to prevent thrombosis during operation and rapid postoperative mobilization may prevent subsequent thrombosis. We would suggest, however, that in similar studies in the future ^{125}I fibrinogen should be given and the legs scanned initially before operation and that the scan should be repeated immediately after the conclusion of the operation and again the next day, but not thereafter unless ward procedures to reduce deep-vein thrombosis are also being studied.

Acknowledgements.—We are grateful to Mr. N. Veall, B.Sc., F.Inst.P., for the initial supply of ^{125}I fibrinogen and for much useful advice, and to Dr. J. S. Glover of the Radiochemical Centre, Amersham, for a further supply of ^{125}I fibrinogen used in this study. We would also like to thank Mr. E. G. Millwood, F.I.M.L.T., for technical assistance.

CARCINOMA OF THE AMPULLA OF VATER AND DUODENUM

By L. H. BLUMGART* and A. KENNEDY

SHEFFIELD ROYAL INFIRMARY AND DEPARTMENT OF PATHOLOGY, UNIVERSITY OF SHEFFIELD

SUMMARY

Thirty-one cases of carcinoma of the ampulla of Vater and duodenum have been classified on the basis of pathological criteria.

Two types of tumour were discernible. Nine were polypoid papillary adenocarcinomas occurring at the ampulla of Vater; 19 were adenocarcinomas without a papillary pattern, of which 4 were duodenal tumours and 15 were ampullary. There were 3 ampullary tumours of mixed type. The carcinomas without a papillary structure were more invasive, more often associated with abdominal pain, more frequently misdiagnosed, and were associated with a higher mortality-rate.

The data were insufficient to draw firm conclusions as to the prognosis but the clinical behaviour was related to the pathology of the tumours.

Lesions in the ampullary region were associated with jaundice which was often intermittent. Lesions outside the ampullary area presented early with vomiting of pyloric type but without jaundice.

The importance of a high index of suspicion in dealing with these lesions and the value of barium-meal examinations are emphasized.

It is noted that pancreaticoduodenectomy for ampullary carcinoma has a mortality of less than 25 per cent if performed by an experienced surgeon and can be considerably lower in clinics specializing in this condition.

We suggest that the pathological classification of these tumours used in this paper may form the basis for further investigations into the diagnostic and prognostic problems which these tumours present.

This classification of ampullary tumours is a factor to be considered in assessing the indications for pancreaticoduodenectomy.

PRIMARY carcinomas are uncommon in the small bowel but a high proportion of those which do occur are found in the duodenum (Jefferson, 1916; Bockus, 1964). The literature on carcinoma of the duodenum is now vast and many hundreds of cases have been recorded (Kleinerman, Yardumian, and Tamaki, 1950; Seeley and Campbell, 1954), but the disease still poses a problem for the clinician and a challenge to the pathologist. There is a marked variation in the reported incidence of the various sites of duodenal carcinoma (Berger and Koppelman, 1942; Resnick and Cooper, 1958; Barclay and Kent, 1962), and the information available is difficult to analyse as many authors have not differentiated between carcinomas arising from the duodenal mucosa and those arising from the ampulla of Vater. This distinction can be difficult to make (Lieber, Stewart, and Lund, 1937), and because carcinomas of the duodenum are most frequent in its second part (Kleinerman and others, 1950) failure to make a distinction renders much of the data almost unintelligible.

Authors who have differentiated between these tumours have only regarded a tumour as being of duodenal origin when it has been clearly separated from the ampulla. This accounts for much of the confusion since some carcinomas arising from the duodenal mucosa have been grouped with carcinomas arising from the epithelium of the ampulla simply because of their location.

In this paper we have attempted to classify carcinomas of the ampulla and of the duodenum on the basis of pathological criteria. The possible significance of this classification in the clinical management of these tumours is explored.

MATERIALS AND METHODS

This study is based on a review of 31 surgically treated cases of carcinoma arising in the duodenum, including carcinomas of the ampulla of Vater. All cases in which the malignancy of the lesion was in doubt were excluded. Also excluded were cases in which there was an extensive involvement of the pancreas as the origin of such tumours could not be determined. Of these 31 cases, 4 have been personally treated, and of the remainder, a further 23 have been traced and either personally seen or their clinical records perused. Four cases have been lost to clinical follow-up and for these only pathological data are available.

The pathological material consisted of 20 specimens from a Whipple's type of procedure and 5 from local resections, but only biopsies were available in the rest of the cases. Of the radical resections, the entire specimen was available for study in 7 cases while in the remainder the material consisted of stored paraffin blocks. The pathological material was studied by one of the authors (A. K.) without knowledge of the clinical history and the cases were divided into groups on the basis of the pathology found. Paraffin sections were studied after staining with haematoxylin and eosin, Masson's trichrome PAS with Alcian blue, and Gomori's method for elastic tissue.

PATHOLOGICAL FINDINGS

The majority of the tumours were readily divisible into two main varieties along the lines described by Edmondson (1967). Of the 31 tumours, 9 were papillary adenocarcinomas and took the form of mushroom or button-shaped masses which protruded into the lumen of the duodenum; this type of tumour we have called type I (*Table I*).

Nineteen tumours consisted of ulcerating or stenosing growths which were adenocarcinomas without a papillary pattern. These tumours usually

---

* Present address: University Department of Surgery, Royal Infirmary, Castle Street, Glasgow G4 0SF.

produced mucin and had a scirrhous stroma; the term used for this form of tumour in a study conducted at the Mayo Clinic is 'type ordinaire' (Monge, Judd, and Gage, 1964). This type of tumour we have called type II. These could be further divided on the basis of their situation (*Table I*).

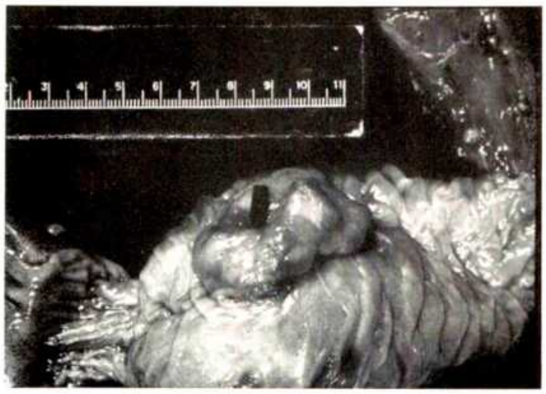

FIG. 1.—An example of a papillary carcinoma at the ampulla of Vater (type I). Note the polypoid shape of this tumour with the central depression which could be seen radiologically (*Fig.* 9). The black rod is in the common bile-duct.

Table I.—A PATHOLOGICAL CLASSIFICATION OF 31 CARCINOMAS OF THE AMPULLA OF VATER AND DUODENUM

PRINCIPAL FEATURES	TYPE	NO. OF CASES
Polypoid papillary tumours of the ampulla	I	9
Non-papillary adenocarcinomas		
Ampullary, ulcerating	IIa	6
Nodules within the ampulla	IIb	9
Duodenal	IIc	4
Tumours of mixed pattern involving the ampulla	III	3

In 3 cases both patterns of growth were present and these have been considered separately as tumours of mixed pattern (type III).

Type I: Papillary Adenocarcinomas.—All of these tumours, and those of mixed pattern, were found at the ampulla of Vater. Eight of the 9 tumours formed a very distinctive type of lesion consisting of a mushroom-shaped tumour which surrounded and replaced the ampulla (*Fig.* 1). The ends of the ducts were buried in the tumour which often appeared to be sprouting out of them. In the remaining case only a biopsy is available and the gross appearance of the tumour is not known.

In size the tumours varied from 0·5 to 3·5 cm. in maximal diameter. The deeper parts of the tumour involved muscle in 7 cases, but clear evidence of complete penetration of the muscle was present in only 2 cases and in no instance was the pancreas involved. Examination of the lymph-nodes was carried out in 5 cases but in none of these was there any metastases.

The tumours were papillary adenocarcinomas (*Fig.* 2); the degree of differentiation was variable, but 5 of the tumours were well differentiated and the papillae were lined by tall columnar cells with eosinophilic cytoplasm and fair
(*Fig.* 3). In 4 cases the cells
pleomorphic and had irregular nu
deeper limits of the tumour, v
being invaded, showed a transitio

group was unusual for the degree of anaplasia and the very marked chronic inflammatory reaction seen. With this exception the cells forming the tumours tended to be large, eosinophilic, and columnar with big vesicular nuclei.

Tumours of type IIb differed only from IIa growths in their lack of ulceration and their situation within the substance of the ampulla. In a number of cases where only a biopsy had been performed it was not possible to place a case in categories IIa or IIb with certainty. Of the 9 cases of type IIb, 5 were definitely submucosal in site and 4 were probably in this position; in 1 case (*Fig.* 6) a small tumour was arising in the duct of Wirsung.

All of these tumours were small in size and some could not be identified before dissecting the specimen (*Fig.* 6); the largest was 1·8 cm. in diameter. In every case there was infiltration of muscle; in 5 cases the muscle had been breached and in 3 the pancreas had been invaded at the edge of the tumour. Lymph-nodes were available in 4 cases, metastases being present in 2 of these.

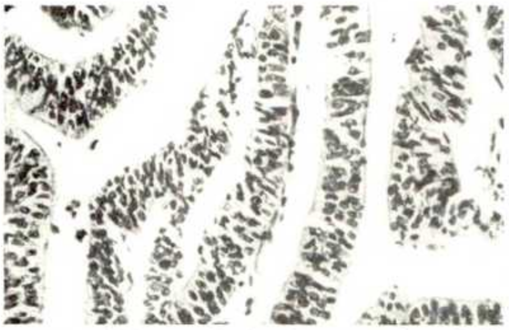

FIG. 3.—A higher magnification of a tumour of type I. The tumour cells are tall and columnar and are arranged on delicate strands of connective tissue. H. and E. (× 145.)

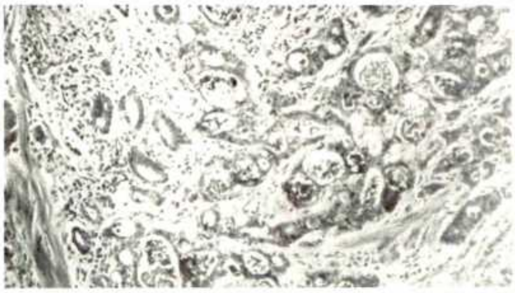

FIG. 5.—A tumour of type II. This is a mucin-secreting adenocarcinoma which is growing in a tubular manner; there is a fibrous stroma which contains a moderate degree of inflammatory reaction. H. and E. (× 50.)

Histologically the tumours closely resembled those of type IIa; all of them were mucin-secreting adenocarcinomas with a marked fibrous reaction.

While types IIa and IIb may be different stages of the same entity the 4 tumours of type IIc differed in that they did not arise at the ampulla, although in 1 case the edge of the tumour did reach the ampullary region, so that all of these tumours are cases of carcinoma of the duodenal mucosa itself (*Fig.* 7). These all occurred in the second part of the duodenum; 3 were proximal to the ampulla and 1 was opposite to the ampulla. In 3 the tumour was a ring stricture and the other was an ulcer (*Fig.* 7). These had all penetrated the muscularis propria but only 1 is known to have invaded the pancreas. The local lymph-nodes were involved in 2 cases and in another case the tumour had spread into the fatty tissue outside the duodenum.

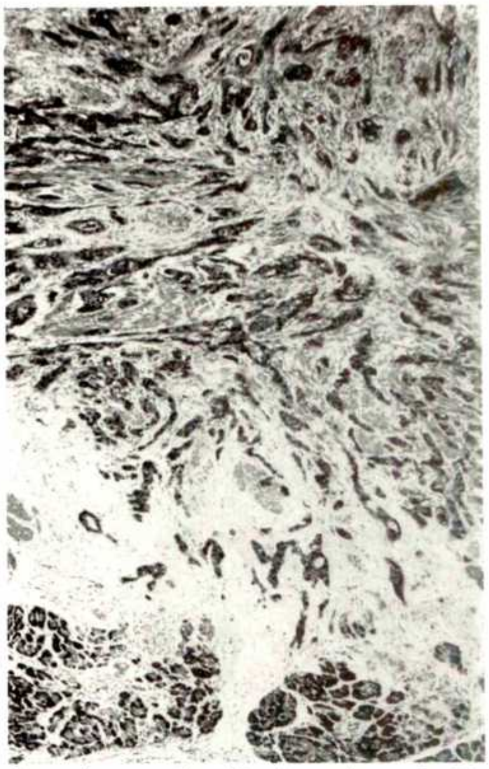

FIG. 4.—A tumour of type IIa arising at the ampulla of Vater. This is a scirrhous adenocarcinoma which has reached the edge of the pancreas in the lower part of the field. H. and E. (× 30.)

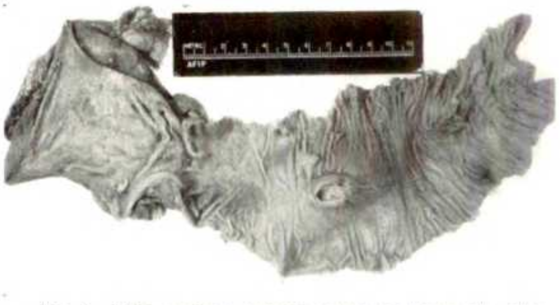

FIG. 6.—This specimen contains a tumour of type IIb. The end of the common duct is widely patent and cup-shaped with an indefinite roughened area on the distal lip. This proved to be a small carcinoma arising at the end of the pancreatic duct.

All of the tumours were moderately or poorly differentiated mucin-secreting adenocarcinomas with a tendency to have a scirrhous stroma which was in 1 instance very dense (*Fig.* 8).

Type III: Tumours of Mixed Pattern involving the Ampulla.—Three tumours could not be placed in either main category, but the study of this small group was hampered by the fact that only biopsies were available. All 3 of the tumours occurred at the ampulla and they contained papillary elements especially in the immediate region of the common bile-duct, while outside the duct the pattern resembled the type-II tumours. The muscle was involved in every case and in 1 instance the pancreas had been invaded.

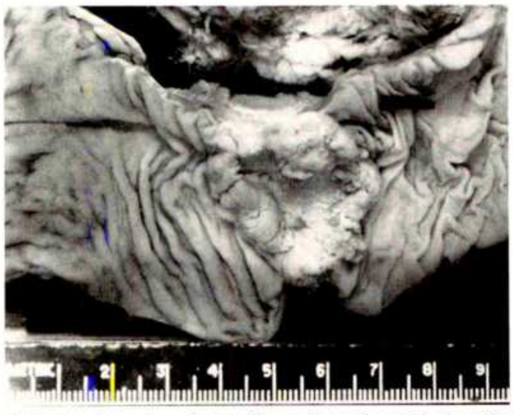

FIG. 7.—A tumour of type IIc; a circumferential ulcerating tumour of the duodenum; the ulcer is completely separate from the ampulla which is marked by the black rod.

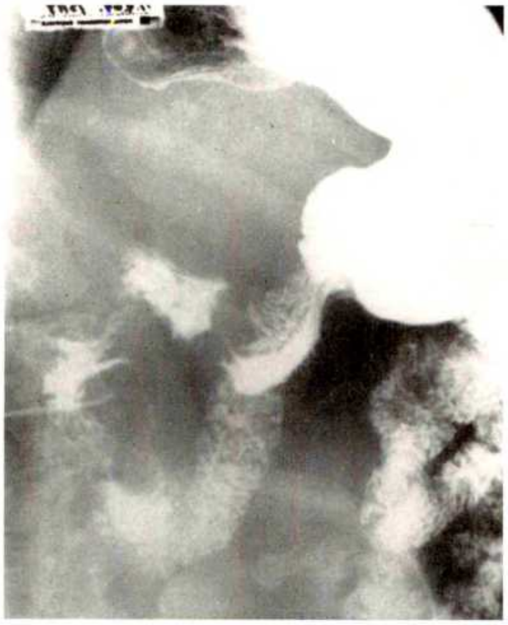

FIG. 9.—A radiograph demonstrating the tumour shown in *Fig.* 1 before it was removed. The tumour can be clearly identified as a type-I carcinoma.

CLINICAL FINDINGS

The clinical follow-up of the 27 patients for whom data were available revealed a number of features previously noted by others but worthy of re-emphasis. More important, it was clear that the classification of the lesions on pathological grounds was to some extent reflected in their clinical behaviour (*Table II*).

There was no significant distinction between the patients with different types of tumour as regards sex. The average age of patients with tumours of types I and III was somewhat younger than that of the patients with type-II lesions (*Table II*). The length of history prior to diagnosis also varied considerably; type-I cases came to operation in an average time of 10·7 weeks from the onset of symptoms, whereas those patients with either type-IIa, type-IIb, or type-III lesions had their operation 22–24 weeks after the onset of their illness. Patients with duodenal lesions outside the ampullary lesion (type IIc), however, presented very early and were submitted to laparotomy in an average of 6·7 weeks from the onset of symptoms (*Table II*).

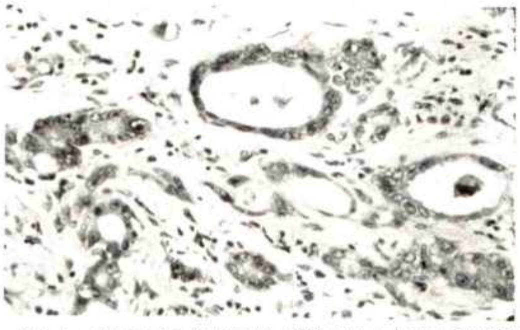

FIG. 8.—A tumour of type II. This was a large ulcerating carcinoma of the duodenum which involved the ampulla at its edge (type IIc). The pattern is similar to that of the ampullary carcinomas of type II (cf. *Fig.* 5). H. and E. (× 50.)

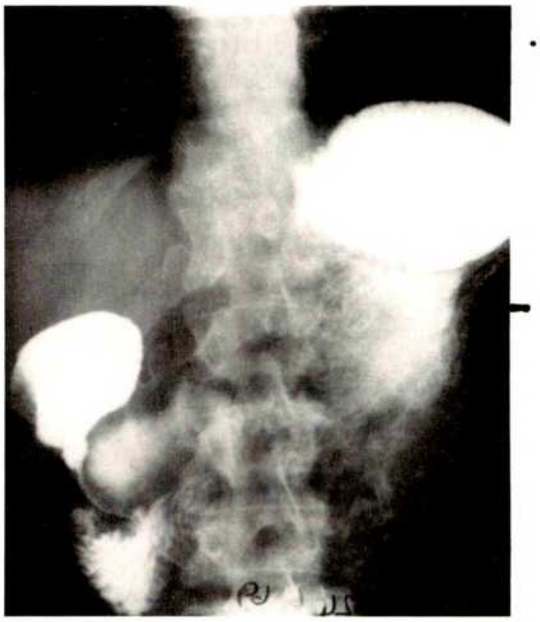

FIG. 10.—In this patient a diagnosis of pyloric stenosis was made, but the barium-meal examination revealed that the obstruction was distal to the pylorus. This was a tumour of type IIc.

Anorexia and vomiting were common presenting features and occurred in 22 of the 27 cases. However, excessive vomiting of a pyloric type associated with a gastric splash was found in only 6 cases. Two of these were patients with a type-I lesion and all 4 patients with duodenal carcinoma (type IIc) presented in this manner.

Jaundice was common and was found in 23 cases, being quite certainly fluctuant in 13 of these. Only the 4 cases with duodenal carcinoma (type IIc) were not jaundiced (*Table II*).

Table II.—CLINICAL FEATURES OF 27 CASES OF CARCINOMA OF THE AMPULLA OF VATER AND DUODENUM

CLINICAL FEATURES	TYPE I	TYPE II			TYPE III
		a	b	c	
No. of cases	8	5	7	4	3
Average age (yr.)	59	65·6	66·6	62·7	52·6
Length of history (wk.)	10·7	24·4	22·3	6·7	22
Anorexia; vomiting	8	4	3	4	3
Vomiting of pyloric type (spash on examination)	2	0	0	4	0
Jaundice	8	5	7	0	3
Pain	1	3	4	0	2
Barium meal done	3	1	0	4	0
Lesion shown	2	0	0	3	0
Misdiagnosis* and delay in diagnosis	1	4	4	1	1

* Other than due to carcinoma of the head of the pancreas.

Pain was frequent and occurred in 10 cases. Nine of the patients with pain had tumours classified as types IIa, IIb, or III, whereas none of the patients with carcinoma of the duodenum (type IIc) experienced any pain at all and only 1 out of 8 cases with type-I lesions gave such a history (*Table II*). The pain was most commonly epigastric or located in the right subchondral region and was occasionally felt in the back. Some patients experienced recurrent attacks of pain.

The gall-bladder was palpable in 19 of the 23 jaundiced patients, and in 2 who were personally observed the gall-bladder, having been initially easily felt, was found impalpable a few days later. In both the jaundice was fluctuant and in 1 the serum bilirubin fell a few days after this observation. One patient who was subsequently found to have a carcinoma arising in the duodenum outside the ampullary region presented initially with deep-vein thrombosis in a leg.

Iron-deficiency anaemia was extremely common but was only severe in 2 cases and there was no difference between the groups in this respect. Overt intestinal haemorrhage occurred on 1 occasion. Faecal occult blood-tests were done in 11 of the 27 cases and were positive on every occasion. Likewise the erythrocyte sedimentation rate was raised in each of the 12 cases in which it was estimated. The reading was often markedly raised, being over 50 mm. in the first hour (Westergren) on 8 occasions. Duodenal cytological studies were undertaken on 1 occasion only and gave a positive diagnosis.

A barium-meal examination was done on 8 occasions and the radiological diagnosis was made on 4 of these (*Fig.* 9). In a further case a preoperative diagnosis of pyloric stenosis was made, but when the radiographs were reviewed postoperatively the lesion was seen clearly demonstrated in the second part of the duodenum (*Fig.* 10).

Misdiagnosis and delay in diagnosis were not infrequent. Where painless jaundice was the presenting feature the most common preoperative diagnosis was carcinoma of the head of the pancreas.

Table III.—OPERATIONS, HOSPITAL MORTALITY, AND SURVIVAL IN 27 CASES OF CARCINOMA OF THE AMPULLA OF VATER AND DUODENUM

OPERATION	SURVIVAL AT TIME OF WRITING					
	Type I		*Type II*		*Type III*	
	Alive	Dead	Alive	Dead	Alive	Dead
Local transduodenal resection	1	1	0	0	0	3
Pancreaticoduodenectomy	4	1	1	10	0	0
Inoperable	0	1	1	4	0	0
Total	5	3	2	14	0	3
Hospital mortality (overall 18·5 per cent)	0		26·3 per cent			
2-year survival (overall 40·7 per cent)	62·5 per cent		31·6 per cent			
5-year survival (overall 11·2 per cent)	25 per cent		5·3 per cent			

Pain appeared to be the clinical feature most likely to lead to diagnostic confusion. An initial diagnosis of gall-bladder disease was made in 7 patients and cholecystography revealed a non-functional gall-bladder in 2 of these. A diagnosis of duodenal ulcer was seriously considered in 1 other case. Yet another patient who was on a variety of drugs for psychiatric disturbance was incorrectly diagnosed as having hepatocellular jaundice, and in 1 patient an initial transient episode of jaundice was ascribed to infective hepatitis. These errors, often leading to delay in diagnosis, were more frequent in cases of types IIa, IIb, and III (*Table II*).

OPERATIVE TREATMENT AND RESULTS

The overall hospital mortality for the entire group of 27 cases was 18·5 per cent with a 5-year survival of 11·1 per cent (3 cases) and a 2-year survival of 40·7 per cent (*Table III*). Seven patients are still alive and well at periods between 2 and 5 years after operation.

Only 1 of the 8 patients with type-I tumours proved inoperable. This patient died after 50 weeks from disseminated cancer. The remaining 7 cases were operable and, of these, 5 underwent pancreaticoduodenectomy and 2 had local transduodenal excision of their growth. Four of the patients who were submitted to pancreaticoduodenectomy are still alive and well and have been followed for periods varying from 2 to 9 years. One of the patients who had a local transduodenal excision died as a result of ischaemic heart disease within 4 months of operation, but the other is alive and well 6 years later. The

5-year survival for type-I cases is 25 per cent and the 2-year survival 62·5 per cent (5 cases) without any hospital mortality (*Table III*).

In contrast, of 19 patients with type-II or type-III tumours, 5 were inoperable. Nevertheless, 1 of these lived 2½ years after a palliative by-pass procedure before dying of metastases, and another aged 70 years* is still alive 3 years after operation. There was only 1 death in the postoperative period in this small group of inoperable cases and the mean survival time was 17 months.

Table IV.—MORTALITY AND SURVIVAL FOR PANCREATICODUODENECTOMY AT THE TIME OF WRITING

TYPE	NO. OF OPERATIONS	HOSPITAL MORTALITY (per cent)	SURVIVAL (per cent)	
			2 years	5 years
I	5	0	80 (4 cases still alive)	20 (1 case still alive)
II	11	36·4 (4 cases)	36·4 (4 cases—3 dead)	9·1 (1 case—dead)
Total	16	25	50	12·5

The remaining 14 cases with type-II or type-III lesions were operable. The 3 cases with lesions of type-III histological pattern underwent local transduodenal excision and all were dead within 2 years of operation. Eleven cases, all of type II, underwent pancreaticoduodenectomy. Only 1 of these patients is still alive 2 years after operation. Two others lived for 2 years and 1 survived 6 years, the latter dying of ischaemic heart disease. All the remaining patients who were submitted to radical operation died within 2 years and 4 of these died in hospital in the postoperative period. The overall 5-year survival for patients with type-II and type-III growths is 5·3 per cent (1 case) and the 2-year survival is 31·6 per cent with a hospital mortality of 26·3 per cent (*Table III*).

Of the entire group of 27 patients, 16 underwent pancreaticoduodenectomy (*Table IV*). The hospital mortality for this operation was 25 per cent with a 2-year survival of 50 per cent and a 5-year survival of 12·5 per cent. However, the patients with type-I lesions had a 2-year survival of 80 per cent (4 cases) without hospital mortality. All 4 of these patients are still alive. This contrasts markedly with a 2-year survival of 36·4 per cent (4 cases of which 3 are dead) and a hospital mortality of 36·4 per cent for pancreaticoduodenectomy in patients with type-II tumours.

DISCUSSION

The clinical features which we have recorded in this series of cases allow comparison with the findings of others and emphasize some of the important points in diagnosis and management. The presenting symptoms underline the importance of jaundice, pain, and vomiting.

Jaundice is an early feature of carcinoma of the ampullary region and a most important manifestation. Our finding that jaundice was clearly fluctuant in over half of the cases is in agreement with that of Monge, Dockerty, Wollaeger, Waugh, and Priestley (1964) and Warren, Veidenheimer, and Pratt (1967). If a clear history of this symptom can be obtained then the diagnosis of a lesion involving or close to the ampulla of Vater is highly likely. This contrasts with carcinoma of the pancreas where fluctuant jaundice is rare. Our observation that the gallbladder may be intermittently palpable is a useful physical sign and if combined with fluctuant jaundice is highly suggestive of an ampullary neoplasm.

Anorexia, nausea, and vomiting were very common and the finding that cases of duodenal carcinoma arising outside the ampullary region present with vomiting as the major symptom is similar to that of Devlin, Platten, and Corrin (1968) and Craig (1969). The importance of bearing in mind the possibility of a duodenal lesion in cases with symptoms suggestive of pyloric stenosis is clearly indicated.

The common occurrence of iron-deficiency anaemia and positive faecal occult blood-tests is an important feature and if associated with jaundice and a high erythrocyte sedimentation rate is highly suggestive of an ampullary lesion (Hall and Krementz, 1968). It is interesting that frank haemorrhage occurred on only 1 occasion.

A striking feature of this series is the early presentation and diagnosis in cases of duodenal carcinoma (type IIc) and of the painless jaundice occasioned by the tumours of type I. By contrast, diagnosis in cases with tumours of types IIa, IIb, and III was much later and pain appeared to be the symptom most likely to cloud the issue, particularly if the jaundice was fluctuant in type.

We would agree with other workers (Barclay and Kent, 1962; Hall and Krementz, 1968; Craig, 1969) in their plea for a high index of suspicion in regard to these lesions. It is only by early diagnosis that the prognosis can be improved. Of the diagnostic procedures available the barium meal is a most important aid and it is vital to obtain good visualization of the duodenal loop (Barclay and Kent, 1962). In 1 example of a type-I tumour the gross form of the tumour was clearly outlined in this way.

Hypotonic duodenography may be a most useful aid. Nevertheless, we would agree with Warren, Braasch, and Thum (1968) in emphasizing that too much reliance should not be placed on negative gastro-intestinal radiology since a small periampullary lesion may not be demonstrable.

Duodenal intubation with aspiration of the duodenal contents and subsequent cytology for malignant cells may also be useful and gave positive results in the 1 case in which it was utilized. However, it should be noted that a negative result does not rule out the diagnosis and false positives have been reported (Rankin and Brown, 1964).

The recent introduction of fibreoptic duodenoscopy (Takemoto, 1968) with facilities to carry out ampullary biopsy and endoscopic pancreatocholedochography (Ogoshi, Tobita, and Hara, 1970) holds out considerable promise for the more accurate diagnosis of lesions in the region of the ampulla of Vater.

---

* This case is classified here as inoperable since although the lesion was small and technically operable the diagnosis was missed at operation and only an incomplete wedge biopsy was taken from a segment of the ampulla.

A striking feature of the cases in this series was the rarity of accurate preoperative diagnosis. It would seem that recognition of the lesion before operation would allow better preoperative preparation for major surgery. However, in cases with clearly established obstructive jaundice or when obstruction cannot definitely be excluded by any other means, laparotomy should be proceeded with.

The 5-year survival for the whole group of 27 patients in this series was 11·1 per cent. However, those patients with type-I tumours had a 5-year survival of 25 per cent (*Table III*). It is difficult to compare these figures with those reported by others since our series is composed of patients with ampullary and duodenal tumours and no pancreatic cancers are included. Furthermore the figures relate to the whole group of cases and include both operable and inoperable patients.

Comparison with the mortality and survival for radical surgery is, however, possible. Hall and Krementz (1968) suggest that when a precise diagnosis of carcinoma of the ampulla or duodenum can be made then a 5-year survival of 30–40 per cent can be expected. They report a hospital mortality of 50 per cent, although most mortality-rates for pancreaticoduodenectomy lie between 20 and 30 per cent (Child and Frey, 1966). It should be noted that surgeons with a special interest in periampullary cancer have achieved 5-year survival-rates of 30–40 per cent with a hospital mortality as low as 13·5 per cent (Warren and others, 1968; Monge, Judd, and Gage, 1964), and recently a mortality-rate of only 2 per cent has been recorded for pancreaticoduodenectomy performed for periampullary cancer (Smith, 1970).

The patients whom we have reported were operated on by a number of surgeons none of whom had a special interest in the treatment of this disease, but the mortality for pancreaticoduodenectomy (25 per cent) compares favourably with that of other series (Child and Frey, 1966; Crile, Isbister, and Hawk, 1970). It is of interest to note that none of the 5 patients with type-I tumours who underwent pancreaticoduodenectomy died postoperatively. The 5-year survival for pancreaticoduodenectomy (12·5 per cent) is low by modern standards (Warren and others, 1968; Smith, 1970), but it is noteworthy that 5 patients who were submitted to this operation are still alive. The 2-year survival is 50 per cent and is 80 per cent (all 4 patients are still alive) for the patients with type-I tumours (*Table IV*). This compares favourably with the 50 per cent 3-year survival recorded recently by Smith (1970). It would seem from the evidence we have presented that the mortality for the operation should not exceed 25 per cent and indeed can be considerably lower. These figures should be compared with the short duration of life following palliative surgery and the fact that such surgery is not itself free of mortality. In our series of cases 1 patient died following a by-pass procedure and the average duration of life after such operations was 17 months; similarly the average survival following biliary by-pass procedures was only 6·5 months and 16 months in two large series of cases recorded by Warren and others (1968), Monge, Docherty, and others (1964), and Monge, Judd, and Gage (1964).

Although at first sight it seems that the cases with type-I lesions fared a lot better than those with type-II or type-III tumours the number of different surgeons involved, the large number of postoperative deaths among patients with type-III lesions, and the small total number of patients make it impossible to differentiate the groups on the grounds of prognosis. Nevertheless, our observations lend some support to the suggestion (Crile and others, 1970) that radical surgery is more frequently indicated in cases with polypoid ampullary lesions.

Several aspects of the pathology of these tumours require comment. In particular there is the question of the validity of the separation of these tumours into two main types. It is probable that, as stated by Edmondson (1967), all the tumours are shades of a continuous spectrum and the presence of the small group of mixed pattern (type III) would support this, but at least the ends of the spectrum can be distinguished from each other. Several tumours of type I had small infiltrating areas in their deep aspects which resembled the type-II pattern of growth. It may be that all of these tumours are basically the same but that the histological pattern is dependent on the surrounding tissue, so that a tumour may excite a dense scirrhous reaction where it is infiltrating muscle but grows as delicate papillae in the duodenal lumen. This interpretation merely reflects the invasiveness of type-II tumours as compared with type-I lesions.

The evidence does not suggest that one variety of tumour is an earlier stage of the other, for the type-II tumours were often smaller than those of type I although the type-I lesions appeared to be less advanced in terms of invasiveness. As far as invasion is concerned, there seems little doubt that the type-II tumours were much more aggressive. If a modified Duke's classification (Astler and Coller, 1954) is applied to those specimens for which all the necessary data are known, of 4 type-I tumours, 1 was stage A, 2 were B_1, and 1 was B_2. By contrast, in 10 type-II tumours 4 were B_2 and 6 were C_2. Furthermore, cytological evidence of anaplasia was much more prominent in the type-II lesions.

Taking this series of cases in isolation, it could be argued that the type-I tumours are carcinomas of the ampulla while the type-II tumours arise from the duodenal mucosa, for all 4 of the tumours which arose away from the ampulla were scirrhous carcinomas (type IIc) and those of type II which arose at the ampulla may have arisen from its overlying duodenal epithelium. Simple and attractive though this hypothesis is it may not be valid, for some of the type-II tumours were arising beneath the duodenal mucosa (type IIb) from the termination of the ducts. Furthermore, some authors have described papillary adenocarcinomas occurring in sites away from the ampulla (Meyer and Rosenberg, 1931; Lieber and others, 1937; Stewart and Lieber, 1937; Miller, Dockerty, Wollaeger, and Waugh, 1951, Monge, Dockerty, and others, 1964). Nevertheless, numerous authors have recognized polypoid, ulcerating, and stenosing varieties of carcinoma in the duodenum and many have commented that ampullary and periampullary lesions are often of the polypoid form (Pic, 1895; Meyer and Rosenberg, 1931; Baggenstoss, 1938; Hoffman and Pack, 1937; Felsen and Wolarsky, 1943; Brenner and Brown, 1955; Burgerman, Baggenstoss, and Cain, 1956; Monge, Docherty, and others, 1964; Edmondson, 1967), so that this type of carcinoma (type I) is a distinctive variety even if it may not be peculiar to the immediate region of the ampulla.

Acknowledgements.—One of us (L. H. B.) operated on some of the cases in this series whilst Senior Registrar to Mr. Clifford D. P. Jones at the Sheffield Royal Infirmary. We would like to record our thanks to him and to Professor H. L. Duthie, Mr. D. H. Randall, Mr. C. H. Talbot, and Mr. J. Lyttle for allowing us to study their cases.

The photography is the work of Mrs. M. Row and the Photographic Department of the United Sheffield Hospitals.

The work was supported in part by funds from the British Empire Cancer Campaign.

LOCAL RECURRENCE IN PRIMARY OSTEOSARCOMA OF THE FEMUR

By PETER HILL
BRISTOL ROYAL INFIRMARY

Summary

Cases of primary osteosarcoma of the lower femur treated by through-femur amputation and reported to the Bristol Bone Tumour Registry have been reviewed from the viewpoint of local recurrence.

There were 2 recurrences within the stump and 4 cases with metastases in the ilio-inguinal region.

It is argued that these figures do not justify the routine use of hip disarticulation with its necessarily cumbersome prosthesis in the primary treatment of these tumours.

A large proportion of osteosarcomas arising in previously normal bone occur in the lower end of the femur, quoted figures varying between 35 and 50 per cent (Jaffe, 1958; Coley, 1960; Lichtenstein, 1965; Dahlin and Coventry, 1967). If these are treated primarily by amputation the effectiveness of through-femur amputation compared with hip disarticulation must be considered in relation to the incidence of local recurrence within the stump. The only figures available for such a comparison are those of Sweetnam (1969), who quotes 9 instances of stump recurrence in 42 cases in a survey prepared for a Medical Research Council Report (1969). Cases of primary osteosarcoma in the lower femur treated by through-femur amputation and reported to the Bristol Bone Tumour Registry were therefore reviewed.

MATERIALS AND METHODS

Bristol Bone Tumour Registry files contain 168 cases of primary osteosarcoma presenting up to 1968. Of these, 55 (30 per cent) occurred in the lower femur. Thirty-three cases were treated by amputation through the femur in the apparent absence of metastases. Thirty-one patients have been reviewed, 2 being excluded because there was inadequate information for assessment, both being cases treated overseas.

Each case had been reviewed by the Registry Panel of pathologists, radiologists, and surgeons and the diagnosis agreed on the basis of a primary malignant bone tumour forming osteoid and/or bone. The incidence and site of local recurrence were decided by reference to Registry records and by correspondence with the hospital, surgeon, and general practitioner involved. In cases where uncertainty still existed the full hospital records were consulted but in only a few instances were radiographs available.

RESULTS

There were 9 survivors and all had survived for more than 5 years. The remaining 22 patients had died at periods between 4 and 86 months after amputation (average, 26 months). Thus, all the cases are accounted for and a local recurrence in the survivors is extremely unlikely.

There were 2 recurrences in the amputation stump, noted at 19 and 11 months after amputation respectively. In addition, there were 4 instances of tumour metastases in the neighbouring ilio-inguinal region at 4, 6, 8, and 19 months after amputation respectively. All those with local recurrence died within a few months of this being noted except for 1 patient with a groin recurrence who survived a further 39 months with local radiotherapy.

DISCUSSION

There appears to have been a swing recently in favour of hip disarticulation rather than primary amputation for the treatment of patients with osteosarcoma of the lower end of the femur. Of such cases reported to the Bristol Bone Tumour Registry in the past 4 years, 6 out of 8 were amputated at hip level. Opinions on the necessity for this vary. Lee and McKenzie (1964) favour hip disarticulation while Jaffe (1958), Coley (1960), Lichtenstein (1965), and Dahlin and Coventry (1967) favour amputation through the femur, although Coley (1960) specifies histological examination of the stump marrow at operation.

A femoral stump, even if short, forms the basis for a prosthesis which is greatly superior to that fitted after hip disarticulation, both in the rapidity and ease with which it is fitted and in the eventual level of function obtained. The first point is of particular importance to those who eventually succumb to their disease (in this series this occurred 27 months, on average, after amputation).

Sweetnam (1969) states that femoral amputation is frequently followed by stump recurrence, quoting 9 such instances in 42 cases (or 7 of 28 who had no other treatment), and suggests that hip disarticulation would eliminate the presenting lesion more completely. This may apply to 1 of the 2 recurrences in the stump in the present series, but in the other further metastases were present when the femoral recurrence was first noted and therefore overall survival would not have been affected although an often troublesome and painful local recurrence would have been avoided.

The 4 ilio-inguinal lesions were almost certainly lymph-node involvement. In 2 cases radiographs of the pelvis and hip showed no bony involvement, while a third was described as 'inguinal nodes'. This frequency of lymph-node involvement is not generally acknowledged although McKenna, Schwinn, and Soong (1966) in a series of autopsy examinations found such spread in 30 per cent of cases. These might appear clinically to be stump recurrences, particularly if the remaining femoral fragment was short. They would, nevertheless, not have been cleared by hip disarticulation unless this had been combined with ilio-inguinal node excision. Even this more major procedure would probably not have affected overall survival in 2 of the 4 patients since these had other metastases at the time of the groin recurrence.

Hence, in this group of 31 patients the life of 1 patient might have been saved if hip disarticulation had been undertaken in every case and a second patient would have been spared the local stump recurrence although his fate was sealed by widespread recurrences and he died within 5 months of the appearance of the stump recurrence. The remaining 29 patients, particularly the nine 5-year survivors, would have been adversely affected to a marked extent.

When considering the outcome of treatment for osteosarcoma of the lower end of the femur in these 31 patients we must give due weight to the quality of life of all these young people, both the fortunate who will survive and the unfortunate majority who will die. We must remember that the seed and the soil are more important than the surgery and not extend the mutilation in the mistaken idea that the surgeon's role can be more effective than is, in fact, unfortunately the case.

These results suggest that in osteosarcoma of the lower end of the femur, as in other more common types of malignant disease, the more major excisions are not necessarily the more effective.

Acknowledgements.—I wish to thank Mr. A. L. Eyre-Brook as a result of whose advice and encouragement this study was made, and also Dr. C. H. G. Price and Mrs. L. E. Nutt of the Bristol Bone Tumour Registry for their great help in dealing with the Registry records.

SUBTOTAL COLECTOMY AND CAECOPROCTOSTOMY

By C. U. WEBSTER and R. R. S. HOWARD

THE RADCLIFFE INFIRMARY, OXFORD

Summary

The technique of subtotal colectomy with caecoproctostomy is described, together with clinical details of 6 patients in whom it was performed. An important feature of the operation is retention of the ileocaecal sphincter which helps to maintain almost normal bowel function.

THE operation of subtotal colectomy and caecoproctostomy is little known among abdominal surgeons. The indications for the operation are few, but include all extensive colonic diseases which have spared the ascending colon and the rectum. The aim of the procedure is to remove all the diseased areas with preservation of as much healthy colon as is feasible; continuity can be achieved by anastomosing the inverted, proximal, ascending colon to the rectal stump.

The operation was described by Wangensteen, Lewis, Arhelger, Muller, and MacLean (1954) as a primary procedure in radical surgery for carcinoma of the colon. Lillehei and Wangensteen (1955) stressed the importance of preservation of the ileocaecal valve in water absorption. Rosi and Cahill (1962) reported 15 patients with polyposis coli in whom subtotal colectomy with caecorectal reconstitution was employed, leaving only 25 cm. of large bowel which they felt they could keep under observation by sigmoidoscopy. In this country Thompson (1971) has used the procedure in several situations, including cases of colitis where the caecum has appeared normal, diverticular disease with complications, multiple adenomata of the large intestine, and multiple malignancies of the colon.

In Oxford limited experience of the operation over a period of years has led us to believe that provided the indications are correct the functional results are outstandingly good.

SURGICAL TECHNIQUE

Selection of patients is made on clinical grounds and the findings of barium studies and sigmoidoscopy. The last must show no evidence, or only minimal evidence, of proctitis.

After standard bowel preparation, the abdomen is explored through a long left paramedian incision and the extent of the disease confirmed. The ascending colon is then mobilized and the bowel divided at a point 10–15 cm. from the base of the caecum. The ileocolic artery and its branches to the proximal ascending colon are preserved with care.

Subtotal colectomy is then performed, removing the distal ascending colon, transverse colon, left colon, and sigmoid. The greater omentum is removed in continuity and the main blood-vessels, including the inferior mesenteric, are divided where suitable. The point of division of the inferior mesenteric artery will be determined by the nature of the sigmoid disease, that is, near the bowel in inflammatory disease but near the aorta in malignant disease. The presacral space is then opened to allow the rectum to be straightened, so that the anastomosis can take place at the level of the sacral promontory. The rectosigmoid is divided between clamps and the colon removed.

The ascending colon is then rotated *counter-clockwise* so as to lie in the midline or the left iliac fossa above the rectal stump. This is an important manœuvre in ensuring the correct lie of vessels in the pedicle.

An end-to-end anastomosis is performed in two layers without clamps, ensuring that both bowel ends bleed. The outer layer consists of interrupted sutures of 00 thread or silk and the inner of continuous 00 or 0 chromic catgut.

Finally, appendicectomy is performed, and after experience with 1 case where caecal ileus developed an appendicostomy tube is inserted through the appendix stump, a small Malecot or Foley catheter being employed. The anorectal ring is dilated and a large-bore flatus tube stitched in situ. *Fig.* 1 shows a diagrammatic representation of this procedure.

The postoperative course is usually smooth. The flatus tube is removed after 48 hours. The appendicostomy tube is left on continuous open drainage initially and occasionally washed gently with saline to ensure that it has not become blocked. It is removed on the fourteenth postoperative day. One case in our series developed a faecal fistula after early removal of the tube because of wound infection but this soon closed.

Recovery is complete by the third postoperative week, by which time the patient is passing three to four semiformed stools a day with control.

A late postoperative barium-enema film is shown in *Fig.* 2.

CASE REPORTS

Case 1. Male, born in September, 1940. This patient was diagnosed as suffering from ulcerative colitis in 1958. He was treated by blood transfusions, steroids, and retention enemas. In 1963 he was admitted to hospital because of progressive anaemia, and later in the same year he was readmitted urgently with a further relapse and severe anaemia. A barium-enema examination at this time showed gross polyposis extending from the sigmoid colon to the hepatic flexure, but on sigmoidoscopy the rectum showed only minor inflammatory changes. Some doubt was expressed as to the precise diagnosis, and despite the absence of a family history the possibility of the case being one of familial polyposis coli was raised. In February, 1964, a caecoproctostomy was performed. The excised colon was extremely bulky owing to polyps, but the rectum and ascending colon were grossly normal. Histological examination showed that the polyps were of the inflammatory type and that the original diagnosis of ulcerative colitis was correct.

During the early postoperative period the patient experienced persistent lower abdominal pain which was almost certainly caused by gaseous distension of the inverted caecum. This gradually settled and he was allowed home on the twenty-fifth postoperative day, by which time he was passing only two stools daily. An interesting feature was that the faecal fat excretion was 18·8 g. in a 24-hour period preoperatively, but by the time of the patient's discharge this figure had fallen to 7·7 g.

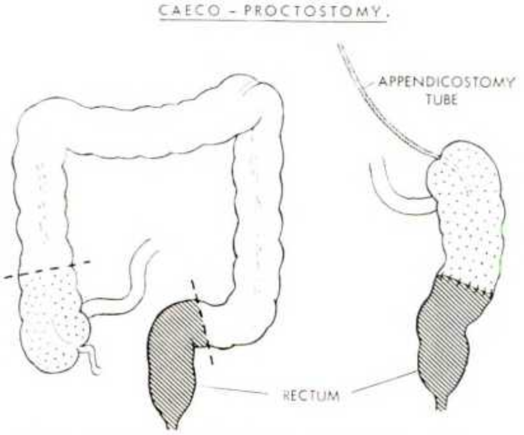

FIG. 1.—Diagrammatic representation of caecoproctostomy.

In November, 1966, by which time the patient was extremely well, he developed an adhesive small-bowel obstruction which required laparotomy. The present situation 6 years after surgery is that he has one bowel action a day which is usually formed. He occasionally has to control his excessive weight-gain by dieting. A recent sigmoidoscopy showed normal rectal mucosa; the haemoglobin is 110 per cent and the sedimentation rate 4 mm. per hour. He is fully employed as an engineer and has fathered 2 children since operation.

Case 2.—Female, born in March, 1915. This single woman who held a responsible post as a secretary was admitted to hospital in 1963 for investigation of diarrhoea, weight-loss, and erythema nodosum. A barium-enema examination showed gross disease extending from the sigmoid to the transverse colon and was suggestive of Crohn's disease. She was treated with oral steroids and retention enemas, and although she gradually improved her skin lesions recurred when the steroids were stopped. In 1965 she relapsed whilst still under treatment and a further barium-enema examination showed stricture formation in the distal transverse colon. In October, 1965, a subtotal colectomy and caecoproctostomy was performed and on this occasion, because of experience with *Case* 1, after appendicectomy a Malecot catheter was introduced so that the caecum could be deflated if necessary. The patient's postoperative recovery was very smooth and she was allowed home on her nineteenth postoperative day, but she continued on steroids and Salazopyrin. The pathology confirmed that the colonic disease was of the Crohn's type.

By June, 1966, the steroids were discontinued, but she continues on small doses of Salazopyrin. She has one bowel action per day with good control, is working full time, and remains in good health 4 years after surgery.

Case 3.—Male, born in March, 1909. This patient who held a post as borough treasurer in a large town developed granular proctitis in 1955. In 1961 a stricture of the sigmoid colon occurred. A defunctioning ileostomy was performed and subsequently the stricture was excised. The isolated colon was treated with steroids for 2 years, but during the course of treatment he developed a large polyp in the left colon. In June, 1963, the polyp was removed by colotomy and the ileostomy was closed. The polyp proved to be of the inflammatory type. However, by 1965 he had developed polyps in the left and transverse colon which radiologically were broad-based and probably adenomatous. He also had mild recurrent symptoms and was advised to undergo further surgery. Having experienced an ileostomy for 2 years, the patient was anxious to avoid a permanent ileostomy, and as his right colon was apparently normal and the rectal changes very minor a caecoproctostomy was performed in November, 1965. The patient was discharged on his twenty-first postoperative day, and when last seen in March, 1969, he was extremely fit. He had three bowel actions a day and on sigmoidoscopy there were only very minor mucosal changes. He has now emigrated to Zambia, having taken up further employment following his retirement in this country. The specimen removed at colectomy showed evidence of ulcerative colitis but with hyperplastic adenomatous polyps in the left colon and splenic flexure.

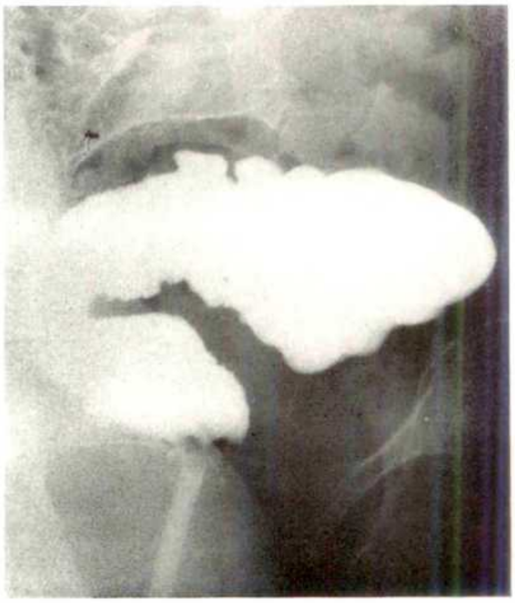

FIG. 2.—Barium-enema film, showing the rectum and inverted caecum.

Case 4.—Male, born in November, 1942. This young garage mechanic originally attended the Radcliffe Infirmary in 1962, giving a 2-year history of left-sided abdominal pain and diarrhoea. A barium-enema examination was consistent with the diagnosis of Crohn's disease of the colon with gross disease from the proximal transverse colon to the sigmoid. Sigmoidoscopy, however, was normal up to 15 cm., at which point the mucosa became cobble-stoned. The patient was treated with systemic and local steroids and Salazopyrin, and he kept reasonably well until late 1965 when he was admitted as an acute case. He was then gravely ill with weakness, prostration, dyspnoea, increasing diarrhoea, and nausea. There was a recorded recent weight-loss of 25 kg. and investigation showed evidence of both gastrocolic and jejunocolic fistulae.

Operation was performed in February, 1966, when the patient weighed 38 kg. He was found to have one gastrocolic, two jejunocolic, one colocolic, and one vesicocolic fistulae. The disease, however, was still confined to the transverse and left colon down to the sigmoid and accordingly, after patching the stomach and the jejunum, a subtotal colectomy and caecoproctostomy was performed. The appendix was removed and a Malecot catheter inserted. The patient was discharged on his forty-first postoperative day to continue on oral prednisolone and Salazopyrin, but by this time he was extremely well, having gained 13 kg. in weight. Within 2½ months of operation his weight had risen to 63 kg. He discontinued taking steroids after 6 months, but continued on Salazopyrin.

The hospital lost touch with this patient in May, 1967, but contact was regained in January, 1970. A recurrence of Crohn's disease had developed in the upper rectum, but this was rapidly controlled by systemic steroids and Salazopyrin. He is fully employed.

Case 5.—Female, born in February, 1910. This woman was a chronic invalid, suffering from hypertension, myxoedema, and a right hemiparesis. In 1967 she developed faecal incontinence and on investigation was found to have a megacolon with colonic inertia and a rectovaginal fistula.

In January, 1968, an extensive sigmoidectomy was performed with a left inguinal colostomy and exteriorization of the rectal stump. The pathological report of the sigmoid colon suggested that the lesion was an acquired idiopathic megacolon, there being no reduction in ganglion cells. In February, 1968, the rectovaginal fistula was repaired and the colostomy was closed. Bowel control following this was poor and her diarrhoea became worse. Her family considered that she was better with a colostomy, but the patient was anxious to avoid this. Barium studies performed in January, 1969, suggested that the left colon, which had become tubular, was the site of ischaemic colitis.

Ultimately, on 31 Jan., 1969, the abdomen was re-explored and subtotal colectomy and caecoproctostomy were performed. The wound around the appendicostomy catheter became infected and as a result the catheter was withdrawn early. A faecal fistula developed which closed in 3 weeks. The pathological report confirmed the presence of ischaemic colitis. The patient's present situation is that her bowel control is better, incontinence is quoted as 'slight' by the district nurse, and she usually passes one formed stool per day. She gets occasional attacks of diarrhoea which are readily controlled by codeine phosphate and at present is attending a day hospital on 2 days a week.

Case 6.—Female, born in August, 1927. This housewife was referred to hospital with a 3-month history of progressive diarrhoea and anaemia. A barium-enema examination showed an irregular sigmoid stricture which was presumed to be a carcinoma. Laparotomy was performed on 13 March, 1969, revealing an advanced sigmoid carcinoma which had infiltrated the transverse colon and mesocolon and the left ovarian tube. A subtotal colectomy was performed with appendicectomy and removal of the left tube and ovary. Continuity was re-established by caecoproctostomy with a Malecot catheter as an appendicostomy tube. The patient was allowed home on her twenty-second postoperative day, and 2½ years after surgery she was well with two or three bowel actions a day and good control. She has no other symptoms.

DISCUSSION

Function.—The most attractive feature of this operation is that, despite removal of most of the colon, almost normal bowel function is retained. Following recovery most patients pass one or two stools per day and these are of normal consistency. This compares favourably with the functional results of ileorectal anastomosis (Baker, 1970; Watts, 1969).

We believe that the ileocaecal sphincter plays an important role in this good functional result. As early as 1931 Ogilvie was led to attempt preservation of the ileocaecal sphincter when resecting the right half of the colon for non-malignant disease, stressing its importance in absorption. Kremen, Linner, and Nelson (1954) showed the value of retaining the ileocaecal sphincter in nutritional adjustment to lower small-bowel excision. More recently, Gazet (1968) has demonstrated that removal or by-pass of the ileocaecal sphincter results in an apparent defect of vitamin-B_{12} absorption and may have a harmful effect upon the animal as a whole. Wangensteen (1943) and Lillehei and Wangensteen (1955) have described the terminal ileum and caecum as the 'water-wringer' of the gut and commented on the absence of diarrhoea following caecorectal anastomosis compared with the persistence of diarrhoea following ileorectal anastomosis.

Indications and Selection.—This operation is particularly suitable for patients with Crohn's disease or ulcerative colitis with sparing of the caecum and rectum, and may also be suitable in ischaemic colitis. It is not the technique of choice for those with carcinoma of the right side of the colon, as adequate excision of lymphatic drainage for this area is not performed. Some patients with multiple or extensive malignancy of the transverse or left colon may be appropriately treated by this procedure. Individual case selection is based upon the results of barium-enema and sigmoidoscopic examination, together with appropriate histological findings on biopsy.

Appendicostomy.—Special attention is drawn to this point for two reasons. The first is that removal of the appendix prevents the possible difficulties of diagnosis and treatment of what would be 'very atypical' appendicitis!

The second reason is that experience with *Case* 1 showed the danger of caecal distension which is readily avoided by this simple means.

Acknowledgements.—We wish to thank Dr. S. C. Truelove for helpful criticism and also Mrs. Linda Ealey and Miss D. Pollard for the typescript.

Post-prostatectomy EPSIKAPRON® is better than post-prostatectomy bleeding*

**This observation has a high degree of clinical significance.*

Post-prostatectomy blood loss may be a litre or more[1,2]. Use of EPSIKAPRON can reduce this loss by 80-90%[3,4]. "The control of blood loss has proved to be not only statistically but also clinically significant"[2]. Blood transfusion, which is costly and not without risk, ". . . can be avoided and draining catheters kept patent without difficulty and removed earlier, which makes the post-operative course smoother and shorter"[3].

PSEUDOCYST OF THE PANCREAS

BY ALAN SIMPSON AND V. K. SRIVASTAVA
WEST BROMWICH AND DISTRICT GENERAL HOSPITAL, STAFFORDSHIRE

SUMMARY

An account of pseudocyst of the pancreas, which is a less common cause of abdominal swelling, is given. Various methods of treatment are described. A series of 8 patients with pseudocyst of the pancreas is reported. The treatment in each case is described.

PSEUDOCYST of the pancreas is an unusual cause of abdominal swelling. The first recorded surgical treatment of the condition was by aspiration (Le Dentu, 1862). Since that time many attempts have been made to find a more satisfactory method of treatment. The methods used have ranged from simple drainage techniques to complete excision of the cyst. Even a century later pseudocyst still presents a surgical problem. The literature contains few reports of this condition and only small series of cases have been recorded, from which it is difficult to draw any definite conclusions. Some aspects of pseudocyst of the pancreas with particular regard to management are discussed in the present paper.

INCIDENCE

Pseudocyst accounts for about 80 per cent of all cases of pancreatic cyst. In 72 patients with acute pancreatitis collected from 1959 to 1969 we have only been able to diagnose pseudocyst in 8 cases. In a similar series described by Louw, Marks, and Bank (1967) the incidence of pseudocyst was 20 per cent.

AETIOLOGY

The main causes of pseudocyst in order of frequency are: (1) acute pancreatitis (and chronic relapsing pancreatitis), (2) upper abdominal trauma, and (3) neoplasm (rare).

Whilst acute pancreatitis accounts for most of these cysts, patients sustaining blows in the upper abdomen (probably in the form of blunt upper abdominal trauma) also account for a considerable number of cases. As early as 1892 Lloyd recognized this association. In a series of 20 patients with a history of upper abdominal trauma quoted by Warren and Hardy (1968) no less than 13 of these patients developed pseudo-pancreatic cyst.

From our observations acute pancreatitis has been the forerunner and the main aetiological factor of pseudocyst in most patients. One case, a child of 14 years, developed pseudocyst after an attack of pancreatitis due to mumps. This cause has also been reported by Attard (1969). We have had no incidents of acute pancreatitis or pseudocyst following blunt upper abdominal trauma. Chronic relapsing pancreatitis has also been mentioned as an important cause of pseudocyst, although no such case occurred in our series. Neoplasm appears to be a rare predisposing cause and only a few incidents have been reported where the cyst was associated with a pancreatic neoplasm.

PATHOGENESIS AND PATHOLOGICAL ANATOMY

During the acute phase of an attack of pancreatitis or, in some cases, following pancreatic trauma considerable quantities of pancreatic exudate rich in digestive enzymes are discharged into the retroperitoneal tissues. Sometimes (probably in the more severe cases when necrosis of the peripancreatic tissue occurs) this exudate is discharged into the lesser sac itself.

We believe that under normal conditions this fluid finds an escape via the foramen of Winslow into the greater sac, thus accounting for the characteristic findings at laparotomy in cases of acute pancreatitis, i.e., blood-stained ascites and fat necrosis. In some cases this ascitic fluid becomes encysted in the lesser sac as a result of blockage of the foramen of Winslow. It probably takes several days for the products of autodigestion to occur in sufficient quantity to form enough sludge to seal the outlet, thus accounting for the delay between an attack of pancreatitis and the appearance of a pseudocyst (*Figs.* 1–4).

In a proportion of cases of pseudocyst a direct connexion between the cyst and the pancreatic duct system becomes established. Such a fistula would explain the fluctuation in the size of some of these cysts affected by a proximal blockage of the pancreatic duct system, this blockage being caused by either scarring or spasm at the sphincter of Oddi or blockage of the actual pancreatic duct system itself or both. We have tried to explain this mechanism in *Fig.* 5. Doubilet and Mulholland (1953) believe that the primary cause is spasm of the sphincter of Oddi which gives rise to pancreatitis and the resulting pseudocyst. The persistence of spasm raises the intraductal pressure and causes the cyst to swell more until the pressure in the cyst increases, owing to pressure transmitted by the neighbouring viscera, and overcomes the intraductal pressure. In this case the cyst will drain once again into the duodenum and spontaneous decompression will occur. On this basis Doubilet and Mulholland (1953) recommend a sphincterotomy as the primary treatment for pseudocyst. This explanation sounds attractive, but fails to answer how a block distal to the sphincter of Oddi could be satisfactorily treated by sphincterotomy since this would not relieve the obstruction and could not therefore reduce the size of the cyst.

DIAGNOSIS

In 72 cases of acute pancreatitis we have adopted the following clinical and radiological criteria in the diagnosis of pseudocyst.

1. History.—*Tables I* and *II* show the type of history obtained in our patients with pseudocyst.

2. Physical Signs.—The main physical sign was that of an intra-abdominal cyst, though in 1 patient ascites was mimicked and in another a brown discoloration of the skin appeared over the cyst (*Fig.* 6).

FIG. 3.—Blockage of the foramen of Winslow causes exudate to become encysted in the lesser sac.

3. Radiographic Aids.—It would be ideal to screen all probable cases of pseudocyst. In our series several patients missed this investigation as a result of diagnosis not being made until abdominal section, or diagnosis had already been made, or the patient's general condition did not warrant this investigation.

However, screening was done in 3 cases and in 2 of them it considerably helped the diagnosis. The most useful findings were: (*a*) distortion of the stomach and transverse colon and an increase in the vertebro-gastric distance, (*b*) displacement of the duodenal cap towards the left of the midline in the antero-posterior view, and (*c*) widening of the duodenal sweep.

4. Intravenous Pyelography.—This was done in some cases where the diagnosis was uncertain. In our series no abnormalities were detected on pyelography (although occasionally a pseudocyst may have to be differentiated from a renal cyst).

Table I.—PRESENTING HISTORY OF PATIENTS WITH PSEUDOCYST OF THE PANCREAS

History	*No. of Cases*
Recent attack of acute pancreatitis	6
Chronic relapsing pancreatitis	Nil
Blunt upper abdominal trauma	Nil
Operative procedure on pancreas and/or adjacent organ	Nil
Miscellaneous	
None of the above	1
Mumps causing pancreatitis	1

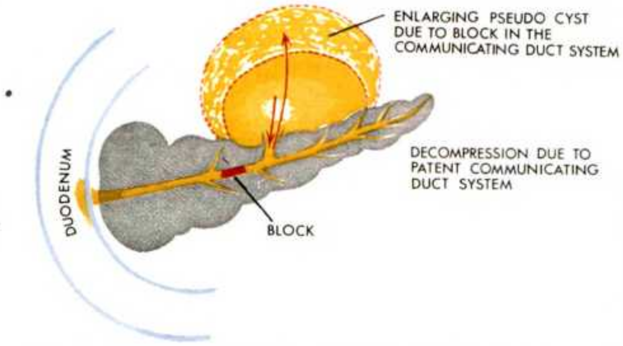
5. Chest Radiography.—This was done routinely. No evidence of extension of the cyst into mediastinum was found in any of our patients.

6. Serum Amylase.—This investigation was done shortly after admission in 6 out of the 8 patients.

In 5 patients the serum amylase was elevated to a figure of 1600 Somogyi units and in the remaining case to 800 Somogyi units. Serum amylase seems to be often markedly elevated in cases of pseudocyst.

TREATMENT

As there is invariably an obstructive element present in pseudocyst, inadequate free drainage is present and almost always requires some form of surgical drainage procedure. This is necessary not only to cure the condition but also to prevent the dangerous complications which may follow conservative policies. These complications include spontaneous rupture of the cyst giving rise to severe peritonitis, gastro-intestinal haemorrhage, and pancreatic abscess, and there is also the possibility of association of carcinoma of the pancreas.



ENLARGING PSEUDO CYST DUE TO BLOCK IN THE COMMUNICATING DUCT SYSTEM
DECOMPRESSION DUE TO PATENT COMMUNICATING DUCT SYSTEM
BLOCK
DUODENUM

FIG. 5.—Fluctuation in size of a pseudocyst owing to a fistulous connexion with the pancreatic duct system.

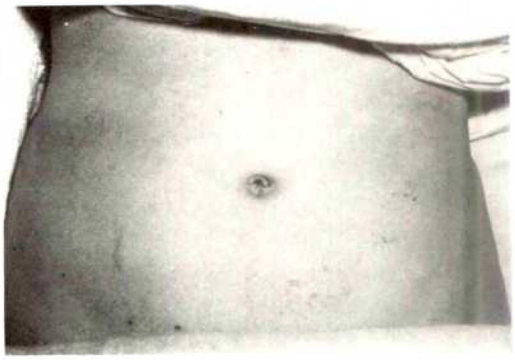


FIG. 6.—Brown discoloration of the skin of the area over the pseudocyst.

The only satisfactory surgical treatments that have been used so far fall under the heading of some form of drainage procedure. It is rarely possible to excise the cyst because of anatomical difficulties and the nature of the pathology.

Surgical Treatments.—

- *a*. External drainage.
  - i. Marsupialization.
  - ii. Drainage through a catheter or tube.
- *b*. Internal drainage.
  - i. Cystogastrostomy.
  - ii. Cystojejunostomy.
  - iii. Cystoduodenostomy.
  - iv. Drainage through a Roux-en-Y-type of procedure.
- *c*. Combination of internal and external drainage through a T-tube put in a cystogastrostomy wound.
- *d*. Excision is rarely possible, but should be attempted in the following circumstances:—
  - i. When there is the possibility of a carcinoma.
  - ii. If the cyst is easily accessible, such as when a cyst arises from the wall of the pancreas.

External Drainage.—External drainage has been fairly widely used for the management of pseudocyst but it has the disadvantages of prolonged leakage, the occasional establishment of a pancreatic fistula (both being associated with skin necrosis), and sometimes the occurrence of gastro-intestinal haemorrhage. External drainage by marsupialization was first introduced successfully by Gussenbauer in 1882, though Warren and Baker (1962) reported satisfactory results from simple drainage using a Depezzer catheter and they considered this method to be not only superior to marsupialization but also particularly suitable for deeply situated cysts. Louw and others (1967) reserved this procedure for desperately ill patients and for cases where the cyst wall is friable and unsuitable for suturing. It is interesting to note that Louw and his colleagues reported no less than 2 deaths out of 6 patients whom they treated by this method, both patients dying from severe gastro-intestinal haemorrhage. A further 2 patients developed chronic pancreatic fistula and in the light of these experiences they now avoid external drainage procedures wherever possible.

Table II.—PRESENTING SYMPTOMS IN PATIENTS WITH PSEUDOCYST OF THE PANCREAS

Symptom	*No. of Cases*
Upper abdominal pain	7
Swelling in upper abdomen	8
Dyspepsia	2
Motor disturbances of upper gastro-intestinal tract due to mechanical effects	2
Miscellaneous, such as fever and chills	Nil

Internal Drainage.—Internal drainage for a pseudocyst was first reported in 1915 by Jedlicka. At least four types of internal drainage have been used:—

Cystogastrostomy: This is a popular method and is particularly suitable for dealing with cysts in the lesser sac. Louw and others (1967) recently reported this form of management in 15 of their patients and were successful in obtaining satisfactory results in all but 2 of them.

Cystoduodenostomy: This method of internal drainage is suitable for dealing with pseudocysts which are adjacent to the head of the pancreas.

Cystojejunostomy: This was first introduced by Heme and Hann in 1927. It is probably the best method of internal drainage for managing pseudocysts and has been most successfully used by Hoxworth, Mattheis, Coith, and Altemeier (1963) and Parshall and Remine (1965) in their series. Louw and others (1967) reserve this method for cysts presenting to the left of the stomach or between the leaves of the transverse mesocolon.

Drainage through a Roux-en-Y-type of procedure: In 1946 Konie described a method using a Roux-en-Y-type of procedure. He made a formal anastomosis to a Roux-en-Y segment of jejunum or to a loop of jejunum defunctioned by entero-enterostomy, and in 3 patients who were treated by this method excellent results were obtained.

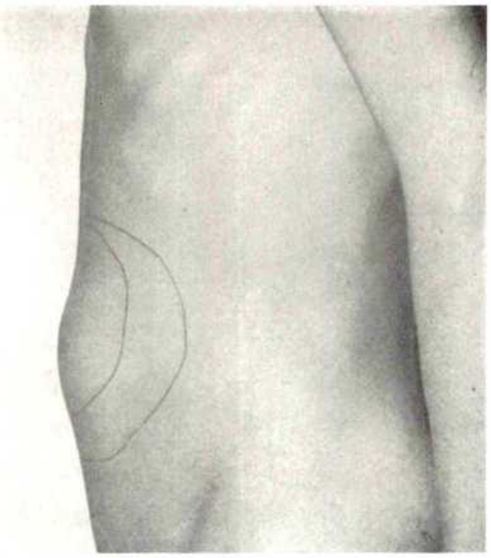

FIG. 7.—*Case* 2. Central abdominal swelling on presentation.

The chief advantage of these internal drainage procedures is avoidance of external fistula and its associated problems, and the main disadvantage is that when the cyst is friable, thin, and often indefinable it is impossible to do a satisfactory anastomosis.

Warren and Baker (1962) have reported 5 cases where internal drainage was complicated by massive gastro-intestinal haemorrhage.

Excision.—Simple excision of a pancreatic cyst is seldom feasible. It has a limited application to patients where the cyst is in the tail area of the pancreas and also where there is a possibility of a neoplasm. As early as 1882 Bozeman did a successful excision.

In our series most of these methods of treating a pseudocyst have been used. The 8 cases of pseudocyst which form the present series are briefly described below, mentioning their subsequent progress and the results of treatment.

CASE REPORTS

Case 1.—A 75-year-old woman was admitted to hospital with typical acute pancreatitis. Ten days after the onset of the attack when the severe symptoms had subsided abdominal distension began, and in 2–3 days' time an ascites-like picture had formed. The serum amylase was raised to 1600 Somogyi units and in view of enlarging ascites it was decided that laparotomy was now necessary. Owing to her poor general condition external drainage by marsupialization was performed. She recovered from the operation quite well but it took several weeks for the discharge to subside, and during this time she was considerably troubled by skin necrosis. During the fifth week she developed a further mild attack of acute pancreatitis, but finally after about 7 weeks the cyst dried up and she was discharged from hospital.

Case 2.—A 14-year-old boy presented at the surgical out-patients' department with a central abdominal swelling (*Fig.* 7). He gave no clear history of pancreatitis but 6 weeks previously he had had an attack of mumps. He was admitted to hospital for diagnostic purposes, and a barium-meal examination, an intravenous pyelogram, and a cholecystogram were all negative. Owing to the rapid enlargement of the swelling it was necessary to carry out a laparotomy, when a large pseudocyst was found to be present between the stomach and the transverse colon. The wall of the cyst was thick and it was possible to do a cystogastrostomy (*Fig.* 8 A). He made a good recovery from this procedure until some 6 months later when he developed further upper abdominal pain and tenderness. At this stage it was decided that a further drainage procedure should be performed. A second internal drainage operation, involving anastomosis of the cyst via a Roux-en-Y loop to the jejunum, was performed. Following this the patient made an uneventful recovery (*Fig.* 8 B).

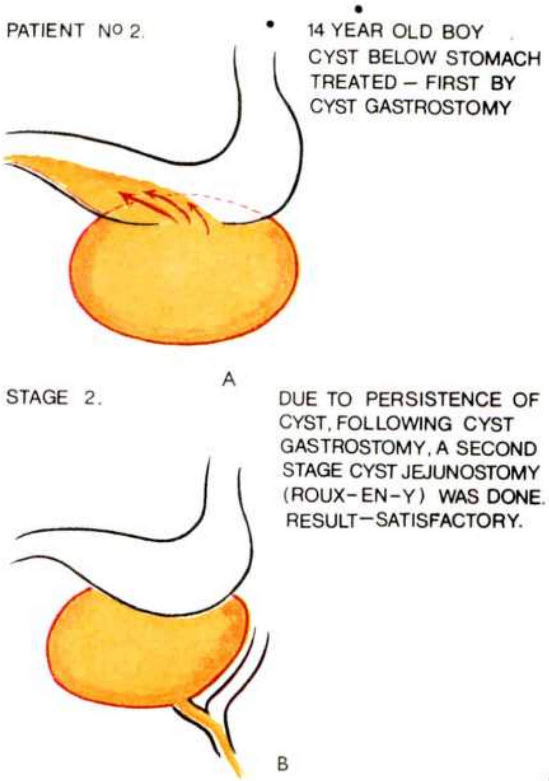

FIG. 8.—*Case* 2. A, Initial treatment by cystogastrectomy. B, Six months later a cystojejunostomy was carried out for persistence of the pseudocyst. A satisfactory result was achieved.

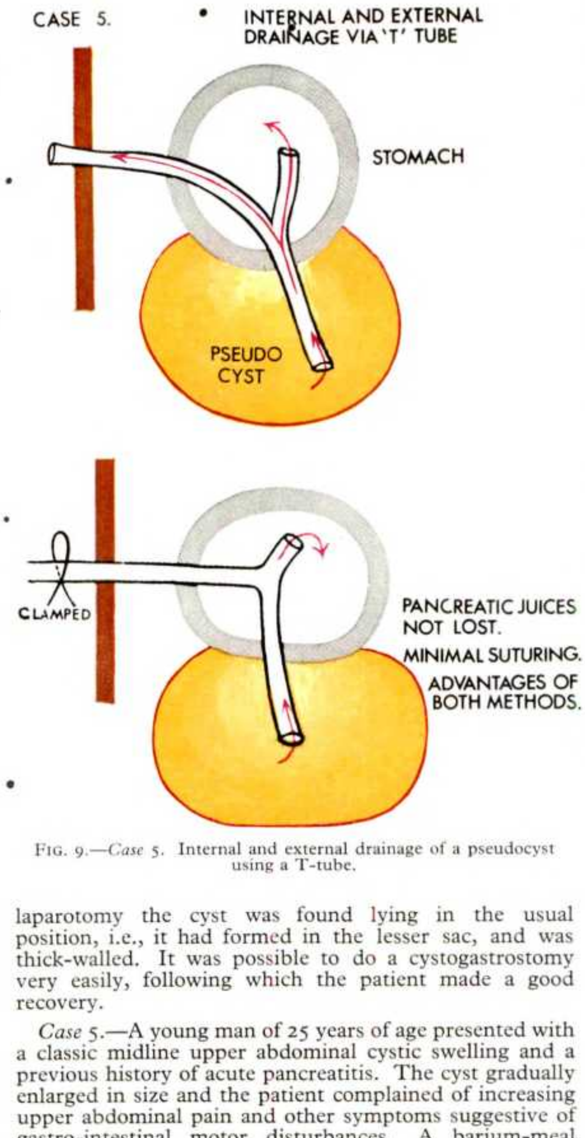
Case 3.—A 45-year-old man was admitted with acute pancreatitis. He was desperately ill for several days and just as he started to recover it became obvious that he was developing a pseudocyst. This cyst rapidly enlarged and it was necessary to do a laparotomy. At operation the wall of the cyst was friable and almost indefinable, and the only possible way of managing the case was by external drainage, this time using a Foley catheter. His general condition gradually improved but he then developed a pancreatic fistula. The skin was becoming increasingly digested and it was decided to try to implant the fistula into the jejunum, forming a type of Roux-en-Y procedure. This was done with an excellent result.

Case 4.—A 34-year-old woman had a typical attack of acute pancreatitis and several days later developed a pseudocyst which rapidly expanded, necessitating operation. At laparotomy the cyst was found lying in the usual position, i.e., it had formed in the lesser sac, and was thick-walled. It was possible to do a cystogastrostomy very easily, following which the patient made a good recovery.



CASE 5.
INTERNAL AND EXTERNAL DRAINAGE VIA 'T' TUBE
STOMACH
PSEUDO CYST
CLAMPED
PANCREATIC JUICES NOT LOST.
MINIMAL SUTURING.
ADVANTAGES OF BOTH METHODS.

FIG. 9.—*Case* 5. Internal and external drainage of a pseudocyst using a T-tube.

Case 5.—A young man of 25 years of age presented with a classic midline upper abdominal cystic swelling and a previous history of acute pancreatitis. The cyst gradually enlarged in size and the patient complained of increasing upper abdominal pain and other symptoms suggestive of gastro-intestinal motor disturbances. A barium-meal examination was suggestive of pancreatic pseudocyst. His serum-amylase level was markedly elevated. A laparotomy was carried out and the diagnosis was confirmed. The cyst was large and so friable that any type of formal anastomosis was quite out of the question. Drainage of the cyst was effected by means of a T-tube placed into the cyst via the posterior wall of the stomach (one arm of the T into the cyst, the other arm of the T was left in the stomach, the long arm of the T being brought out through the abdominal wall). This method offered internal drainage from the cyst into the stomach and also an external means of drainage, thus allowing qualitative and quantitative assessment of the cyst as well as radiographic assessment of the cyst cavity. Gradually the external drainage reduced to a minimum and the long arm of the T-tube was clamped off. This caused neither pain nor discomfort to the patient. One week after clamping the T-tube a quantity of Gastrografin was introduced into the T-tube, but this showed no entry of dye into the cyst cavity, probably indicating complete decompression and obliteration of the cyst. The T-tube was then removed and the patient made an excellent recovery. Several months have now gone by and he has had no further trouble (*Fig.* 9).

Case 6.—A 50-year-old woman presented with a cystic mass in the epigastrium. A diagnosis was not made prior to laparotomy, at which a retrogastric pseudocyst was found. A cystogastrostomy through the posterior wall of the stomach was easily performed, since which she has made a satisfactory recovery.

Case 7.—A 53-year-old woman presented with a large mass in the epigastrium. A provisional diagnosis of carcinoma of the head of the pancreas was made and at operation this was confirmed, but the mass was found to be of multiple cystic origin arising from the head of the pancreas. A subtotal pancreatectomy was performed, the patient making a satisfactory recovery until the tenth postoperative day when she died from a coronary thrombosis. The histology report confirmed the diagnosis of a multiple cyst arising from the head of the pancreas.

Case 8.—A 28-year-old woman presented in the first instance with a very severe attack of acute pancreatitis. After a very stormy period she gradually improved and was discharged home. Later she developed a central abdominal swelling which gradually enlarged and suddenly underwent spontaneous rupture while she was at home. She was admitted to hospital in a moribund condition and at this time we felt that she was too ill to be subjected to laparotomy. After several days her condition improved sufficiently to undergo exploration, when there was evidence of oedema of the pancreas and a recent peritonitis. The gall-bladder was full of gall-stones and a cholecystectomy was performed. Following this she made an uneventful recovery.

INTRACRANIAL SUBDURAL ABSCESS

By D. I. ANAGNOSTOPOULOS AND PETER GORTVAI

REGIONAL CENTRE FOR NEUROLOGY AND NEUROSURGERY, OLDCHURCH HOSPITAL, ROMFORD, ESSEX

SUMMARY

Thirty-two cases of intracranial subdural abscess were treated between 1947 and 1969 in two neurosurgical centres. Five patients (15·6 per cent) died. When an E.N.T. focus is detected clinically or radiologically the abscess is always related to it. Four of the 5 fatalities harboured pus along the falx cerebri. Angiography is used to aid localization and to detect further collection of pus. Limited experience in the use of gamma scanning for localization is encouraging. Pus in the subdural space is drained through bur-holes and antibiotics are administered locally. Broad-spectrum bactericidal antibiotics are used in high dosage as the initial treatment and cerebral oedema is controlled by mannitol and dexamethasone in the drowsy or unconscious patient. Surgical decompression should be considered when comatose patients do not respond to bur-hole drainage of the pus and medical measures.

SUBDURAL abscess is one of the types of intracranial suppuration. Pus forms in the potential space between the dura and arachnoid as a consequence of bacterial infection from the surrounding structures or from distant sites by spread via the blood-stream.

Kubik and Adams reviewed the literature in 1943 and described 14 cases. Antibiotics were not in use at that time and 12 patients died.

Schiller, Cairns, and Russell (1948) reported on the use of penicillin in subdural abscess, and recorded a mortality of 30 per cent in patients who received penicillin both locally and systemically. Hitchcock and Andreadis (1964), using local and systemic broad-spectrum antibiotics, reported a similar mortality-rate: 10 dead out of 29 cases. Garfield (1969) had an overall mortality of 38 per cent in 38 cases; local penicillin and streptomycin were employed with systemic antibiotics. Mortality was higher in patients whose systemic antibiotic treatment was considered inadequate or inappropriate in retropsect. Further recent series have been published by Bhandari and Sakkari (1970) and Torres, Yarzagary, and West (1970).

CLINICAL MATERIAL

Thirty-two cases of subdural abscess were seen between 1947 and 1969 at Oldchurch Hospital, Romford, and at the Derbyshire Royal Infirmary.

The age and sex distribution is given in *Table I.* More than half the cases were in the 10–30 years age-group. Males outnumbered females in a ratio of 3 : 1.

The primary site of infection is set out in *Table II.* In two-thirds of the cases sepsis originated in the paranasal air sinuses or the middle ear. Cases of intracerebral abscess which ruptured into the subdural space have been excluded from this study.

The presenting signs and symptoms are summarized in *Table III.* Fever was invariably present and temperatures ranged from 38 to 39° C. Hemiparesis, associated with dysphasia when the dominant hemisphere was affected, was a common feature. Headache, vomiting, and papilloedema—the classic triad of raised intracranial pressure—were also often seen. Epileptic attacks occurred in half the cases.

Table I.—AGE AND SEX DISTRIBUTION OF PATIENTS WITH INTRACRANIAL SUBDURAL ABSCESS

Age	*Male*	*Female*
1 mth.–10 yr.	2	—
10–30 yr.	18	5
31–51 yr.	3	1
51 yr. and over	1	2
Total	24	8

Table II.—PRIMARY SITE OF INFECTION IN PATIENTS WITH INTRACRANIAL SUBDURAL ABSCESS

Primary Site of Infection	*No. of Cases*
Paranasal sinuses	18
Frontal sinus	11
Sphenoidal sinus	1
Multiple	6
Otitis	6
Meningitis	2
Trauma (fractured skull)	1
Treatment of subdural haematoma	1
Upper respiratory tract	3
Orbital cellulitis	1

Table III.—PRESENTING SYMPTOMS AND SIGNS IN PATIENTS WITH INTRACRANIAL SUBDURAL ABSCESS

Symptoms and Signs	*No. of Cases*
Fever	32
Neck rigidity	32
Headache	28
Vomiting	19
Epilepsy	16
Hemiparesis	23
Papilloedema	18
Dysphasia	10
Homonymous hemianopia	4

The level of consciousness on admission was classified as follows:—

Category A: alert and correctly orientated (5 cases).

Category B: drowsy and disorientated (21 cases).

Category C: responding only to painful stimulation (6 cases).

These categories correspond to those used by Garfield (1969).

Investigations.—Skull radiographs were available for examination in 16 cases. In 13 there was opacity of one or more of the paranasal air sinuses. The sutures were widened in 2 cases and in 1 case there was osteomyelitis of the skull. In 2 cases with a history of trauma the skull radiograph showed a fracture.

The white-cell count in the peripheral blood was increased in all the cases, the total count ranging from

10,000 to 17,000 per c.mm. with an increase in the number of polymorphonuclear cells. The erythrocyte sedimentation rate was increased in most cases. The range observed was 7–140 mm. (Wintrobe).

An electro-encephalogram was obtained in 13 patients preoperatively. Correct localization of the abscess was given in 3 cases only, and the localizing feature in these cases was the presence of delta waves.

Carotid angiography was performed in 19 cases. In 11 correct localization of the abscess was possible; in 3 a shift of the midline structure was observed. A collection of pus beside the falx was demonstrated in 3 cases. In 5 cases the angiogram was normal.

In all 18 patients where the primary site of infection was E.N.T. sepsis correct localization was possible in retrospect on considering the site of the sepsis.

Gamma scan of the brain was undertaken in 2 patients and in both the increased peripheral uptake was suggestive of a subdural abscess.

Preoperative ventriculography or air encephelography was not used in this study.

Lumbar puncture was performed preoperatively in 22 cases. The pressure was always raised to 200–300 mm. of cerebrospinal fluid. The total protein content was elevated in every case, the range being 60–220 mg. per ml. The cell count was also increased in every case. Culture of the cerebrospinal fluid yielded no growth in 19 of the 22 cases. Streptococci, staphylococci, and *Proteus vulgaris* were each isolated on a single occasion.

Table IV.—RESULTS OF CULTURING THE SUBDURAL PUS FROM PATIENTS WITH INTRACRANIAL SUBDURAL ABSCESS

Organisms cultured	*No. of Cases*
Haemolytic streptococci	2
Non-haemolytic streptococci	4
Anaerobic streptococci	1
Coagulase-negative staphylococci	2
Coagulase-positive staphylococci	2
Proteus vulgaris	2
Fusiform bacilli	1
No growth	16

Isolation of Organisms.—Lumbar puncture, when performed before referral to the neurosurgical unit, usually gave a picture of sterile meningitis. The offending organisms, when isolated, were cultured from pus obtained at operation. The results of culture from subdural pus in 30 cases are given in *Table IV*. In just over a half of the cases the pus was sterile. Streptococci and staphylococci were isolated from most of the remainder.

TREATMENT

All the cases were treated by making multiple burholes over the affected region and evacuation of the pus. Catheters were left in the subdural space. Penicillin, 20,000 U., with streptomycin, 50–100 mg., were instilled daily. Broad-spectrum antibiotics were prescribed systemically in every case. One of the following antibiotics was used as the initial treatment: penicillin 4–6 MU. with streptomycin 1 g., daily; chloramphenicol 2–3 g. daily; cephaloridine 4 g. daily. Further appropriate antibiotics were given if indicated by the results of the culture or if the clinical condition of the patient failed to improve.

Epileptic seizures, when present, were controlled by the administration of phenobarbitone and phenytoin. Valium was used intramuscularly or intravenously in a few cases for status epilepticus.

Medical measures were taken to combat cerebral oedema in drowsy and unconscious patents (categories B and C); 500 ml. of 10 per cent mannitol solution were given initially and repeated 6-hourly if there was no improvement. Most of the more recently treated patients were also given dexamethasone intramuscularly, 10 mg. initially and 4 mg. 6-hourly.

No improvement in the patient's conscious level after 24 hours was considered an indication for a wide craniotomy and decompression, combined with a limited frontal or temporal lobectomy when there was massive herniation of the brain after opening the dura. Craniotomy was performed in 4 cases.

CLINICAL RESULTS

Of the 32 cases presented here, 27 survived and 5 patients (15·6 per cent) died. Sixteen of the patients suffered epileptic attacks before operation. Twelve of these continued to have fits postoperatively. Sixteen of the survivors suffered epileptic attacks of a greater or lesser severity 1–2 years after operation. Nine patients were hemiparetic but only 1 was severely disabled. Some dysphasia was discernible in 6 cases. In 1 patient the presenting homonymous hemianopia persisted.

Of the 5 patients who died, no less than 4 had a sizeable extension of the subdural pus along the medial surface of the affected cerebral hemisphere next to the falx cerebri.

DISCUSSION

Age and Sex Incidence.—More than half the cases occurred in the 10–30-year age-group. Such a finding is not general and the relative youth of the case material may have contributed to the low mortality. However, the age of the patient had no significant effect on the mortality-rate in Garfield's (1969) survey of cerebral abscesses.

Males outnumbered females by 3 : 1 in this series. We feel that the preponderance of males is significant and may be related to the larger incidence of E.N.T. sepsis in the male.

Diagnosis.—A glance at *Table III* suffices to see that a certain differential diagnosis from meningitis or meningo-encephalitis is not possible on the grounds of clinical signs and symptoms alone. The incidence of focal neurological signs and of epilepsy is higher than is normally expected in meningitis, and therefore the diagnosis of intracranial pus can be suspected.

Lumbar puncture was performed in many of the cases because meningitis was suspected. We were not able to ascertain the degree of risk, but we would agree with previous authors (Gregory, Messner, and Zinneman, 1967; Duffy, 1969; Garfield, 1969) that lumbar puncture causes deterioration in the clinical state of the patient with a space-occupying lesion in the cranium. Neurosurgical investigations should be instituted without lumbar puncture if an intracranial abscess is suspected on the grounds of meningitis complicated by hemiparesis, raised intracranial pressure, or fits.

Epilepsy.—Half the cases had epileptic seizures before operation, a figure comparable to that of Hitchcock and Andreadis (1944). During the follow-up 16 of the patients suffered from epilepsy, 12 of whom had had preoperative seizures. Epilepsy is a common complication amongst the survivors of subdural abscess and postoperative epilepsy is three times more frequent in patients who had attacks before operation.

Localization of the Abscess.—When the source of the infection is sinusitis or middle-ear disease, the site of the abscess is closely related to the primary infection. Angiography localized the abscess 11 times in 19 cases, a moderately high success rate, against which must be balanced the fact that in 5 cases the angiogram was normal. The angiographic findings in subdural empyema have been fully discussed by Torres and others (1970). On the anteroposterior projection there is often a crescentic avascular area over the surface of the cerebral hemisphere and the medial edge of this area is often scalloped, which differentiates subdural empyema from the rather similar picture of a subdural haematoma. In subdural haematoma the medial edge of the avascular area is smooth.

Our limited experience with gamma scanning is highly encouraging, but there seems to be no doubt at the present time that a bur-hole judiciously placed near the primary site of infection should be made when the clinical picture is suggestive of an abscess, even when the angiogram is negative. A gamma scan is a useful adjunct but treatment must not be delayed if scanning is not available within a few hours.

Bacteriology and the Use of Antibiotics.—The sensitivity pattern of the organisms cultured from pus could not be accurately analysed from the available data. We would hazard a guess that of the 14 instances of positive culture listed in *Table IV*, some organisms would certainly be resistant to penicillin and some of the cocci would be likely to be resistant. We therefore do not agree with Gregory and others (1967) and Garfield (1969) that penicillin alone in a high dosage is a suitable primary treatment. We favour the systemic use of bactericidal broad-spectrum antibiotics in high dosages.

Mortality.—The mortality of 5 patients out of 32 (15·6 per cent) is low by previous standards, but the 5 deaths require special consideration in the effort to reduce mortality in the future.

We have considered the possibility that the patient's conscious level on admission influences the mortality. All the patients in category A (alert) and in category C (comatose) survived, the 5 fatalities being in category B (drowsy) on admission.

Of the 5 fatalities, 4 patients had a sizeable extension of the abscess along the falx cerebri. The subdural pus may represent rupture of an intracerebral abscess. When there is no improvement on appropriate treatment the presence of further undrained pus must be considered and a carotid angiogram should be taken.

Raised Intracranial Pressure.—Once pus has been localized and drained, enough time must be gained for the antibiotics to control the infection. The inflammatory process itself is associated with cerebral oedema. A subdural abscess is often complicated by thrombophlebitis of the cortical veins or even of the venous sinuses which causes further oedema of the brain. The use of intravenous mannitol with dexamethazone will often decrease cerebral oedema. In spite of treatment with antibiotics and medical measures to combat cerebral oedema the patient's level of consciousness may fail to improve. Surgical decompression should be considered if a comatose patient is not improving in 24 hours. This principle is illustrated by the following case.

CASE REPORT

A boy of 16 was admitted drowsy but answering simple questions. A month previously he had been hit on the left eye by a tennis ball and had developed an intra-orbital abscess, which had been drained and treated with systemic penicillin and streptomycin. Three weeks later he had become feverish with headache and vomiting. The lumbar cerebrospinal fluid pressure at that time was 230 mm.; protein 200 mg. per ml., sugar 75 mg. per ml., white cells 49 per c.mm. The fluid was sterile.

When transferred to the neurosurgical unit there was neck rigidity, photophobia, tenderness over the right side of the forehead, left hemiparesis, and left hemianopia. Gamma scan of the brain showed increased uptake over the edge of the right cerebral hemisphere, and carotid angiography demonstrated a subdural abscess. On the day of admission the abscess was evacuated through bur-holes. The patient was given chloramphenicol, 10 per cent mannitol intravenously 8-hourly, and dexamethasone 10 mg. on admission and 4 mg. 6-hourly.

In spite of treatment the patient responded only to painful stimuli the next morning. The pupils were fixed and dilated. Fourteen hours after the bur-hole drainage a large right frontal flap was turned and the dura was opened. There was a small amount of residual subdural pus. Two large cortical veins were thrombosed. The frontal lobe was so swollen that the wound could not be closed. The frontal pole was amputated 10 cm. behind its tip, the dura was left open, and the scalp was closed in layers. During the next week the patient became alert but had a left hemiparesis. One year after operation he was walking unaided and was seeking employment.

Acknowledgements.—We should like to thank Messrs R. H. Shephard, Julian J. Taylor, B. Fairburn, and J. Andrew for permission to include patients who have been under their care.

RENAL FUNCTION AND HYPERTENSION IN PRIMARY HYPERPARATHYROIDISM

By S. D. CHOWDHURY and J. G. GRAY

NORTH STAFFORDSHIRE ROYAL INFIRMARY, STOKE-ON-TRENT, STAFFORDSHIRE

SUMMARY

Fifteen patients with histologically proven primary hyperparathyroidism have been investigated with special reference to renal function and the occurrence of hypertension. The patients have been followed up clinically, biochemically, and radiographically for a period of 8 months to 5 years after surgery. In all cases the serum-calcium levels returned to normal immediately after parathyroid adenectomy.

Satisfactory renal function was maintained in all but 1 of the cases who had had normal preoperative renal function tests. However, renal damage once established persisted and even progressed after parathyroid adenectomy. Renal function, therefore, did not improve after operation.

At follow-up examination a decrease in the number of renal calculi was found in only 2 cases. None of the patients showed formation of new renal calculi or increase in size of those present preoperatively.

Hypertension was present in 6 patients preoperatively. Six months after operation 2 more patients became hypertensive. Both of these patients had shown evidence of renal damage preoperatively. In another case the patient became normotensive 3 months after operation. The severity of renal functional impairment did not bear any relationship to the degree of hypertension although it is possible that the hypertension is secondary to the renal lesion.

RENAL complications are well recognized in patients with hyperparathyroidism; it is not surprising, therefore, that renal damage with subsequent alterations in renal function may ensue. A survey of 15 patients with primary hyperparathyroidism, operated on by one of us (J. G. G.) at the North Staffordshire Hospital Centre between 1966 and 1970, has been carried out, with particular reference to renal function and hypertension and the relationship of these two factors. Five of the 15 cases presented initially with urological symptoms, and the remainder with neurological or bone and joint or abdominal symptoms (*Table I*). On radiological examination, however, 10 cases were found to have nephrolithiasis or nephrocalcinosis; 2 of the remaining cases had passed renal calculi previously.

MATERIALS

This series comprised 15 patients with primary hyperparathyroidism; 8 were male and 7 were female. Their ages ranged from 20 to 60 years, with 10 cases over 40 years of age. The lesion in each case proved to be a simple adenoma of the chief-cell or clear-cell variety, arising in the inferior glands in 11 cases (*Table II*).

Two patients required a second operation because their serum-calcium levels, which fell initially following the first operation, rose again above normal levels. In 1 case a further tumour was found embedded in the lower pole of the thyroid gland following thyroidectomy. This was thought to be a second tumour, although the possibility of it being an extension of the original tumour could not be ruled out. In the second case a tumour was found situated at the lower pole of the thyroid gland at the initial operation and confirmed on frozen section to be parathyroid tissue. The second exploration revealed another tumour lying behind the manubrium sterni. In both cases the serum calcium returned to normal levels following the second operation.

Total	15	2	6	2	5

METHODS AND DIAGNOSIS

Serum Calcium.—All the patients underwent a full blood and urine examination pre- and postoperatively. The diagnosis of primary hyperparathyroidism was made essentially on the classic biochemical triad of hypercalcaemia, hypophosphataemia, and hypercalciuria. The biochemistry was carried out in the Metabolic Unit Laboratory

(*Table III*). Two patients (Nos. 9 and 11; *Table III*) exhibited fluctuations in the serum-calcium levels which were between raised and normal on random blood-samples taken during the preoperative period. The diagnosis of primary hyperparathyroidism was confirmed by failure of parathyroid suppression with both calcium infusion and steroids.

Table III.—Serum Calcium and Phosphate Levels in Patients with Primary Hyperparathyroidism

Case No.	Serum Calcium (mg. per cent)		Serum Phosphate (mg. per cent)	
	Pre-operative	Post-operative	Pre-operative	Post-operative
1 H. B.	14·4	9·2	2·4	2·5
2. L. D.	14·0	9·4	2·5	3·2
3. E. E.	14·0	10·0	2·5	2·6
4. J. H.	15·2	6–10·2	1·9	3·0

12. E. L.	11·0	10·5	1·9	2·7
13. A. S.	14·1	10·2	1·8	2·2
14 W D.	12·0	8·8	2·3	3·5
15. R. H.	13·1	8·1	2·3	3·1

Bone Disease.—Skeletal radiographic surveys and bone biopsies were carried out to establish the presence or absence of bone changes.

Renal Function.—Renal function was estimated by assessment of the blood-urea, plasma creatinine, and creatinine clearance, and by intravenous pyelographic studies.

Hypertension.—The presence and degree of hypertension were studied. Blood-pressure readings were taken in the recumbent position after a period of rest. The 'normal' blood-pressure was taken as 140/90 mm. Hg. The diastolic pressure, being a measure of arteriolar pressure, was considered more important than the systolic pressure in assessing the degree of hypertension. All the patients with hypertension were screened to exclude other causes.

RESULTS

The patients have been followed up for a period of 8 months to 5 years after surgery.

Serum Calcium.—In all cases the serum-calcium levels fell to normal immediately after parathyroid adenectomy. However, in 2 cases (Nos. 4 and 11; *Table III*) the calcium levels were found to have risen above normal about a year after the first operation. The calcium levels remained raised until a second exploration. In 1 case (No. 4) a further tumour was found embedded in the lower pole of the thyroid gland. In the other case (No. 11) a second tumour was found behind the manubrium sterni. The calcium levels returned to normal after the second operation.

In all except 2 cases (Nos. 7 and 13; *Table III*) the serum-phosphate level rose above 2·5 mg. per cent. Prior to operation only 2 cases (Nos. 2 and 3) had persistent serum-phosphate levels of 2·5 mg. per cent. All the other cases had serum-phosphate levels below this figure.

Bone Disease.—Five of the cases (Nos. 1, 3, 4, 11, and 15; *Table IV*) showed the presence of osteitis fibrosa on skeletal survey and these results were confirmed by bone biopsy. Patients with bone changes all had renal function impairment.

Renal Function.—None of the patients had a urinary infection either pre- or postoperatively. This was confirmed on several midstream specimens of urine taken at intervals.

Table IV.—Findings of Intravenous Pyelography and Bone Biopsy in Patients with Primary Hyperparathyroidism

Blood-urea.—The blood-urea was elevated in 4 cases preoperatively (Nos. 4, 7, 11, and 15; *Table V*). In 1 of these cases (No. 7) the blood-urea returned to normal levels 3 months after parathyroid adenectomy and it has subsequently remained normal. In 1 other case (No. 1), although the blood-urea was normal preoperatively, it became elevated 3 months after operation and has remained elevated since.

Plasma Creatinine.—Four patients (Nos. 1, 4, 11, and 13; *Table V*) had a raised plasma-creatinine level preoperatively. Two of these patients (Nos. 4 and 11) also had a raised blood-urea. Another case (No. 1) developed a raised blood-urea 3 months postoperatively. The fourth case (No. 13) with a raised plasma-creatinine level had no other evidence of renal functional impairment. A further patient (No. 14) developed a raised plasma-creatinine level 6 months after parathyroid surgery.

Creatinine Clearance.—In 14 cases the creatinine clearance was determined. Four of these (Nos. 1, 4, 11, and 15; *Table V*) were low preoperatively and these results were mirrored in the preoperative blood-urea and plasma-creatinine results. A further 4 cases (Nos. 3, 7, 9 and 14) showed low creatinine-clearance levels 6 months after operation. One of these (No. 9), however, was a laboratory error. The other 3 cases have shown a persistently low creatinine clearance. They also had other signs of renal impairment, namely, a raised blood-urea and plasma creatinine or poor function on radiographic examination.

Intravenous Pyelographic Studies.—Three patients (Nos. 6, 10, and 15; *Table IV*) presented with ureteric colic and required removal of their urinary-tract stones as they were causing obstruction. One was impacted in the pelvi-ureteric junction and required a pyelolithotomy (No. 6; *Table V*). The other 2 patients had stones removed from the lower end of the ureter by Dormia extraction (Nos. 10 and 13). Their renal function, as assessed by intravenous pyelographic studies, blood-urea, plasma creatinine, and creatinine clearance, was satisfactory both before and after removal of the stones (*Table III*).

15. R. H.	58	64	1·4	1·2	45	51

Two cases (Nos. 3 and 11; *Table IV*) showed poor function on radiographic examination. One of these (No. 3) had a non-functioning left kidney. As this patient is also hypertensive she is at present under consideration for a nephrectomy. The remaining 13 patients showed adequate function as assessed by radiology.

Five cases (Nos. 1, 6, 8, 13, and 14) had unilateral renal calculi and 3 cases (Nos. 7, 10, and 11) had bilateral stones. None of these was causing obstruction as they were small and situated in the renal parenchyma. Three patients (Nos. 4, 10, and 15) had bilateral nephrocalcinosis. One of these patients (No. 10) also had bilateral renal calculi. Two patients (Nos. 5 and 12) had passed calculi following attacks of ureteric colic previously but their radiographs on the present occasion were clear.

It is evident from a comparison of the renal function studies and the radiographic findings that the disturbance in renal function was not associated with urinary-tract obstruction in this series.

After parathyroid surgery subsequent intravenous pyelography did not show any change in the size of the renal calculi, although 2 patients did pass several stones spontaneously. None of the patients showed formation of new renal calculi or growth of those present preoperatively after operation.

Blood-pressure.—Nine of the patients were normotensive preoperatively whilst 6 were hypertensive (*Table VI*). Three of the latter cases (Nos. 4, 7, and 9) had severe hypertension (diastolic pressure over 120 mm. Hg) and 3 (Nos. 1, 14, and 15) had moderate hypertension. Two patients (Nos. 3 and 11) who were previously normotensive developed moderate hypertension 6 months after operation. One patient (No. 15) who was hypertensive preoperatively became normotensive 3 months after operation. The hypertensive patients are moderately well controlled on drug therapy.

Relationship between Impaired Renal Function and Hypertension.—Six of the 15 patients (Nos. 1, 3, 4, 7, 11, and 15; *Table V*) had impairment of renal function preoperatively. Four of these (Nos. 1, 4, 7, and 15) also had hypertension. Six months postoperatively the other 2 patients with renal insufficiency (Nos. 3 and 11) also became hypertensive. Renal function did not improve after parathyroid adenectomy. In 3 cases (Nos. 1, 7, and 11; *Table I*) renal function continued to deteriorate, as shown by a rising blood-urea and creatinine or a lowering of the creatinine clearance. In 1 case (No. 14) impairment of renal function became apparent 6 months after operation. This patient was hypertensive preoperatively. The severity of renal functional impairment did not bear any relationship to the degree of hypertension.

DISCUSSION

Renal damage in hyperparathyroidism is probably caused by hypercalciuria and hypercalcaemia (Epstein, 1968), although a direct action of parathormone on the renal tubule cannot be excluded (Edvall, 1958). The incidence of hypertension is increased, as compared with a similar series for the same age and sex in the rest of the population, and is thought to be secondary to the renal lesion (Hellstrom, Birke, and Edvall, 1958).

Hellstrom and others (1958), in a series of 105 cases, showed that almost all their patients had renal insufficiency. They found that renal damage and hypertension persisted and in some cases progressed after parathyroid adenectomy. Hellstrom and Ivemark (1962) confirmed these results and showed that a raised preoperative blood-urea carried a poor prognosis. Out of 20 cases with a raised preoperative blood-urea, 16 had died prior to the follow-up examination, 12 from uraemia. Unfortunately, the authors do not state the time interval between operation and death. Mathiesen, Murj, and Sanders (1967) showed that one-third of their patients developed renal insufficiency and hypertension in spite of the fact that no evidence of renal damage had been found preoperatively. Pyrah, Hodgkinson, and Anderson (1966) found that 28 per cent of their patients developed hypertension in the postoperative period. Frank, Nathan, Lazebrik, and De Vrigs (1968) described an improvement after parathyroid surgery in over 75 per cent of their patients who had had renal insufficiency preoperatively. Three patients showed an improvement in both urea and creatinine clearance postoperatively. Despite the improvement in renal function all of their cases showed persistence of hypertension. Ohlsson (1970) found that renal function was preserved following parathyroid adenectomy. However, hypertension was still a problem, being present in 40 per cent of his patients.

Our results indicate that satisfactory renal function may be maintained in those cases with normal preoperative renal function tests. However, renal damage, once established, persists and may even progress after parathyroid adenectomy. Urinary infection was not present in any of our cases. Several midstream urine specimens were cultured from every patient, both pre- and postoperatively. None of them grew organisms at any time. This would suggest that infection is not a factor in producing the renal damage of primary hyperparathyroidism. In only 1 case did hypertension improve after surgery. Two other patients developed hypertension postoperatively and both of these had renal damage, suggesting that the hypertension may have been secondary to the renal lesion. Urinary-tract obstruction was not a causative factor in producing renal damage.

Acknowledgements.—We have pleasure in acknowledging the help of Dr. W. van't Hoff, who is in charge of the Metabolic Unit, North Staffordshire Royal Infirmary, and Dr. G. M. Aber, who gave advice on the renal function studies. We also thank our colleagues who referred the cases.

SPLENOSIS

A CASE REPORT AND SOME CONSIDERATIONS ON THE FUNCTION OF SPLENOTIC TISSUE

By W. J. MACKIE* and D. F. MILLER
DIVISION OF GENERAL SURGERY, VICTORIA INFIRMARY, GLASGOW

SUMMARY

A further case of intra-abdominal autotransplantation of splenic tissue is presented. The main importance of the condition probably lies in its recognition at laparotomy.

In the present case although the autotransplanted tissue was histologically similar to normal splenic tissue no normal splenic function could be ascribed to it.

The term 'splenosis' refers to the condition of autotransplantation of multiple small splenic nodules following traumatic rupture of the spleen. The condition is an uncommon one, only 51 cases being recorded in the world literature, including 3 in the British literature. A further case is described, together with some investigation of the condition.

CASE REPORT

A. C., born on 4 April, 1950. This boy of Italian extraction was admitted to hospital on 18 Aug., 1967, following a road-traffic accident. He had collided with the rear of a stationary vehicle while cycling and on admission was noted to be suffering from a laceration of the left thigh and bruising of the left upper abdomen and lower chest wall. He was observed for some 12 hours but at the end of this period laparotomy was thought advisable. At operation a stellate tear in the diaphragmatic surface of the spleen was noted and there was blood in the peritoneal cavity. Splenectomy was performed and the patient's recovery was rapid and uneventful.

On 10 Oct., 1969, the patient was readmitted complaining of severe colicky lower abdominal pain and vomiting of 24 hours' duration. He had just returned from 6 weeks' holiday in Europe. His abdominal pain was initially central but later became more marked in the right iliac fossa.

On examination he was mildly pyrexial (temperature 36·5° C.) and slightly dehydrated, with a dry, coated tongue and noticeable foetor. Examination of the abdomen revealed generalized lower abdominal guarding and rigidity, more pronounced on the right side.

---

* Present address: Surgical Registrar, Department of Surgery, Glasgow Royal Infirmary, 84 Castle Street, Glasgow, C.4.

Bowel-sounds were hyperactive but not obstructive in character. The white-blood count was 6400 per c.mm. It was felt that the patient was suffering from acute appendicitis and the abdomen was explored through a right grid-iron incision.

Operative Findings and Procedure.—On visualizing the peritoneal cavity free fluid was immediately noted, but this was not purulent, and the appendix was macroscopically normal. Further exploration revealed a small-bowel obstruction due to a loop of terminal ileum about 60 cm. from the ileocaecal valve having become adherent to the peritoneal aspect of the previous left paramedian scar.

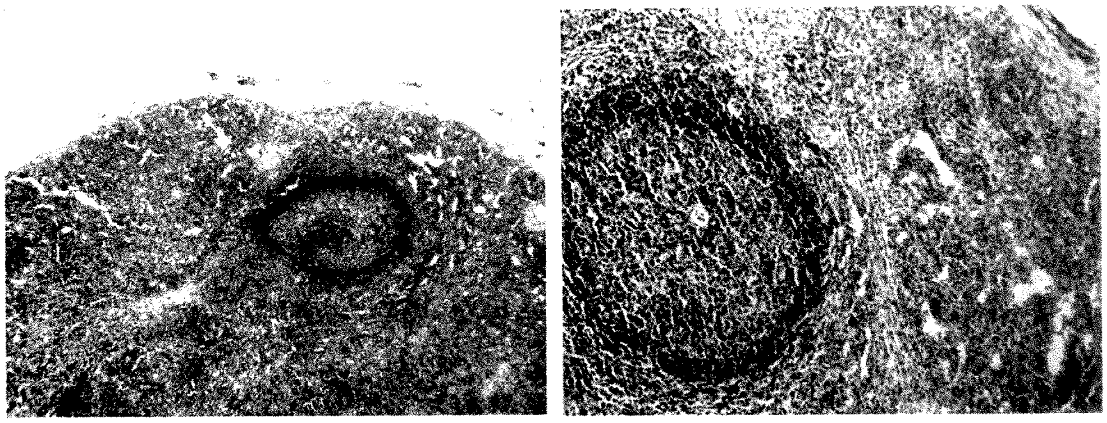

Fig. 1.—Photomicrographs of the splenotic tissue. A, Low-power view, showing splenotic tissue with a well-defined capsule, a lymphoid follicle, and pulp containing many small sinusoids. (× 30.) B, Detail, showing a lymphoid follicle on the left with a central arteriole, pulp and sinusoids on the right, and a boundary capsule on the top right. (× 84.)

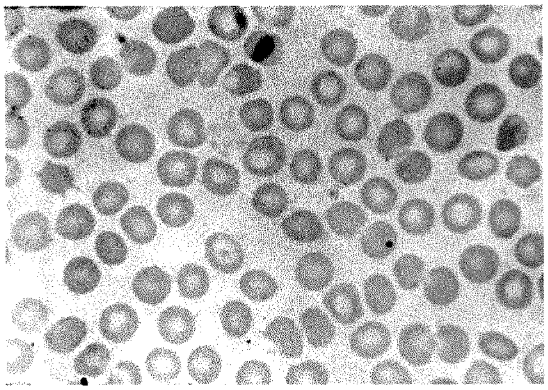

Fig. 2.—Photomicrograph of the peripheral blood-film of 2 March, 1970. Leishman's stain. (× 332.)

It was also noted that the small intestine, small intestinal mesentery, greater omentum, parietal peritoneum, and caecum were studded with small nodules (2 mm.–1 cm.) of purplish-violet tissue. This tissue was not unlike splenic tissue in appearance and one of the larger nodules was removed from the serosal surface of the caecum and sent for histological examination. There were about 20–30 nodules of this tissue in the peritoneal cavity.

The obstructed loop of ileum was freed from its attachment to the splenectomy scar, no nodules of splenic-like tissue being noted at this point. The abdomen was closed in a routine manner. Postoperative recovery was uneventful, apart from a brief period of paralytic ileus during which time intravenous fluids were administered. The wound healed normally and the patient was discharged on the tenth postoperative day.

Histology.—The specimen submitted for examination was a small nodule of very vascular tissue, measuring 10 × 5 × 4 mm. It had the structure of a normal spleen with sinusoids filled with blood and well-defined lymphoid corpuscles which, however, did not contain ellipsoids. There was a capsule which was thick and intact. Photomicrographs of the splenotic tissue are shown in *Fig. 1*.

Investigations.—Since the peripheral blood-film in splenectomized individuals contains an abnormally high number of red blood-cells containing Howell-Jolly bodies and an increased number of target cells it was decided to investigate the peripheral blood-film of this patient in the late postoperative period. A venepuncture was performed on 2 March, 1970. The usual haematological estimations were carried out, and several blood-films were made with special stains. The full haematological picture is given in *Table I*, and a photomicrograph of the blood-film illustrating Howell-Jolly bodies and target cells is shown in *Fig. 2*.

Table I.—Results of the Haematological Investigations

Haemoglobin	14·4 g.
Packed-cell volume	44 per cent
Mean corpuscular haemoglobin	33 per cent
Red-blood count	$5{\cdot}14 \times 10^6$ c.mm.
Mean corpuscular volume	87 c.μ
Reticulocytes	1 per cent
Platelets	320,000 c.mm.
Differential white-blood count:—	
Neutrophils	43 per cent
Eosinophils	3 per cent
Basophils	1 per cent
Lymphocytes	46 per cent
Monocytes	7 per cent
Blood-film:—	
A moderate number of target cells were present and some red-blood cells contained single Howell-Jolly bodies (approximately 1 per cent of red-blood cells). Siderocytes were present, as were occasional giant platelets. The picture was compatible with hyposplenism.	

DISCUSSION

The patient presented here has been shown to have the condition 'splenosis', that is, multiple intra-abdominal autotransplants of splenic tissue following traumatic rupture of the spleen. The condition was originally described by Albrecht in 1896, and the term 'splenosis' was coined by Buchbinder and

Lipkoff in 1939. The condition is a rare one, only 3 cases appearing in the British literature, in spite of the fact that traumatic rupture of the spleen is a not uncommon result of severe trauma. Nodules of splenotic tissue have been reported in sites other than the abdominal cavity, notably the thoracic cavity, and in the layers of the abdominal wall in relation to an abdominal wound. That the condition is almost certainly a true autotransplantation and not a metaplasia has been demonstrated by the experimental reproduction of the condition in animals.

The surgical importance of the condition lies mainly in its recognition and differentiation from haemangiomata or endometriomata. Nodules of normal autotransplanted splenic tissue (splenotic tissue) do not normally give rise to any pathological effects, except perhaps as in the cases of Cotlar and Cerise (1959) and Zachary and Emery (1959). In the former, splenotic tissue adhering to the serosal surface of the small bowel gave rise to intestinal colic which was relieved by resecting the affected bowel. In the latter case, which was similar to the one described here, the terminal ileum was adherent to the peritoneal wall and was obstructed and, at this point, splenotic tissue was present. Postoperative adhesions with associated splenotic nodules were also the cause of intestinal obstruction in the cases of Davis, Alexander, and De Young (1963) and Prasad and Beck (1968).

Where autotransplantation has occurred in a patient with a previously abnormal spleen pathological effects have been described owing to continuing splenic function (Gill, 1944; Stobie, 1947). This evidence that splenotic tissue is capable of function is supported by Rogers (1963). Zachary and Emery (1959) quote a personal communication suggesting that the resultant mass of splenotic tissue collectively assumes the size of a normal spleen. With these thoughts in mind, we investigated the present case for evidence of functioning splenotic tissue.

The histology of the transplanted tissue was found to be similar to, if not identical with, normal splenic tissue. This was also the finding in most other reported cases of splenosis, except in the cases of Shaw and Shafi (1937), Bunch and Spivey (1946), and Storsteen and ReMine (1953).

In contrast, examination of the peripheral blood-film demonstrated that it was consistent with that of a splenectomized or hyposplenic person. This raises the question of how much splenotic tissue is necessary to revert the splenectomized person's blood-film to normal, if it is indeed capable of function at all. We can find no definite answer to this. As further investigation in our case would have entailed the use of radioactive material it was not thought to be justifiable. We must, therefore, assume from our findings that either the splenotic tissue had no function or insufficient autotransplanted tissue was present to change the peripheral blood-film.

Acknowledgements.—We are grateful to Mr. H. C. Reid for permission to report this case, to Dr. R. W. Payne for advice and interpretation of the blood-films, and to Dr. J. E. Craik for the histological reports.

ISOTOPE VENOGRAPHY

By J. H. HIGHMAN, E. O'SULLIVAN, and E. THOMAS

RADIOLOGICAL AND CLINICAL PHYSICS DEPARTMENTS, ST. MARY'S HOSPITAL, LONDON

SUMMARY

An isotope method of venography using ^{99m}Tc as pertechnetate (or MAA technetium) and a gamma camera is described. Initial results are encouraging. Good visualization of the major venous channels in the lower limbs and pelvis can easily be obtained. Venous occlusion and the formation of collaterals, particularly in the pelvis, are well shown. It appears to be possible to infer the presence of deep venous occlusion in the calf when delayed filling is seen through normal popliteal and femoral veins. The procedure is entirely painless and can easily be performed in the out-patients' department. It avoids the pain consequent on injection of the usual radiographic contrast media and the phlebitis which may also follow their injection. It does not afford the same degree of anatomical detail but this is of minor importance if operative intervention is unlikely.

The combination of the Anger gamma camera and modern artificially produced short-lived isotopes has meant that pictures of gamma activity can be obtained in short periods of time and thus even rapidly changing distributions of isotopes can be recorded. The gamma camera has been used to perform investigations analogous to those carried out by conventional radiography such as angiocardiography (Matin and Kriss, 1970) and aortography (Rosenthal, 1966a, b; Freeman and Mindelzun, 1968; Tori, Marabini, and Fattovitch, 1970). Venography has also been described by Rosenthal (1966c). With growing interest in venous occlusion and pulmonary infarction it was decided to investigate the potential value of isotope venography by using the gamma camera, adapting the method specifically for assessment of the veins of the lower limbs and pelvis. This paper presents the details of the method as it is currently used and also gives some preliminary results.

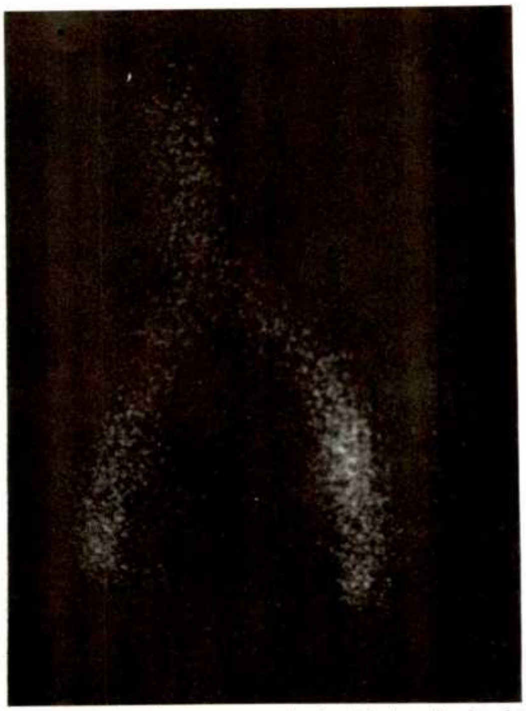

FIG. 1.—Film taken 10–20 seconds after injection, showing the external and common iliac veins uniting to form the inferior vena cava.

MATERIALS AND METHODS

The patient lies supine on the examination table under the gamma camera. A small butterfly cannula is inserted into a vein on the dorsum of each foot and patency is maintained by slow intermittent injections of normal saline. The patient is then carefully positioned under the camera head so that the region of the upper femoral veins, the iliac veins, and their union into the inferior vena cava is shown. The position is checked by taking a single polaroid picture with isotope markers placed on the symphysis pubis and the umbilicus. The camera head is lowered so that it is as close to the patient as possible; slight angulation towards the patient's head is helpful. Isotope is injected bilaterally, a bolus effect being obtained by inflating cuffs above each ankle prior to injection and following the isotope with a small 'chaser' injection of 2–3 ml. saline. Each injection contains 1 m.c. of ^{99m}Tc pertechnetate in about 0·3 ml. of saline. The camera timer should be started simultaneously with the injection to check the first

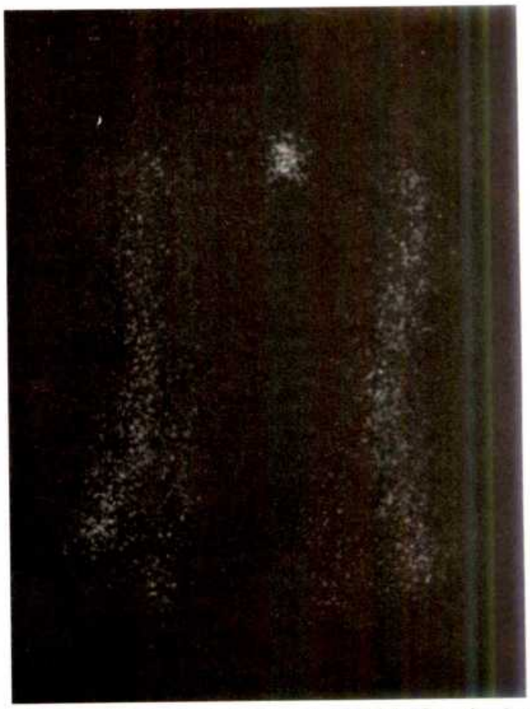

FIG. 2.—Film taken 50–60 seconds after injection, showing the common femoral veins and the lower part of the external iliac veins. The saphenous veins can be seen on each side uniting with the femoral veins. The central marker is above the symphysis.

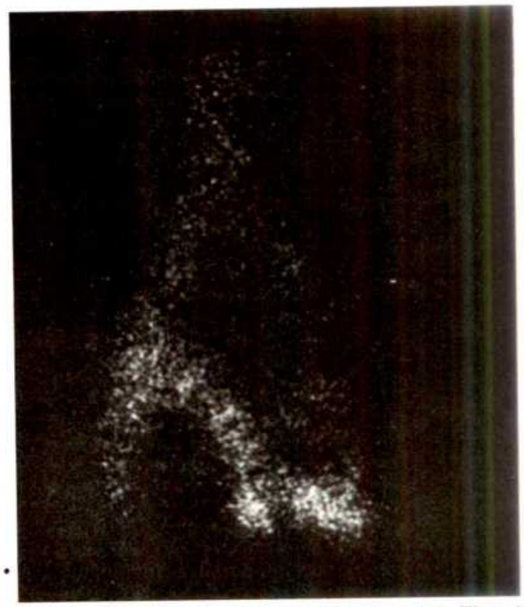

FIG. 3.—Film taken 25–35 seconds after injection. There is occlusion of the left common iliac vein. A large collateral system is seen transferring isotope from the left to the right side.

appearance of isotope under the crystal, and 10-second polaroid exposures are taken. Each series consists of 4–5 films. In some cases of venous occlusion films taken at longer intervals (up to 3 minutes) may be necessary to show lingering isotope. A second series can be taken of a different region if indicated, e.g., to show the femoral and popliteal veins when the positioning markers may be placed on the symphysis and between the knees. In order to overcome background activity from the first injections 2 m.c. should now be injected on each side. A third series is not practicable as the level of background activity greatly interferes with visualization.

Bilateral simultaneous injections seem to be essential as interpretation depends in part on the comparative rate at which isotope appears and fades from each side.

Equally satisfactory results have been obtained using ^{99m}Tc MAA when the injection procedure can produce both venograms and lung scans. This is particularly convenient when looking for venous occlusion and associated pulmonary infarction.

RESULTS

The normal appearances of isotope venograms are illustrated in *Figs.* 1 and 2. *Fig.* 1, which was taken 10–20 seconds after injection and centred on the pelvis, shows the wishbone configuration of the external and common iliac veins uniting to form the inferior vena cava. The arrival and fading of isotope were simultaneous on both sides and isotope density on the two sides was similar. *Fig.* 2, which was taken 50–60 seconds after injection and centred over the thighs (marker on symphysis pubis), shows the femoral veins and the lower part of the external iliac veins. The saphenous vein on each side can be seen medially and uniting with each femoral vein. Again, appearance, clearing, and density are equal on both sides although considerable individual variation in flow is shown in these 2 cases.

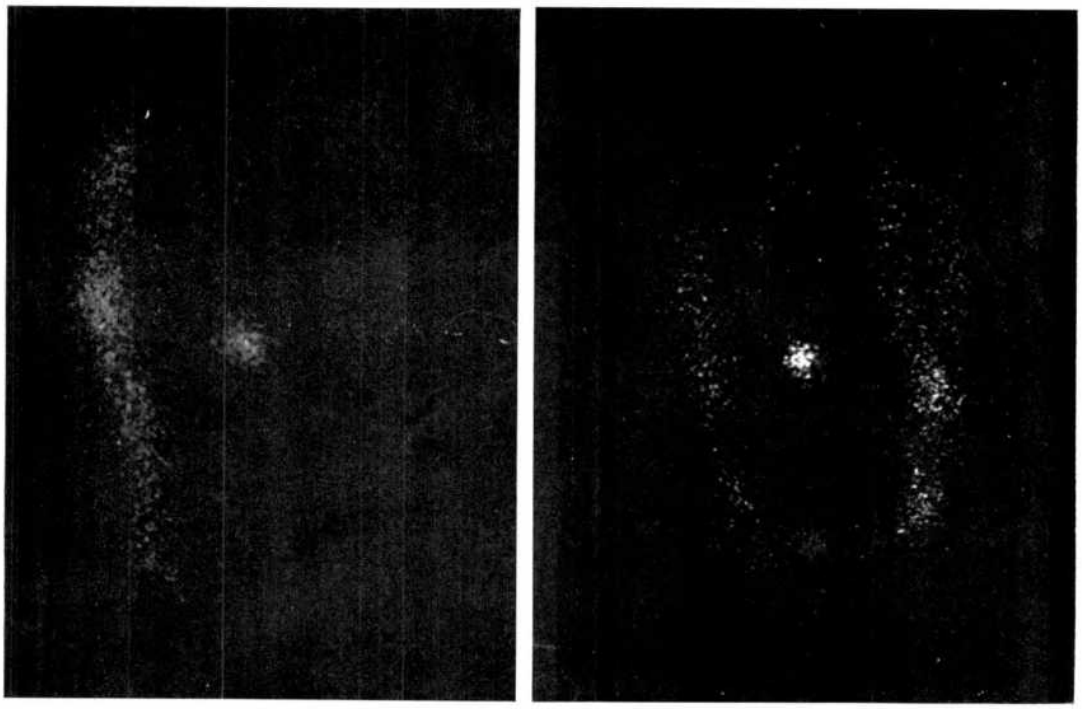

FIG. 4.—A, Film taken 5–15 seconds after injection, showing normal appearances on the right side. B, Film taken 25–35 seconds after injection. The isotope on the right side is fading, and isotope has appeared on the left side, being delayed relative to the right side. Deep-vein thrombosis was inferred and confirmed by routine venography.

Two pathological situations are illustrated in *Figs.* 3 and 4. *Fig.* 3 shows a left iliac vein occlusion with formation of a collateral from left to right. *Fig.* 4 A shows normal venous drainage through the right femoral vein taken 5–15 seconds after injection, but a later film (*Fig.* 4 B) taken at 25–35 seconds shows residual activity on this side and the appearance of a faint, delayed isotope pattern on the left. The combination of unilateral delayed flow through normal venous channels (the popliteal vein also appeared normal but is not illustrated) implied deep venous occlusion in the calf which was confirmed by conventional venography.

IN BRONCHITIS early optimism confirmed by further clinical experience

“On the basis of our earlier experience,[1] we said of trimethoprim that ‘we believe it to represent a major discovery and to have far-reaching therapeutic possibilities.’ Not only have we had no subsequent reason to alter this belief, but in our view some very promising possibilities have yet to be explored.”[2]

More effective than ampicillin or tetracycline

In the reduction obtained in sputum volume and purulence SEPTRIN* has been shown to be superior to either ampicillin or tetracycline.[3,4]

Highly active against both primary and secondary invaders

“. . . not only are the two primary pathogens *Strep pneumoniae* and *H influenzae* sensitive, but so are secondary invaders such as klebsiella which often replace them after antibiotic treatment.”[2]

“It is seldom at the completion of a clinical trial that authors are inclined to classify an antimicrobial . . . , but in this case, on our results, we feel that the combination of trimethoprim plus sulphamethoxazole can only be considered excellent on the criteria originally specified, namely the elimination of the infecting microorganism.”[5]

STERCORAL PERFORATION OF THE SIGMOID COLON

By D. C. CARTER and J. R. KIRKPATRICK

DEPARTMENT OF CLINICAL SURGERY, EDINBURGH UNIVERSITY

SUMMARY

Stercoral perforation of the sigmoid colon is probably more common than is generally appreciated. The condition should be considered in patients who present with peritonitis, localizing signs in the left iliac fossa, and a history of chronic constipation. Operation after a period of resuscitation offers the only hope of survival and resection of the affected sigmoid colon with exteriorization appears to be indicated.

Two additional examples of this condition are described and the salient features are reviewed.

THE presence of faecaliths in the rectum is a relatively common finding in surgical practice, particularly in patients with organic disease, the elderly, the debilitated, and the bedridden. Although often associated with troublesome constipation and spurious diarrhoea, and on occasions with rectal bleeding, the condition is generally amenable to prompt diagnosis and treatment. While faecaliths are observed less frequently in the sigmoid colon, it is now recognized that their presence in this situation may carry a higher risk of serious morbidity and even mortality.

Berry (1894) was probably the first to describe a case of stercoral perforation of the sigmoid colon, his patient being an elderly male who had suffered from chronic constipation for many years. Since that time similar cases have been reported sporadically, but Liedberg (1969) could collect only 17 cases from the literature. In view of the apparent rarity of the condition 2 further cases are reported and the salient features reviewed.

CASE REPORTS

Case 1.—A 67-year-old female was admitted as a surgical emergency with a 24-hour history of generalized abdominal colic, progressive pain in the left iliac fossa, and vomiting.

The patient gave a history of similar attacks of colic and vomiting extending over 20 years but on only one occasion, 5 years previously, had the pain approached its present magnitude. On that occasion a subsequent outpatient barium-enema examination had been performed in her local hospital and she was advised that her symptoms were due to faecal overloading of the colon and that constipation should be avoided. After colonic lavage her own doctor considered that the colon had been evacuated satisfactorily but volunteered the information that 'something could possibly have been left behind'. Despite occasional mild attacks of colic and vomiting the patient had remained reasonably well up to the time of her present admission. Regular bowel movements had been achieved by a wide variety of laxatives, the daily administration of cascara being her ultimate choice. On the day of admission the bowels had apparently opened normally, with the passage of a formed stool.

On examination the patient was obese, flushed, but not obviously shocked. (Temperature, 37·6° C.; pulse 100 per minute, sinus rhythm; blood-pressure 150/80 mm. Hg; white blood-count 16,800 cells per c.mm.; blood-urea 43 mg. per cent; serum electrolytes normal.) The abdomen was generally tender with maximal tenderness and guarding localized to the left iliac fossa. Bowel-sounds were present but infrequent. Rectal examination revealed no abnormality except a positive faecal occult-blood test. A chest radiograph was normal. Abdominal plain films showed faeces in the large bowel and suggested a rounded opacity in the left iliac fossa.

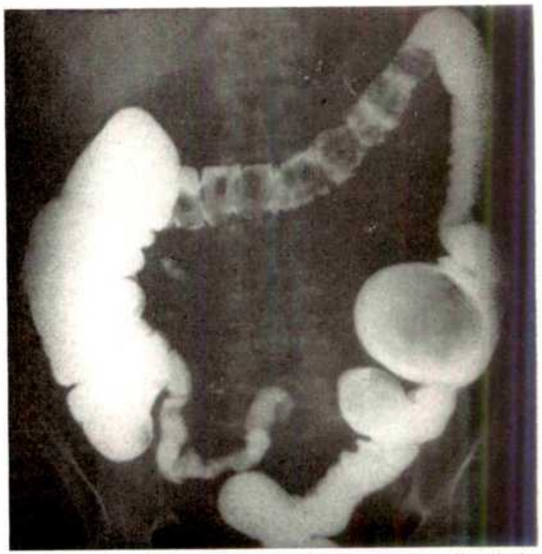

FIG. 1.—*Case* 1. Barium-enema film, showing two diverticula in the lower descending and sigmoid colon; both appear to contain a rounded faecalith.

Laparotomy was undertaken shortly after admission on the clinical diagnosis of perforated diverticular disease of the sigmoid colon with paracolic abscess formation. At operation a paracolic collection of pus was encountered around a grossly distended sigmoid and descending colon. The cause of these findings was revealed as a necrotic area, 2 cm. in diameter, on the antimesenteric aspect of the midsigmoid colon overlying a solid immovable mass within the bowel. In view of the uncertain nature of the mass and the doubtful viability of the bowel around the necrotic area, a 16-cm. length of sigmoid colon was resected with exteriorization of both the proximal and distal colon. A large Portex drain was led down to the left iliac fossa through a separate stab incision and the patient was commenced on kanamycin (0·5 g. b.d.).

On opening the resected specimen the lumen was found to be almost completely occluded by a faecalith, measuring 10 × 8 cm., which had caused pressure necrosis of the overlying bowel wall. Microscopy revealed extensive mucosal ulceration around this necrotic area with marked inflammatory changes throughout the bowel wall. Distal to the main lesion a solitary diverticulum, measuring

3 × 2 cm., protruded from the bowel wall. The mucosa within the diverticulum showed superficial ulceration with focal replacement of the submucosa and muscle layers by granulation tissue. Marked melanosis coli was apparent throughout the resected specimen.

The patient's postoperative course was uneventful except for a wound infection, and colonic continuity was restored 4 weeks after the initial laparotomy. Her subsequent recovery was satisfactory and she was discharged home 8 days later with normal bowel function and has maintained excellent progress since. The original outpatient barium-enema films have since become available and reveal the presence of two faecaliths in the sigmoid region at that time (*Fig.* 1).

Case 2.—A 61-year-old female was admitted as a surgical emergency complaining of the gradual onset of colicky lower abdominal pain with vomiting.

The patient's past history included chronic osteomyelitis of the left femur since childhood which still gave rise to pain and a discharging sinus. She had suffered from sarcoidosis for 5 years for which she was receiving long-term corticosteroid therapy (prednisone 5 mg. b.d.). She occasionally required to take laxatives for constipation and the bowels had last opened with the painful passage of a hard stool 2 days prior to admission. She had lost 12 kg. in weight over the preceding 4 months and she had been anorexic with occasional vomiting—symptoms that she attributed to her osteomyelitis.

On examination she appeared ill, was noticeably dehydrated, and vomited intermittently. (Temperature 35·6° C.; pulse 120 per minute, sinus rhythm; blood-pressure 120/40 mm. Hg; haemoglobin 10·6 g. per cent; white-blood count 21,800 per c.mm.; blood-urea 41 mg. per cent; electrolytes normal.) Abdominal examination revealed lower abdominal tenderness, most marked on the left side, with guarding. Bowel-sounds were infrequent. Rectal examination revealed a mass of hard faeces and a positive faecal occult-blood test. A chest radiograph was consistent with pulmonary sarcoidosis while abdominal plain films showed the presence of free gas in the peritoneal cavity and faecal masses in the descending colon.

After an initial period of resuscitation, laparotomy was undertaken on the diagnosis of perforation of a hollow viscus (probably colonic diverticular disease) with peritonitis. Exploration revealed stercoral perforation of the sigmoid colon with faecal soiling of the peritoneum and gross paracolic infection. A large faecalith, 8 × 7 cm. in diameter, was partially protruding through a necrotic area of the antimesenteric border of the midsigmoid region. Resection of a 16-cm. segment of bowel was therefore performed with exteriorization of both the proximal and distal colon. A large Portex drain was led down to the left iliac fossa through a separate stab incision and the patient was commenced on parenteral kanamycin (0·5 g. b.d.) and ampicillin (500 mg. q.d.s.). Intravenous fluid requirements were monitored by regular assessment of the central venous pressure and her steroid régime was increased with parenteral hydrocortisone.

Pathological examination of the colon revealed a perforation, 4 cm. in diameter, overlying the faecalith. The proximal colon was thin-walled with flattening of the mucosa and was packed with hard faeces. Microscopy showed extensive ulceration of the mucosa with inflammation in all the layers and areas of necrosis, most marked around the perforation site. There was no evidence of neoplasia, diverticulum formation, or primary vascular disorders.

The patient made a satisfactory recovery with early function of the proximal colostomy although she remained pyrexial for 7 days with persistent elevation of the white-cell count. At the time of discharge to convalescence (13 days after laparotomy) the white-cell count was still 11,600 cells per c.mm., a finding interpreted as a feature of her discharging osteomyelitis sinus.

The patient was readmitted after a month's convalescence for the restoration of bowel continuity and she had no abdominal complaints at that time. At operation an abscess was encountered deep to the distal colostomy, but anastomosis was performed satisfactorily and her postoperative course was uneventful with rapid return to normal bowel function. She was discharged to convalescence 10 days after reoperation and has maintained satisfactory progress. It is anticipated that amputation may be required to deal with her residual orthopaedic problem.

DISCUSSION

It is difficult to determine the true incidence of stercoral perforation of the sigmoid colon. In a consecutive series of 175 routine autopsies Grinvalsky and Bowerman (1959) found 8 cases of stercoral ulceration of the large bowel, 4 of which were complicated by stercoral perforation of the sigmoid colon, an incidence of 2·3 per cent. It seems probable that the literature does not reflect accurately the true prevalence of the condition, particularly in the elderly, debilitated, and institutionalized patient.

Abnormal colonic function in the form of chronic constipation would appear to be the predisposing factor in stercoral perforation. However, it must be emphasized that, as in *Case* 1 of our report, faecaliths may persist for long periods in spite of an apparently regular and normal bowel function. It is probable that the larger of the faecaliths observed 5 years earlier on barium-enema films had remained in situ and had ultimately given rise to stercoral ulceration and perforation. In view of the virtually complete obturation of the colon revealed at operation it appears that only by the use of regular laxatives could earlier intestinal obstruction have been avoided. The precarious existence led by this patient is emphasized by her history of intermittent episodes of subacute intestinal obstruction.

In this context it is worth remembering the constipating nature of radiological examinations using barium and some forms of medical therapy. As Brearley (1954) and Berger and Shaw (1961) have pointed out, some of the medication employed in the treatment of duodenal ulceration, notably aluminium hydroxide and mixtures containing bismuth, may promote constipation. In the event of stercoral perforation the clinical diagnosis may readily be confused with that of perforated peptic ulcer in such patients. While these considerations were not apparent in our cases, the association between steroid therapy and perforated diverticular disease has recently been stressed (Canter and Shorb, 1971) and could confuse the preoperative diagnosis in patients on long-term steroid therapy. Diverticular disease has not been reported as a significant factor in stercoral perforation, but the pathologist's report in *Case* 1 raises the possibility that the original faecalith formation may have taken place in a large solitary diverticulum outwith the faecal stream. Whatever the cause of faecalith formation, the work of Grinvalsky and Bowerman (1959) now leaves little doubt that the ultimate perforation results from ischaemic necrosis due to pressure on the overlying colonic wall.

An accurate preoperative diagnosis was not achieved in either of our cases and was probably academic in that laparotomy was strongly indicated from the clinical picture of peritonitis. While the persistence of localizing signs in the left iliac fossa in a patient with a history of chronic constipation should raise the possibility of stercoral perforation, it is probable that the majority of cases will still be regarded as due to complicated diverticular disease or colonic neoplasia. In retrospect the correct diagnosis was readily available in *Case* 1 in view of the history, the clinical findings, and the presence of the faecalith on the abdominal radiograph. In *Case* 2 the responsible faecalith was not apparent radiologically.

There can be little doubt that surgical intervention after adequate resuscitation offers the only prospect of survival after stercoral perforation of the sigmoid colon. In the 19 patients now collected from the literature the 8 unoperated cases died whereas 9 of the 11 cases undergoing operation survived. There is no place for simple suture of the perforation with transverse colostomy as this does not remove the offending faecalith and perpetuates the risk of further complications. Resection of the affected segment of colon with its contained faecalith and exteriorization of both the proximal and distal colon offers the best approach. Subsequent restoration of continuity is unlikely to be difficult and can be undertaken as a planned procedure when conditions are favourable. A case could be argued for enlargement of the perforation to form a loop colostomy in the left iliac fossa with simultaneous removal of the faecalith. In our experience the extent of impaired colonic viability precluded this approach. Similarly, it may occasionally be justifiable to carry out an end-to-end anastomosis at the time of resection, but in this situation a protective transverse colostomy would seem mandatory and the patient will still require a second operation to restore normal function.

Acknowledgement.—The authors wish to thank Mr. I. B. Macleod for permission to publish details of *Case* 2.

OBSERVATIONS ON ACUTE PANCREATITIS

A RETROSPECTIVE CLINICAL STUDY

BY W. J. GILLESPIE
THE ROYAL INFIRMARY, EDINBURGH

SUMMARY

1. Aetiological features were sought in a retrospective review of 93 cases of acute pancreatitis diagnosed and treated in Edinburgh hospitals between 1961 and 1970.

2. The incidence of alcoholism or precipitation by an excess of alcohol was 23 per cent, a figure which accords with reports from other parts of the world but which has no precedent in Great Britain. Possible reasons for this are discussed. There were no other unusual features.

3. The need for a prospective study to reassess our current experience in Great Britain is stressed.

THE wealth of literature on acute pancreatitis which has followed the first description of the disease in 1842 by Classen has been well reviewed in recent years (Richman, 1956; White, 1966). It is generally accepted that the disease is of multifactorial aetiology. Although Joske (1955) pleads to the contrary, most workers have accepted that gall-stone disease is an important aetiological factor. Certainly in a post-mortem study from Edinburgh (Gillespie, 1973) the incidence of gall-stone disease in a population dying of acute pancreatitis was much higher than one would expect in a random population sample, and it seems likely that the conditions are truly related. Trauma and a variety of metabolic disturbances are also apparently involved, and there has been a recent surge of interest in the role of viruses. In most countries of the world, although not, apparently, in Britain, alcoholism and over-indulgence in alcohol appear to play an important role in precipitating the clinical attack.

This paper presents a retrospective case-note search to quantify the incidence of known and presumed aetiological factors in clinical cases occurring in south-east Scotland in the decade 1961–70.

The limitations of retrospective study are well known and were accepted prior to the commencement of the search. As the search proceeded it became evident that only broad trends could be discerned as the quality of case recording and the nature and depth of case investigation varied greatly in different units. Therefore, no attempt was made to gather all the cases presenting in Edinburgh in the decade. This would have been a difficult exercise as certain hospitals had no adequate case-retrieval method during the major part of the decade. The cases reviewed, therefore, are the first 93 records offered by the record officers of the Royal Infirmary of Edinburgh and the Edinburgh Northern Hospital Group. They are broken down by source in *Table I*.

RESULTS

In patients under 60 years of age there is a preponderance of cases in males (male : female ratio, 2 : 1) but this ratio is reversed over the age of 60 (male : female ratio 1 : 3) (*Fig.* 1).

Amongst the men under 60 (*Fig.* 2) 19 out of 35 cases have a history of precipitation by a drinking bout or of alcoholism. In patients over 60 gall-stone disease accounts for around half of the cases while the other half has obscure aetiology. A summary of the aetiological features is given in *Table II*. Details of the patients in whom alcohol seemed to play a part are shown in *Table III.*

1968–70	Royal Infirmary, Edinburgh	General surgical General medical	30 9

DISCUSSION

Taylor (1949), in his Hunterian Lecture, stated that he had never seen a case of alcoholism in his series of patients. Pollock (1959) wrote: 'In not one single patient in the present series was there any association with alcohol excess.' In another Hunterian Lecture on the topic, Trapnell (1966) found 4 alcoholics among 403 patients with pancreatitis in the Bristol area, an incidence of 1 per cent. In contrast with this British experience, there is no doubt that in North America, South Africa, and

Table III.—THE INCIDENCE OF ALCOHOLISM AND ALCOHOLIC EXCESS

CASE NO.	AGE AND SEX	DETAILS
13	44 F.	Known alcoholic of many years' standing
14	20 M.	One of his episodes of the disease followed a drinking bout
51	27 M.	Onset followed heavy drinking bout
91	25 M.	Onset followed heavy drinking bout. Known heavy drinker
85	22 M.	Drinks 24 pints per week
53	29 M.	Alcoholic. Delirium tremens in ward
50	29 M.	Alcoholism confirmed at psychiatric interview
76	28 M.	Onset followed heavy drinking bout
4	36 M.	Onset followed heavy drinking bout
80	31 M.	Publican. Regular drinker
88	39 M.	Alcoholic; family evidence
79	43 M.	Onset followed drinking bout. Known heavy drinker
54	42 M.	Alcoholism confirmed at psychiatric interview
36	48 M.	Onset followed heavy spirit drinking bout
71	48 M.	Onset followed heavy drinking bout
83	59 M.	Onset followed ingestion of 10 whiskies
58	55 M.	Brewer's drayman. Onset followed heavy drinking bout
1	54 M.	Alcoholism confirmed at psychiatric interview
27	56 M.	Onset followed heavy drinking bouts (5–6 pints every night)
77	55 M.	Returns clerk in brewery. Stopped drinking after first attack
84	63 M.	Onset followed heavy drinking bout

Australia the proportion of cases which are associated with alcoholism and alcohol excess is between 20 and 65 per cent. The subject has been well reviewed by Richman (1956) and White (1966).

It has been the impression of many doctors in clinical practice in Edinburgh that alcohol might be incriminated from time to time in the genesis of the acute attack. In the present series 21 of 93 patients were either alcoholics or suffered their acute attack after excess of alcohol. Three of the 5 alcoholics were seen, it is true, in a specialist unit but the other cases presented randomly, mostly to general surgical units. It seems likely that some of those who are recorded simply as suffering an attack after an excess of alcohol may be alcoholics and, indeed, the incidence of alcoholic excess may be underestimated.

The incidence of alcoholism in Great Britain has been estimated by Williams (1965) to be 400 per 100,000. If this is so, we might expect 0·4 case per 100. In this series of 93 cases there are 6 certain alcoholics, an incidence of 6·5 cases per 100.

Two factors may be involved in determining the difference between this series and previous series in Great Britain. They are as follows:—

1. The incidence of alcoholism may have been underestimated in the past. Many alcoholics may have concealed the fact at the time of their attack, just as they are believed to have concealed it from their general practitioners (Bewley, 1970).

2. There may be differences in drinking and dietary habits between south-east Scotland and central and southern England.

There is a need for a prospective survey of the problem in different centres to reassess the importance of alcoholism.

The incidence of gall-stone disease in this series is 32 cases out of 93 (34 per cent), which accords with many other series but is lower than the 61 per cent recorded by Pollock (1959) and the 52 per cent cited by Trapnell (1966) in Great Britain. There were no overt cases of mumps and only 1 case which could be considered postpartum in origin. Seven per cent of Joske's patients (1955) had hyperlipaemia. In this series hyperlipaemia had been sought only on 13 occasions and was not found: there is, therefore, no evidence to offer of its significance in this region.

Acknowledgements.—My thanks are due to the various consultant surgeons and physicians for permission to carry out this search, to the records staff of the Royal Infirmary of Edinburgh and of the Edinburgh Northern Hospitals, and to Mr. T. J. McNair and Mr. J. W. W. Thomson for their help and encouragement.

FUNDOPLICATION FOR HIATUS HERNIA

BY R. H. FRANKLIN, F. I. IWEZE, AND M. S. OWEN-SMITH
ROYAL POSTGRADUATE MEDICAL SCHOOL AND HAMMERSMITH HOSPITAL, LONDON

SUMMARY

Eighty-eight patients who had symptomatic hiatus hernia were treated by fundoplication during 1967–70. Worth-while symptomatic benefit was achieved in 88 per cent of the patients who had reflux only and in 80 per cent of those who had radiologically demonstrable strictures as well as reflux.

Both as a primary and 'salvage' operation fundoplication gave equally good results, relieving 86 per cent of patients of their symptoms.

THE term 'reflux oesophagitis' was used first by Barrett (1950). This concept was a turning point in the understanding of the group of conditions which were known to affect the lower end of the oesophagus.

The commonest association with reflux has been found to be a sliding oesophageal hiatus hernia (Allison, 1951). Accurate reduction of the hernia and the restoration of normal anatomy do not always relieve the symptoms. In some cases the hernia is effectively repaired but reflux still occurs. Other patients may have reflux without a hiatus hernia, and in some the oesophagus is shortened by fibrosis and it is impossible to reduce the lower end into the abdominal cavity. These difficulties may be overcome by the operation of gastric fundoplication which was introduced by Rudolph Nissen in Switzerland in 1956. In this operation the fundus of the stomach is wrapped around the lower end of the oesophagus to form a cuff.

This paper presents the results of 88 symptomatic patients with hiatus hernia treated by fundoplication at the Kingston and Hammersmith Hospitals under the care of one consultant in the years 1967–70.

PATIENTS AND METHODS

All the patients in this series had one or more symptoms judged to be due to reflux oesophagitis, namely: regurgitation, reflux pain or heartburn, dysphagia, and vomiting.

A barium-swallow examination in all the cases confirmed the presence of gastro-oesophageal reflux or a hiatus hernia with or without reflux, spasm, ulceration, or stricture.

Oesophagoscopy and biopsy were not carried out in all the cases, but were not omitted in any case where the diagnosis was in doubt or the benign nature of a stricture or ulcer was uncertain.

Gastric acid secretion studies were carried out in all the cases where there was a suspicion of duodenal or gastric ulceration except in those cases of stricture in which a Ryle's tube could not be introduced.

Selection for Operation.—Operation was performed for one or more of the following reasons:—

1. Severe dysphagia.
2. Failure to control symptoms by adequate medical treatment, consisting of postural control, weight reduction, and the use of drugs such as antacids and antispasmodics.
3. Patients in whom previous operations had failed to control symptoms.
4. Persistent blood-loss.

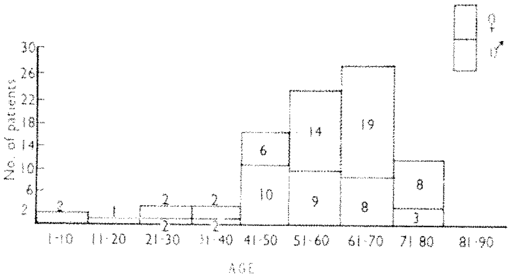

FIG. 1.—Age distribution in 88 patients undergoing fundoplication for hiatus hernia.

Operative Technique.—Fundoplication was performed via an abdominal incision in all except 1 case. In this case perforation of the oesophagus occurred during mobilization of a short oesophagus and to protect the repaired oesophagus fundoplication was carried out through a left thoracotomy. The operative technique employed was as follows.

A size 16F Ryle's tube is passed into the stomach transnasally. Inability to pass this size tube indicates the necessity for resection of the stricture.

The abdomen is explored through a midline upper abdominal incision and any associated pathology noted, particularly of the gall-bladder, stomach, and duodenum.

Access to the hiatus is achieved by mobilization and retraction of the left lobe of the liver and incision of the peritoneum in front of the distal oesophagus and cardia.

The hernia is reduced and the lower end of the oesophagus drawn down into the abdomen. The margins of the right crus of the diaphragm are clearly defined.

The fundus of the stomach is freed by division and ligation of the short gastric vessels and, in most cases, the left gastric vessels also. An effort is made to avoid injury to the spleen, but where the surgeon considers that access would be made easier and safer thereby, the spleen is removed. The hiatus is narrowed with interrupted thread sutures which approximate the margins of the right crus behind the oesophagus. The terminal oesophagus is then surrounded by a cuff of stomach obtained by wrapping the freed fundus around the back of the oesophagus, passing it through the divided lesser omentum, and securing it to the anterior wall of the stomach with interrupted thread sutures. This procedure constitutes the Nissen fundoplication.

Our modification of the Nissen procedure consists of rolling the plicated fundus of the stomach circumferentially up on the oesophagus with interrupted thread sutures in such a way as to produce an 'unspillable' inkwell effect and adding pyloroplasty. Vagotomy is carried out when a duodenal ulcer and/or high gastric acid secretion is present.

Postoperative Assessment.—All the patients have been interviewed at follow-up clinics both at the Hammersmith and Kingston Hospitals. Eighteen patients had fundoplication in 1967, 21 in 1968, 26 in 1969, and 23 in 1970; the results were assessed in December, 1970.

Radiological studies were not performed routinely for the purpose of this review but were carried out where persistence of significant symptoms made it necessary to do so.

The results of surgery were graded as 'symptomless', 'improved', 'failed', and 'died'.

There were 88 patients in this series (46 at Hammersmith Hospital and 42 at Kingston Hospital).

The ages varied from 10 to 80 years, more than half of the patients falling in the fifth to seventh decades (*Fig.* 1). There were 53 females and 35 males. There were 84 sliding herniae and 4 para-oesophageal herniae.

RESULTS

Six out of the 88 patients died in the immediate postoperative period. This gives an operative mortality of 6·8 per cent.

Three of the patients aged 68, 75, and 77 years died of bronchopneumonia on the second, eighth, and fifth postoperative days respectively.

One patient, a hypertensive man aged 65, died on the fourth postoperative day following splenectomy, fundoplication, and cholecystectomy. On the third postoperative day he suddenly developed acute chest pain and pulmonary oedema, thought to be due to a pulmonary embolus or myocardial infarct, and died in spite of attempts at resuscitation.

One patient developed a subphrenic abscess and died of peritonitis and bronchopneumonia following drainage of this abscess. He was aged 71 and died on the tenth postoperative day.

One patient, aged 63, died on the fourth postoperative day of acute dilatation of the stomach, the Ryle's tube having become inadvertently displaced.

Failures.—There were 6 failures in the series, i.e., an incidence of 6·8 per cent.

Case 1.—M. E., a man of 30 years, was admitted with a 7-year history of reflux, retrosternal pain radiating to the jaw, and inability to swallow solids, although he could swallow warm liquids. A barium-meal examination preoperatively was reported as showing a sliding hiatus hernia with two pouches thought to be ulcers at the lower end of the oesophagus. A fundoplication did not relieve his symptoms. Subsequent manometric studies revealed that he also had achalasia of the cardia. Since review in December, 1970, he has become symptom-free.

Case 2.—S. C., a man of 71 years, had total dysphagia, and a barium-swallow examination showed a high impassable stricture at the level of the clavicles thought at first to be a malignant stricture. Two biopsies of the stricture showed gastric epithelium and the diagnosis of Barrett's oesophagus (Barrett, 1950) was made. Bouginage did not relieve his symptoms and a fundoplication did not relieve his dysphagia. He could hardly swallow his own saliva and had a permanent gastrostomy. One year later he was proved to have an inoperable carcinoma.

Table I.—OVERALL RESULTS OF FUNDOPLICATION FOR HIATUS HERNIA

HOSPITAL	DIED	ALIVE	NO SYMPTOMS	IMPROVED	NO RELIEF
Hammersmith Kingston	4 2	42 40	32 33	6 5	4 2
Total	6	82	65	11	6
Percentage	6·8		73·9	12·5	6·8
			86·4		

Case 3.—L. C., a 53-year-old woman, had no relief whatsoever from a fundoplication operation. Since a thyroid operation 13 years previously she had had a most impressive and bizarre type of generalized twitching and nervousness for which extensive neurological investigations led to a diagnosis of 'hysteria'. However, a barium-meal examination showed persistent herniation of the stomach into the chest, and we consider her symptoms to be genuine.

Case 4.—N. A., a woman of 68 years, has had no relief of any of her symptoms of dysphagia, reflux, and heartburn following fundoplication in 1967. Barium-meal examination shows the persistence of a small sliding hernia with reflux in spite of good evidence of fundoplication below the diaphragm.

Case 5.—I. C., a woman of 68 years, had an exploration of the common bile-duct in 1963, transabdominal repair of hiatus hernia and splenectomy in March, 1966, transthoracic repair of hiatus hernia in September, 1966, and was not relieved by fundoplication in 1968.

Case 6.—L. B., a woman of 66 years, had a sliding hiatus hernia with stricture treated by bouginage and pylorectomy in 1962 and was not relieved by fundoplication in 1967. She subsequently had a gastrostomy, followed by resection of the stricture and a colon graft. This failed to relieve her symptoms. She then had a further resection and a Roux-en-Y jejunal graft and following this procedure is able to swallow normally.

Cases improved by Fundoplication.—Sixty-five of the 88 patients, i.e., 73·9 per cent, were completely relieved of all their symptoms, and 11 others (12·5 per cent) were improved; i.e., 86·4 per cent were symptomatically improved by the operation. Of the patients who were improved after operation, only 2 still have fairly severe symptoms. Overall, therefore, it can be said that of the 82 patients who survived the operation, 76 have improved sufficiently to have thought the operation worthwhile and have been glad to have had the operation. These results are shown in *Table I.*

Patients who had Stricture (*Table II*).—This is a very important group of patients for whom resection is often advocated. In fact some of these patients were admitted with a view to resection.

Table II.—RESULTS OF FUNDOPLICATION FOR HIATUS HERNIA IN PATIENTS WHO ALSO HAD OESOPHAGEAL STRICTURE

TYPE OF STRICTURE	HOSPITAL	DIED	ALIVE	NO SYMPTOMS	IMPROVED	NO RELIEF
Barium-swallow strictures confirmed at operation or oesophagoscopy	Hammersmith Kingston	1 0	15 7	8 5	4 1	3 1
	Total	1	22	13	5	4
	Percentage	4·4		56·5	21·7	17·4
				78·2		
'Spasmodic strictures', i.e., barium-swallow strictures not confirmed at operation or oesophagoscopy	Hammersmith Kingston	0 0	4 0	4 0	0 0	0 0
	Total	0	4	4	0	0
	Percentage			100		
All 'strictures' shown on barium-swallow film	Total	1	26	17	5	4
	Percentage	3·7		63	18·5	14·8
				81·5		

All 4 patients who had spasmodic strictures, i.e., patients in whom strictures were shown on the barium-swallow film but which were not confirmed at operation or oesophagoscopy, were completely cured of their symptoms.

Of the group that had established strictures, no less than 13 of the 22 patients who survived operation were completely cured of their symptoms and 5 others improved following fundoplication.

Thus, of 27 patients in whom a barium-swallow examination showed the presence of a stricture associated with a hiatus hernia, 81·5 per cent have obtained worth-while relief following fundoplication, and this result is worthy of emphasis, considering the alternative method of treatment advocated.

Patients who had Hiatus Hernia with Reflux only but No Stricture (*Table III*).—Forty-nine of the surviving 56 patients in this group were completely symptom-free and 5 others improved, i.e., 54 out of the surviving 56 patients benefited from the operation. One of the 2 failures was the patient who was subsequently shown to have achalasia.

Patients in whom Previous Operations had failed to control Symptoms (*Table IV*).—There were 23 patients in whom a variety of previous operations had either failed to control symptoms or provided only temporary relief. One of them died, and of the remaining 22, 17 were completely symptom-free and 3 others improved following fundoplication.

The nature of the previous operations is shown in *Table V*. We consider that the relief and improvement of symptoms in 86·7 per cent of these patients are again worthy of comment, considering that these are failures from other standard operations for hiatus hernia.

Table III.—RESULTS OF FUNDOPLICATION FOR HIATUS HERNIA IN PATIENTS WITH REFLUX BUT NO OESOPHAGEAL STRICTURE

HOSPITAL	DIED	ALIVE	NO SYMPTOMS	IMPROVED	NO RELIEF
Hammersmith	3	23	20	2	1
Kingston	2	33	29	3	1
Total	5	56	49	5	2

			86·7		

Table V.—NATURE OF PREVIOUS OPERATIONS IN 23 PATIENTS

TYPE OF OPERATION	KINGSTON HOSPITAL	HAMMERSMITH HOSPITAL	TOTAL NO. OF PATIENTS
Transthoracic repair	3	6	9
Transabdominal repair	0	5	5
Transthoracic and trans-abdominal repair	1	1	2
Pylorectomy, pyloroplasty, and gastro-enterostomy	3	2	5
Others	—	2	2
Total	7	16	23

Patients who had Fundoplication as a Primary Operation (*Table VI*).—Five of the 65 patients in this group died and 56 out of the surviving 60 patients were helped by the operation. The surviving failures included *Case* 1, who also has achalasia, and *Case* 2, who had an impassable stricture at the level of the clavicles associated with Barrett's oesophagus which later proved to be a carcinoma.

Complications.—The complications encountered in this series are shown in *Table VII*. The last two complications merit special mention.

Gastric Distension.—In 1 case gastric distension led to death and in another to a burst abdomen. Provision of adequate gastric decompression either via a transnasal tube or, if this fails, gastrostomy in the immediate postoperative period is emphasized.

Diarrhoea.—Two cases of diarrhoea postoperatively were encountered in patients who had not had vagotomy as a deliberate procedure. In 1 patient fundoplication was carried out at the primary operation. She developed diarrhoea; barium-meal and follow-through and barium-enema examinations were normal apart from rapid transit time. An insulin test, however, suggested complete vagotomy, but the patient has not accepted to come into hospital for further investigations to exclude other possible causes of her diarrhoea. The other patient had a splenectomy, abdominal repair of hiatus hernia, and pyloroplasty in 1967 but had persistent symptoms. A fundoplication was carried out subsequently. Vagotomy was not done deliberately. Postoperatively she developed diarrhoea which was extensively investigated. Eventually an insulin test suggested a complete vagotomy and she is believed to have post-vagotomy diarrhoea.

Table VI.—RESULTS OF FUNDOPLICATION FOR HIATUS HERNIA IN PATIENTS WHO HAD NOT HAD A PREVIOUS OPERATION

HOSPITAL	DIED	ALIVE	NO SYMPTOMS	IMPROVED	NO RELIEF
Hammersmith	3	27	18	5	4
Kingston	2	33	30	3	0
Total	5	60	48	8	4
Percentage	7·7		73·8	12·3	6·2
			86·1		

Table VII.—COMPLICATIONS IN THE SERIES OF 88 PATIENTS UNDERGOING FUNDOPLICATION FOR HIATUS HERNIA

COMPLICATION	TOTAL NO. OF CASES	NO OF DEATHS
Intestinal obstruction	4	—
Subphrenic abscess	5	1
Deep-vein thrombosis	5	—
Burst abdomen	2	—
Wound abscess	5	—
Chest infection	8	3
Intercostal neuralgia	1	—
? Pulmonary embolus	1	1
Gastric distension	4	1
Diarrhoea	2	—

Splenectomy.—Splenectomy was performed in 52 out of 88 patients (61 per cent). Twenty-four of these patients (46 per cent) had some complication after operation. By contrast, 36 of 88 patients did not have splenectomy (39 per cent) and 7 of these (20 per cent) had complications. Therefore the incidence of complications in the group that had splenectomy was significantly higher than in the group that did not have this procedure ($\chi^2 = 9{\cdot}63$, $P < 0{\cdot}01$).

Vagotomy and Pyloroplasty.—Vagotomy and pyloroplasty were carried out in 23 out of 88 patients

(26 per cent). In none of these patients was there any complication that could be attributed to that operation *per se*.

Relief of Individual Symptoms.—Reflux pain was relieved in about 90 per cent of patients, regurgitation in 83 per cent, and vomiting in 87·5 per cent.

DISCUSSION

The Nissen fundoplication creates a cuff of stomach around an intra-abdominal length of oesophagus. Any rise in pressure in the stomach tending to cause reflux is immediately blocked by the equivalent rise in pressure in the cuff around the oesophagus. Affolter and Rosetti (1970), Moran (1971), and Morgan (1971) have all demonstrated that fundoplication augments the pressure normally exerted by contraction of the distal oesophageal sphincter mechanism without altering the resting pressure. Another advantage of fundoplication is that if the oesophagogastric junction cannot be reduced below the diaphragm then it may be left in the chest. The procedure will still cure reflux (Nissen, 1960). Nissen and Rosetti (1962), Smiddy and Ross (1964), Krupp and Rosetti (1966), Naef, Savary, and Jacques (1970), Polk and Zeppa (1971), and Morgan (1971) have all reported favourably on the Nissen fundoplication. Other surgical procedures have been devised to produce a similar effect in reducing reflux (Baue and Belsey, 1967; Collis, 1968).

We have presented our experience with the use of fundoplication as a means of surgical treatment of symptomatic hiatus hernia in a consecutive series of 88 patients treated from 1967 to 1970 and reviewed in December, 1970. Fundoplication has achieved good results when used both as a primary operation and as a 'salvage' operation in patients whose previous operations have failed to relieve their symptoms. Good results were achieved in patients who had hiatus hernia with reflux and in whom radiological strictures were demonstrated, and this group we think merits special mention.

A further follow-up of these cases is desirable to be sure that the good results are maintained. It is on record, however, that Tanner and Hardy (1970) noted an 80 per cent improvement in patients whom they had treated by some other technique of repair, and that this figure remained the same in two groups of patients assessed by independent observers at 3 years and 15 years, thus suggesting that the majority of the failures of operation occur early. This has been the experience of Collis (1961) and has also been our impression from the present series.

In the absence of any controlled trial of the many operative procedures (Earlam and Ellis, 1967) that have been used for hiatus hernia, it is not possible to make any statistically valid comparison.

TORSION OF THE ISOLATED FALLOPIAN TUBE

By J. M. MONAGHAN

DEPARTMENT OF OBSTETRICS AND GYNAECOLOGY, WESTERN GENERAL HOSPITAL, EDINBURGH

SUMMARY

Torsion of the isolated Fallopian tube is a relatively rare condition which has been known for over 65 years. The number of cases reported probably exceeds 300. The cases reported here illustrate different presenting signs and causative pathology.

TORSION of the isolated Fallopian tube was first described by R. Hamilton-Bell in a paper entitled 'Torsion of the pedicle in hydrosalpinx and other morbid conditions of the fallopian tube' given to the Obstetrical Society of London in April, 1904.

The actual number of cases reported in the literature is uncertain but would seem to be a little in excess of 300 (Blair, 1961).

This paper reports 2 cases occurring with slightly different presenting signs and causative pathology.

CASE REPORTS

Case 1.—A 19-year-old, nulliparous, unmarried nurse presented with right iliac fossa pain. The pain had come on gradually over the past 2 days and had then remained constant in the right iliac fossa and had not radiated. The pain had not been associated with defaecation or micturition. The patient had been anorexic for 24 hours but there had been no vomiting, diarrhoea, or pyrexia. The patient's last menstrual period had been 12 days prior to admission and her menses were quite regular every month, lasting for 5 days. There was no possibility of pregnancy. There was no previous history of any illness although there was a strong family history of tuberculosis, both parents having been treated in the past. She had had no previous similar episode of pain.

On examination the patient was a pale girl with flushed cheeks; she was lucid and co-operative. She was apyrexial and had no lymphadenopathy, oedema, or jaundice. Her abdomen was slightly obese. There was no obvious organomegaly, but there was marked tenderness and guarding in the right iliac fossa with rebound tenderness present in the right iliac fossa and a positive Rovsing's sign. Rectal examination revealed a rectum loaded with faeces and marked tenderness in the right iliac fossa but no pain or tenderness on movement of the cervix. A provisional diagnosis of acute appendicitis was made and the patient was taken to the operating theatre for laparotomy. The abdomen was opened by a right grid-iron incision and it was immediately noted that the peritoneal cavity contained a considerable quantity of straw-coloured fluid. This was removed by suction, a bacteriology swab taken, and inspection carried out. The appendix, caecum, rectum, and fundus of the uterus appeared to be covered with a large number of small vesicular blebs with a slight haemorrhagic reaction surrounding each bleb. A diagnosis was not made at this time and the appendix which appeared to be quite normal was removed in the usual manner. Further exploration of the abdomen through the incision showed the right Fallopian tube to be turgid and black, oozing dark blood from the fimbrial ostia. As access was very poor through the grid-iron incision this was closed and a lower midline incision performed. The pelvis was then more adequately inspected and the uterus, ovaries, and the left Fallopian tube were noted to be normal. However, the right Fallopian tube seemed to be twisted around itself in a clockwise direction approximately 1½ turns (540°). As the tube appeared to be non-viable it was removed in the usual manner. The abdomen was closed without drainage.

The pathologist's report revealed that the appendix contained threadworms in the lumen with some congestion of the serosa and a little inflammatory exudate on the serosal surface. Sections at three deeper levels through the block were made and revealed definite foci of epithelioid cells in the serosa and showed tubercles in two places with small focal areas of caseation. The Fallopian tube was reported as being deeply congested. On sectioning the empty Fallopian tube thickening of the tube with marked vascular congestion was noted. Numerous follicles of epithelioid cells were present. In some of these there were small areas of caseation and in many there were large multinucleated giant cells associated with a moderate polymorphonuclear leucocyte infiltration of the mucosa. Ziel-Nielsen staining showed occasional acid- and alcohol-fast bacilli. The general appearances were that of a tuberculous salpingitis.

The diagnosis of pelvic tuberculosis was later confirmed by inoculation of curettings obtained at dilatation and curettage of the uterus into a guinea-pig which at autopsy showed progressing tuberculosis. The patient was treated with antituberculous chemotherapy and after a short spell in hospital was allowed home to continue on her chemotherapy.

Case 2.—A nulliparous, married woman, aged 22 years, attended the Casualty Department of the Western General Hospital, Edinburgh, complaining of severe lower abdominal and right iliac fossa pain; she had vomited between nine and twelve times since the previous evening. The patient's bowels had moved normally and 2 weeks prior to this she had had a suspected urinary-tract infection for which no causative organism had been found. The patient's last menstrual period had been 2 weeks prior to her admission and had been quite normal. She reported that during intercourse the previous evening she had experienced marked dyspareunia. The patient had no past medical history of note and her family history was not significant.

The patient was apyrexial and her pulse and blood-pressure was quite normal. She did, however, look ill and was in obvious pain. The pain was reported as beginning the previous evening, coming on quite suddenly, and had lasted almost continuously until admission. The pain was in the right iliac fossa and although being appreciated over the whole lower abdomen did not radiate.

Examination revealed a thin woman holding herself very still. The abdomen was markedly guarded and she had extreme tenderness in the right iliac fossa. Rebound tenderness was elicited. Pelvic examination demonstrated a tender, firm mass in the pouch of Douglas, approximately 5 cm. in diameter, and the mass was quite fixed. Rectal examination revealed an empty rectum and it was possible to delineate a circumscribed tender mass in the pouch of Douglas. The uterus was felt quite separately from this mass. The diagnosis of torsion of a right ovarian cyst was made and arrangements were made for laparotomy. The abdomen was entered by a lower right paramedian incision and the peritoneal cavity was seen to contain a serosanguineous fluid with a few small clots. The right Fallopian tube was noted to be enlarged to approximately 5 cm. in diameter and extremely engorged with blood. The tube was twisted through approximately 1½ turns (540°) on a long mesosalpinx. The right ovary was healthy and distinct from this torsion. The left ovary and tube appeared to be normal as was the uterus. A right salpingectomy was performed in the routine manner and the abdomen was closed with drainage. The patient made a rapid recovery from this procedure and was discharged home after 8 days.

The pathologist's report noted a large haemorrhagic cyst measuring 5 cm. in diameter arising from the Fallopian tube. The floor of the cyst was stained with blood and showed several plaque-like areas of firm, warty growth. Microscopic examination showed that this specimen was derived from the Fallopian tube and associated tissues. The epithelial lining of the tube was normal, with the wall and surrounding tissues very congested and oedematous. Arising in the connective tissues surrounding the Fallopian tube was a cyst lined by a flattened, cuboidal epithelium. In some places the wall of the cyst was thickened and comprised sclerotic fibrous tissue and muscle mixed with areas of recent haemorrhage. The cyst was thought to be parovarian in origin.

The appearances were those of extreme vascular congestion and oedema in the Fallopian tube and parovarian cyst.

DISCUSSION

It would seem that there are no clear pathognomonic features related to the presentation of the condition of torsion of the isolated Fallopian tube. Pain and tenderness in either or both iliac fossae are relatively common and therefore the commonest preoperative diagnosis is that of acute appendicitis. It is not surprising that most of the reports are of involvement of the right side of the pelvis and Blair (1961) stated that 3 out of 4 cases were diagnosed as acute appendicitis. Peritonism or peritonitis was observed, associated with the presence of blood in the peritoneal cavity or close to the gangrenous tube. Nausea and vomiting may occur although these symptoms are more usually associated with ovarian torsion or gastro-intestinal upset.

No completely satisfactory theories of aetiology have been put forward. Torsion of the absolutely normal tube is extremely rare (Blair, 1961). It would appear that torsion is more likely to occur in the presence of an unusually long mesosalpinx or a hydatid, Morgagni, or parovarian cyst, as in *Case* 2. The twisting of the tube in the foetus may persist to some degree in adult life and thus initiate the torting process.

It is possible that torsion may be caused by abnormal motility of the tube and that intra-uterine devices may be instrumental in altering the normal activity and motility of the tube; thus their presence may well be related to the occurrence of torsion. It would seem feasible that torsion should be associated with marked congestion of the tube which may occur in a disease process or at certain stages in the menstrual cycle. Torsion would probably occur as the veins of the mesosalpinx are longer than the arteries and more distensible. Thus venous congestion would tend to cause the veins to rotate around the arteries which are more rigid. Artery blood-flow would continue because of the higher pressure, increasing the torsion and thus further causing gross venous congestion. Various theories have been put forward related to acceleration or deceleration of the body; notably the Sellheim theory proposed by Hugo Sellheim (1870–1936) and quoted by Blair (1961). Abnormalities of the pelvic organs related to previous surgery may also be an aetiological factor. A case of torsion following Pomeroy sterilization (Kendrick, 1965) and 1 following hysterectomy (Bowers, 1940) have been reported. It would seem likely that torsion following surgery is related to abnormal positioning or the presence of adhesions or adhesive bands around which the tubes can twist (Jeffcoate, 1969).

Tubal disease is a very important factor, and Bland-Sutton in 1904 commented: 'It is a fact that the Fallopian tube, when distended with simple fluid and blood, pus or even when gravid, does twist its pedicle.'

Temple in 1950, reporting 2 cases of torsion occurring in association with a pyosalpinx, commented that the occurrence of torsion is even more rare in the pyosalpinx as it is usually bound down by adhesions. Other authorities as far back as Targett in 1904 considered that almost all cases of twisted pyosalpinx were tuberculous. In the present *Case* 1 there was indeed a tuberculous salpingitis and it is possible that congestion associated with this process was instrumental in causing the torsion.

It seems that the major predisposing factor in the aetiology of torsion is an increase in the size of the tube, whether this is due to disease, associated anatomical abnormalities, or even physiological states such as pregnancy or menstruation.

A direct relationship with menstruation has not been established by any writer on this subject. However, it is interesting that there have been few cases of torsion of the isolated tube in premenarchical patients (Blum and Sayre, 1937). On the other hand, Jeffcoate (1969) states that in his experience torsion occurs usually in the child or adolescent.

The diagnosis has never been made preoperatively. It is therefore important that the operator diagnosing appendicectomy in the menstruating female should bear in mind the possibility of gynaecological pathology. I feel that there is a very good case for utilizing a lower right paramedian incision in this type of case which would obviate the necessity to perform two incisions which does occur from time to time. The advantages are obvious. Some attempts have been made to conserve the torted tube and it is imperative that the contralateral tube and ovary should be inspected before a firm decision is made to remove the diseased tube. If the causative pathology is an abnormally long mesosalpinx then plication of the mesosalpinx may be performed.

Good results have been reported using conservative measures and Rogers (1925) saved one tube from bilateral torsion and Blair (1961) in his series of 4 cases not only saved one tube but the patient went on to have a normal successful pregnancy. It is important, however, that if conservation is envisaged a further diagnosis as to aetiology should be made. If conservation had been attempted in *Case* 1 the diagnosis of tuberculosis could possibly have been missed.

PROGNOSIS

These patients will have a very similar prognosis to the patient who has had a salpingectomy for ectopic pregnancy.

Following salpingectomy the chances of conception are reduced and the risks of a tubal pregnancy are increased to 10–15 per cent of all pregnancies, i.e., forty times greater than the overall risk of 0·3 per cent (Jeffcoate, 1969).

In *Case* 1 the patient will run a very high risk of tubal pregnancy if she conceives at all as it is almost certain that the contralateral tube has some involvement in the tuberculous process.

Thus, isolated torsion of the Fallopian tube is an uncommon condition which is rarely if ever diagnosed prior to operation. This is a diagnosis which should be considered and such cases exemplify the advantages of using a right lower paramedian incision to open the abdomen in a female of fertile years where a diagnosis is in doubt.

Acknowledgements.—I would like to thank Mr. A. T. R. Hamilton, Raigmore Hospital, Inverness, for permission to report *Case* 1, and Dr. F. R. Clark, Western General Hospital, Edinburgh, for permission to report *Case* 2.

SHORT NOTES OF RARE OR OBSCURE CASES

ATHEROSCLEROSIS AND ANEURYSM FORMATION IN A SAPHENOUS VEIN-GRAFT

By ALBERTO G. DE LA ROCHA, RONALD S. PEIXOTO, and RONALD J. BAIRD*
DEPARTMENT OF SURGERY OF THE UNIVERSITY OF TORONTO AND THE TORONTO WESTERN HOSPITAL

Summary

A case in which a saphenous vein by-pass graft inserted 5 years previously developed atherosclerosis and aneurysm formation 3–4 years later is described.

The autogenous saphenous vein is the preferred conduit for repair of occluded arteries in the leg and is also used with increasing frequency for coronary-artery repair. It is easy to suture, remains patent in low-flow situations, and has a very low incidence of long-term complications.

Atheromatous deterioration and aneurysmal formation in a saphenous vein-graft are extremely rare. In a 10-year review of 295 saphenous vein-grafts in 1967 Darling, Linton, and Razzuk did not find evidence of these complications.

The present report is a case of atheromatous deterioration and aneurysmal dilatation in a saphenous vein-graft which had been inserted 5 years previously.

CASE REPORT

The patient, a 63-year-old male, was admitted in 1970 for treatment of intermittent claudication. Five years before, in January, 1965, he had been operated upon in another hospital and a saphenous vein by-pass graft had been inserted from the left common femoral artery to the popliteal artery. On examination in 1970, he had a large abdominal aneurysm and diminished femoral pulses bilaterally. The proximal portion of the vein-graft was enlarged to approximately 2·5 cm. in diameter and the patient stated that he had been aware of increased pulsation in this area for about 1 year.

An aortogram revealed aneurysms in the aorta and both iliac arteries. Both external iliac arteries were narrow. The vein by-pass was patent and the proximal 5 cm. were dilated and aneurysmal.

At operation in October, 1970, the aortic and iliac aneurysms were excised and an aortofemoral by-pass graft was inserted. Dissection in the left groin revealed a fusiform aneurysm of the proximal 5 cm. of the vein-graft. One portion of the wall of the fusiform aneurysm was the site of a small false aneurysm and a yellow, atheromatous-appearing content was exuding from it (*Fig.* 1).

Since the patient had no usable segment of saphenous vein in either leg and since there was the possibility

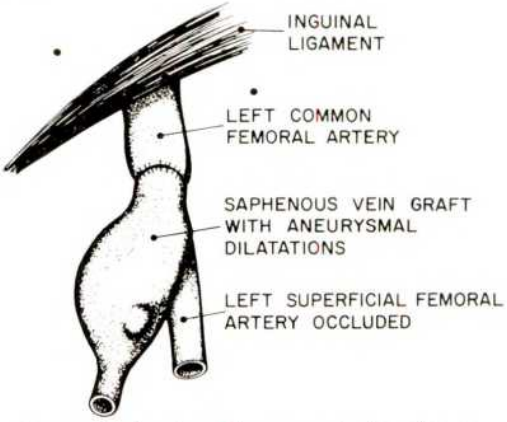
of other areas of deterioration in the by-pass graft the aneurysm was resected, the vein by-pass was ligated, and a femoropopliteal prosthetic by-pass was inserted.



INGUINAL LIGAMENT
LEFT COMMON FEMORAL ARTERY
SAPHENOUS VEIN GRAFT WITH ANEURYSMAL DILATATIONS
LEFT SUPERFICIAL FEMORAL ARTERY OCCLUDED

FIG. 1.—The location of the aneurysm in the saphenous vein-graft.

On gross examination the wall of the venous aneurysm was thickened and yellow. Histological examination revealed extensive atherosclerosis with subintimal fibrosis and cholesterol deposition (*Fig.* 2).

DISCUSSION

Both atheromatous deterioration and aneurysm formation in saphenous vein-grafts in the arterial system are very rare. Beebe, Clark, and DeWeese (1970) described atheromatous changes in a man with hypercholesterolaemia and hyperlipidaemia. We have been unable to find a report of an aneurysm in a saphenous vein-graft. Pillet and Roux (1969) reported a fusiform aneurysm in a superficial femoral vein-graft which had been used as a replacement for a section of superficial femoral artery.

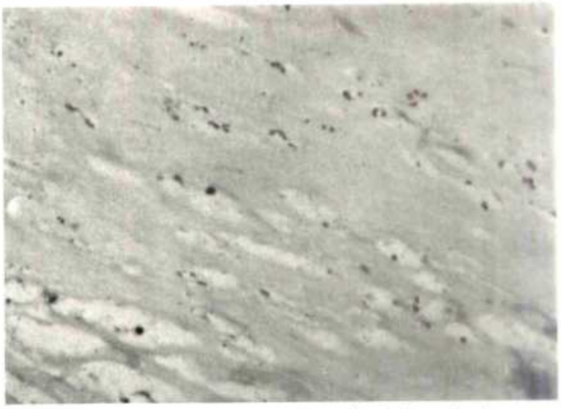


FIG. 2.—Histological section of the wall of the vein showing cholesterol deposits and giant-cell formation.

The present report shows that although atheromatous deterioration and aneurysm formation in a saphenous vein-graft are extremely rare they may occur.

ADULT HYPERTROPHIC PYLORIC STENOSIS

BY JOHN A. E. MacDONALD

WESTERN INFIRMARY, GLASGOW

SUMMARY

Adult hypertrophic pyloric stenosis is an uncommon condition which when encountered is usually mistakenly diagnosed as carcinoma of the antrum. It is a benign disease resulting from hypertrophy of the circular fibres of the pyloric canal and is recognizable radiologically by narrowing and elongation of the pyloric canal. The aetiology is in doubt but the condition is probably congenital. The treatment of choice is partial gastrectomy.

SINCE the disease was first described by Jean Cruveilhier in 1835 adult hypertrophic pyloric stenosis has remained something of a surgical curiosity and, to date, fewer than 200 cases have been described in the world literature. In the majority of the cases the diagnosis has been made at operation, the preoperative diagnosis usually being carcinoma of the antrum or peptic stricture.

The following case report illustrates a further example of this unusual condition.

CASE REPORT

HISTORY.—A 42-year-old male presented with a 7-week history of epigastric pain, anorexia, and rapid weight-loss of about 6·3 kg. Vomiting occurred copiously every second or third day, the vomitus containing semi-digested food particles recognizable as having been eaten some time previously. Prior to this he had suffered from mild dyspepsia for a number of years without vomiting.

EXAMINATION.—No abnormality was found other than slight epigastric tenderness. A succussion splash was not elicited at the initial examination but was subsequently found to be present.

BARIUM STUDIES.—A barium-meal examination showed excess fasting juice. The pyloric canal was narrowed and elongated and bulged into the duodenal cap (*Fig.* 1). The mucosal pattern looked abnormal and peristalsis was restricted. A crater was present on the lesser curvature and had the appearance of a benign ulcer (*Fig.* 2). The possibility of benign adult hypertrophic pyloric stenosis was considered, but carcinoma of the antrum could not be excluded.

OPERATION.—The musculature of the pyloric canal was found to be smoothly and uniformly hypertrophied with a maximum thickness of 1·2 cm. The duodenum was normal with no evidence of peptic ulceration. Situated on the lesser curvature was a large ulcer which was obviously benign. A Polya gastrectomy was performed.

The postoperative course was complicated by a pulmonary infarct on the tenth postoperative day. The patient, however, subsequently recovered and enjoyed complete relief of his gastric symptoms.

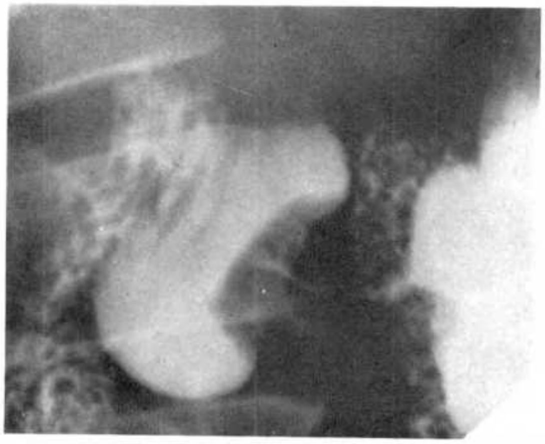

FIG. 1.—Barium-meal radiograph, showing narrowing and elongation of the pyloric canal and bulging into the duodenal cap.

HISTOLOGY.—Examination of the pyloric canal showed diffuse hypertrophy of the circular muscle coat of the pylorus, confirming the diagnosis of hypertrophic pyloric stenosis (*Fig.* 3).

DISCUSSION

Pathology.—The thickness of the muscle of the normal adult pyloric canal ranges from 4 to 7 mm. with an average of 5·1 mm. In adult hypertrophic pyloric stenosis this measurement is increased to 1–1·5 cm. on average, but measurements of up to 3 cm. have been recorded (Knight, 1961). This increase is mainly due to hypertrophy of the circular muscle component, involving either the whole circumference of the pylorus or a focal segment of it. Focal hypertrophy frequently occurs at the 'torus'— the point at which the two oblique loops of circular fibres meet at the lesser curvature (Keet, 1956).

Radiology.—Although a number of diagnostic features have been postulated, these are by no means consistent and the condition commonly eludes radiodiagnosis. The first important paper on the radiological aspects of the condition stressed the importance of bulging of the pyloric muscle into the duodenal cap (Kirklin and Harris, 1933) and this point was reiterated by subsequent authors (Sherman, Yen, Bowden, and Selby, 1959). This feature, however, may be produced in normal subjects by manual pressure on the stomach.

The presence of a cleft between the hypertrophied muscle and the fibres of the pylorus itself has been demonstrated not infrequently, and has been considered by many to be of diagnostic importance (Twinning, 1933; McNaught, 1957; Sherman and others, 1959). Again this is not a constant finding.

The most consistent sign is elongation of the narrowed pyloric canal, often with 'funnelling' of the proximal end (Keynes, 1965).

Aetiology.—This remains in doubt. Prolonged pylorospasm has been suggested as a possible cause, but it is difficult to see how such a common finding could be a significant factor in such an uncommon condition.

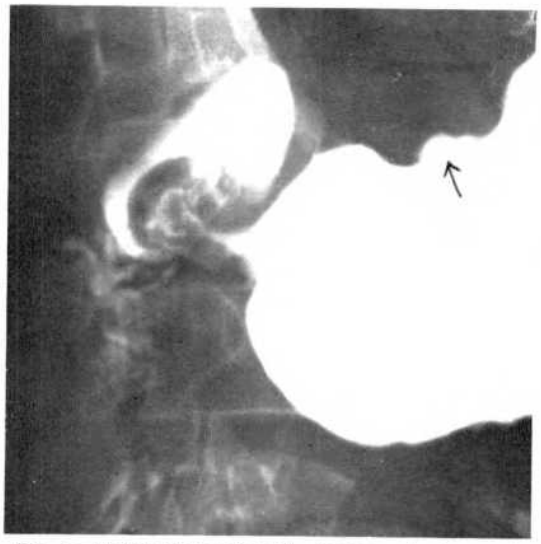

FIG. 2.—Barium-meal radiograph, showing a benign gastric ulcer on the lesser curvature.

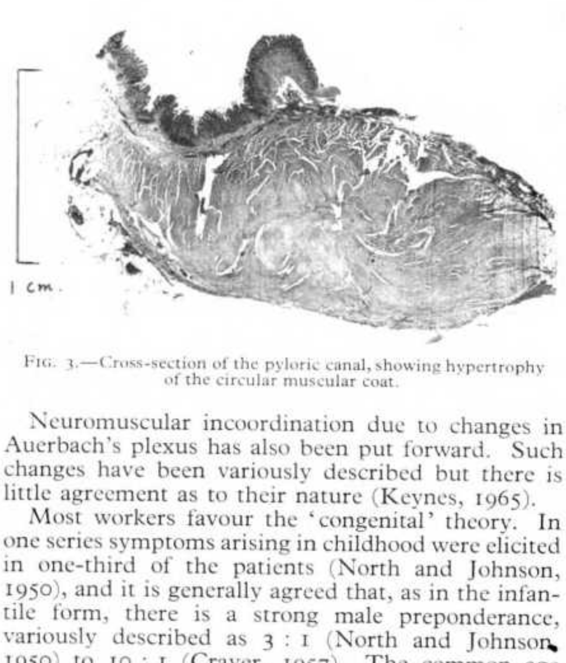

FIG. 3.—Cross-section of the pyloric canal, showing hypertrophy of the circular muscular coat.

Neuromuscular incoordination due to changes in Auerbach's plexus has also been put forward. Such changes have been variously described but there is little agreement as to their nature (Keynes, 1965).

Most workers favour the 'congenital' theory. In one series symptoms arising in childhood were elicited in one-third of the patients (North and Johnson, 1950), and it is generally agreed that, as in the infantile form, there is a strong male preponderance, variously described as 3 : 1 (North and Johnson, 1950) to 10 : 1 (Craver, 1957). The common age of onset of symptoms, however, is 31–60 years (North and Johnson, 1950), and why the majority of patients remain asymptomatic until middle age is not clear. It may be that the condition is aggravated or merely brought to light incidentally by concomitant gastric pathology; although sometimes occurring alone the condition is much more commonly associated with some other abnormality such as gastric ulcer, hypertrophic gastritis, or gastric polyposis (Keynes, 1965). It has been suggested that in these circumstances the hypertrophy may be a secondary phenomenon but in fact the converse is probably true (McCann and Dean, 1950), as it has been shown experimentally in dogs that occlusion of the pylorus produces gastric ulceration (Dragstedt, 1954).

Treatment.—As regards treatment it is generally agreed that the procedure of choice is a Billroth-I gastrectomy (North and Johnson, 1950; Craver, 1957; Knight, 1961).

A Ramstedt pyloromyotomy, indicated in the infantile form, is not recommended as it predisposes to diverticulum formation through the large defect in the pyloric musculature (McCann and Dean, 1950).

In the debilitated patient in whom a partial gastrectomy might be considered excessively hazardous either a Heineke pyloroplasty (Knight, 1961) or a gastro-enterostomy (Craver, 1957) is acceptable, although the former may prove technically difficult if the pylorus is grossly thickened, while the latter has the serious disadvantage of precluding visualization of a lesion which it may be difficult to distinguish from carcinoma.

Acknowledgement.—My thanks are due to Mr. K. Fraser for permission to publish the case report and for advice in the preparation of this paper.

INTRAPULMONARY LIPOMA ASSOCIATED WITH MULTIPLE PULMONARY HAMARTOMAS

BY E. L. JONES, J. J. LUCEY, AND A. BRIAN TAYLOR
DEPARTMENT OF PATHOLOGY AND QUEEN ELIZABETH HOSPITAL, UNIVERSITY OF BIRMINGHAM

SUMMARY

A pulmonary lipoma is described in a 64-year-old male, involving the right middle lobe, associated with a separate area of intrapulmonary ossification and a central intrabronchial hamartoma.

It is postulated that the lipoma most probably arose from one of the multiple pulmonary hamartomas.

PULMONARY lipomas are rare tumours, and to date 39 cases have been reported in the English literature. Lipomas of the lungs may be divided into (*a*) bronchial and (*b*) subpleural, depending on their site of origin. The majority of examples reported are endobronchial lipomas arising from the submucosa of a large bronchus. In this report we describe a peripheral intrapulmonary lipoma associated with pulmonary ossification and a polypoid intrabronchial hamartoma.

CASE REPORT

A man of 64 years was investigated for an episode of haemoptysis, which had been small in amount, 2 weeks earlier. He had few other symptoms but had been a pipe smoker. Twelve years previously he had had a radiograph of the chest which was reported as showing old tuberculosis. At the present time a chest radiograph showed a patch of calcification with a little fibrosis at the right apex. There was also a little indefinite nodular shadowing in the region of the right middle lobe.

Bronchoscopy revealed a small 'warty tumour' arising from the lower wall of the right upper-lobe bronchus and causing partial obstruction of the lumen. A biopsy was taken and showed a mildly chronic inflammatory-cell infiltrate in dense fibrous stroma, the surface being lined by respiratory-type epithelium.

Bronchography showed severe stenosis within the origin of the right upper lobe bronchus and also complete non-filling of the middle lobe. There was compensatory emphysema in the lower lobe.

Thoracotomy was performed by Mr. D. B. Clarke and the right upper and middle lobes were resected with sleeve resection of the main bronchus at the origin of the upper lobe to include the whole of the tumour there. The middle lobe contained a mass surrounded by bullous emphysema.

Postoperative recovery was complicated by sputum retention but expansion of the lower lobe was obtained and the patient recovered and was discharged on the twelfth day. Five weeks later there was slight further haemoptysis, but bronchoscopy and biopsy showed only granulation tissue at the site of resection.

PATHOLOGY.—The resected specimen consisted of the upper and middle lobes of the right lung. Dense fibrous adhesions were present in the transverse fissure and over the pleural surface of the upper lobe. Collapsed, thin-walled, emphysematous bullae were located at the periphery of the middle lobe. A large ill-defined mass (*Fig.* 1), measuring 7 × 4 × 4 cm., expanded the middle lobe. The lobulated fatty mass extended up to the pleural surface of the lobe. No intrabronchial fatty tumour was found. A firm sessile polyp (1 cm. in diameter) was situated at the origin of the upper-lobe bronchus, partially obliterating the lumen and resulting in collapse and induration in the distal lung. An ill-defined calcified focus (2 cm. in diameter) was located at the periphery of the upper lobe.

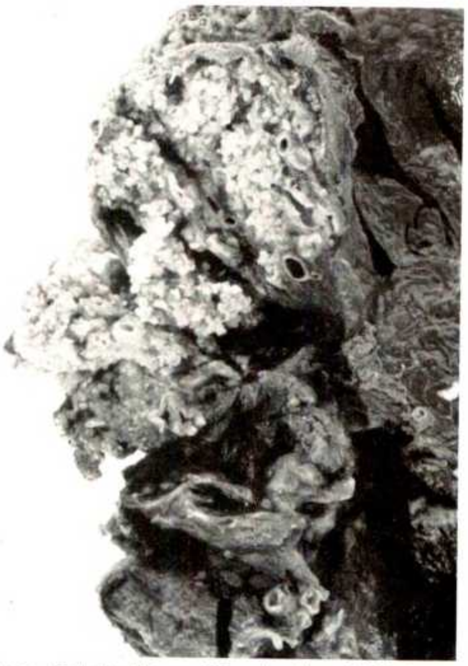

FIG. 1.—Lobulated lipoma filling the right middle lobe.

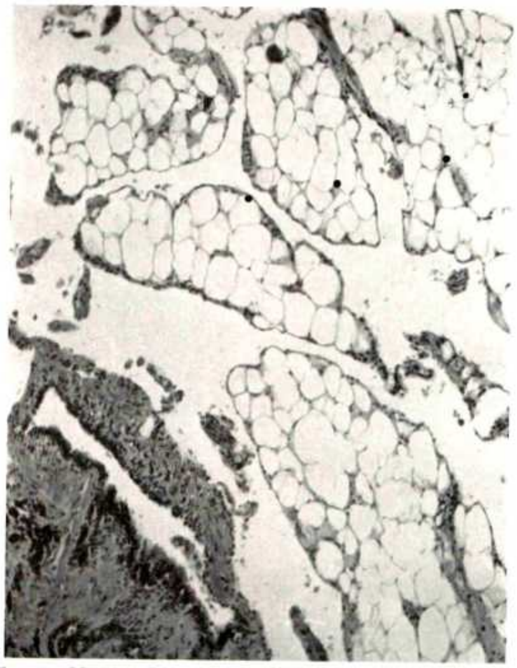

FIG. 2.—Mature adipose tissue separated by thin fibrous septae. H. and E. (× 162.)

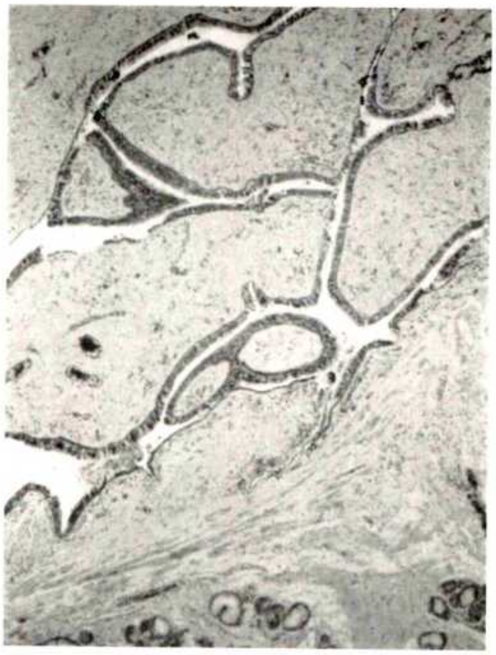

FIG. 3.—Cleft-like spaces lined by non-ciliated columnar epithelium in intrabronchial hamartoma. H. and E. (× 162.)

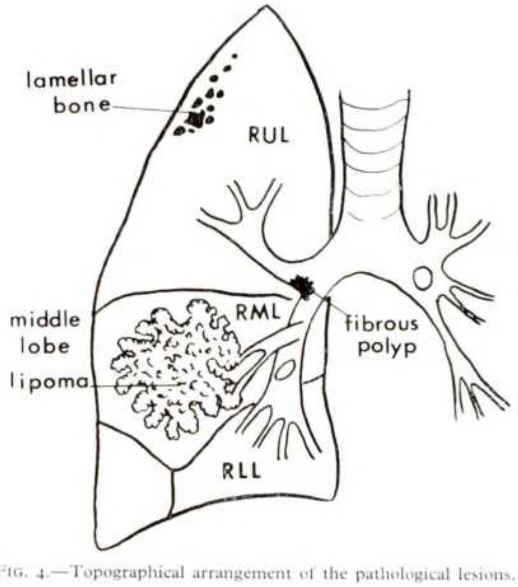

FIG. 4.—Topographical arrangement of the pathological lesions.

Histologically the mass in the middle lobe was a simple lipoma consisting of mature vascular adipose tissue (*Fig.* 2) forming delicate lobules encircling the bronchi and accompanying vessels.

The orifice of the upper-lobe bronchus was partially occluded by a hamartomatous polyp consisting of a fibrovascular stroma traversed by slit-like clefts covered by non-ciliated, columnar-celled epithelium (*Fig.* 3).

A further hamartoma consisting of foci of metaplastic bone was located at the apex of the upper lobe (*Fig.* 4). There was no evidence of pre-existing fibrosis. The bone consisted of mature lamellar trabeculae enclosing fatty haemopoietic marrow (*Fig.* 5).

DISCUSSION

Fat is a normal constituent of the bronchial wall and is located in the submucosa of the bronchi down to 1 mm. in diameter (Watts, Claggett, and McDonald, 1946); it may also be found beneath the pleura.

Lipomas may arise from the fatty tissue within the lung and are divided into (*a*) those in the bronchi and (*b*) those beneath the pleura.

Pulmonary lipomas are rare tumours—only 39 cases are recorded in the English literature—although they are probably commoner than appears from the published cases.

Table I.—REPORTED CASES OF INTRAPULMONARY LIPOMAS

* Average.

Bronchial lipomas account for the majority of the cases, and present as dumb-bell-shaped tumours projecting into the lumen of large bronchi.

Subpleural lipomas are very rare; such tumours were reported by Shapiro and Carter (1954) and Spencer (1968). The occurrence of a mainly peripheral intrapulmonary lipoma has been described by Touroff and Seley (1951), Shapiro and Carter (1954), and Plachta and Hershey (1962). Only 2 other reports concern middle-lobe lipomas (Staub, Barker, and Langston, 1965; Ramsey, Oster, and Foreman, 1969).

Intrapulmonary lipomas are much commoner in males (*Table I*), tending to occur around the fifth decade but with an age range from 29 to 78 years (average age, 52 years). Their size varies from 1·3 × 1 cm. to 7·8 × 4·2 × 2·3 cm. The tumour in the present case, measuring 7 × 4 × 4 cm., is the largest yet recorded. They appear to be slightly more common on the left than on the right side (*Table I*).

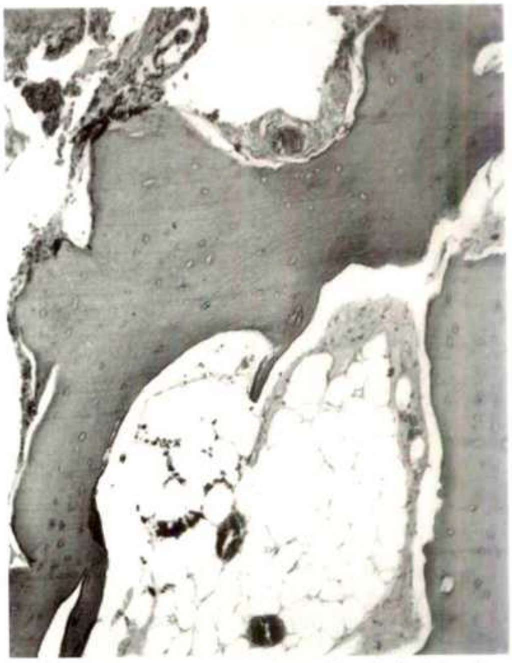

FIG. 5.—Cancellous bony trabeculae and enclosing fatty tissue containing foci of red marrow (bottom left). H. and E. (× 162.)

In the present case an unusual and interesting feature was the presence of osseous metaplasia (*Fig* 4) in the upper lobe. Nodular heterotopic ossification may occur within the lung alveoli in mitral stenosis, in organized inflammatory tissue, occasionally in the walls of a chronic cavity, and very rarely by a process of metaplasia within normal lung (Spencer, 1968). In our case there was no evidence of any pre-existing fibrous scarring in relation to the intra-alveolar bone. The bony trabeculae enclosed mature adipose tissue containing foci of metaplastic bone-marrow.

Metaplastic ossification and bone-marrow formation are also recognized in the centres of chondromatous hamartomas.

The 2 cases described by Bellin, Libshitz, and Patchefsky (1971) showed foci of metaplastic cartilage in association with myxomatous tissue within the lipoma. This cartilaginous metaplasia is very uncommon in bronchial lipomas, and Som and Feuerstein (1951) were the only other authors to note it in these tumours.

Metaplastic ossification and cartilagenous metaplasia have been described in lipomas in other sites

(Plaut, Salm, and Truscott, 1959). An alternative interpretation of the metaplastic osseous and adipose tissue in the upper lobe in the present case is that it was due to ossification occurring in a second intrapulmonary lipoma.

The polypoid tumour arising from the upper-lobe bronchus is a typical bronchial hamartoma consisting of non-ciliated, columnar-epithelial-lined, slit-like clefts between a fibrovascular stroma (*Fig*. 3).

Microscopically, bronchial hamartomas may also contain fat, although it is usually inconspicuous since it is distributed between bulky lobules of cartilage. They reproduce any of the components of bronchial tissue, including areas of fibrocartilage, bone, epithelial-lined clefts, glands, and smooth muscle (Spencer, 1968).

Bellin and others (1971) stated that the finding of cartilaginous metaplasia in pulmonary lipomas, as seen in their 2 cases and in that of Som and Feuerstein (1951), is very rare and should be differentiated from bronchial hamartomas.

In this report we suggest that the middle-lobe lipoma most probably developed from one of the multiple hamartomas present.

INTRALUMINAL DIVERTICULUM OF THE DUODENUM

By N. M. PAPALEXANDRIS AND D. LINCOLN LEWIS

ROYAL SALOP INFIRMARY, SHREWSBURY

IN contrast with primary and secondary diverticuli of the duodenum, which are fairly common, the intraluminal diverticulum of the duodenum is a very rare entity.

CASE REPORT

Mr. S. N., a theological student, aged 20 years, attended the Royal Salop Infirmary on 18 June, 1969, complaining of upper abdominal pain and vomiting soon after meals for 12 months. The pain was described as intermittent and localized in the epigastrium, and it never occurred at night. Intermittent discomfort and nausea followed almost immediately after meals and both the nausea and pain were relieved by vomiting. There was no history of melaena or haematemesis and no bowel irregularities were reported. Complete physical examination revealed nothing positive apart from slight epigastric tenderness. Routine investigations of the blood, urine, and stool did not reveal any abnormality.

A barium-meal examination (*Figs*. 1, 2) was done and the following was reported: 'In the descending part of the duodenum there is shown to be a blind-ended tubular duplication of the gut; this is lying within the lumen of the duodenum and when filled with barium it extended into the middle third of the transverse part of the duodenum. The opening within the main alimentary channel is in the second part of the duodenum near the ampulla. The duodenal cap was irritable and rather difficult to fill; there was slight tenderness to palpation and there does seem to be a deformity of the right fornix.' A tentative diagnosis of intraluminal diverticulum of the duodenum, though rare, was made and the patient was admitted on 14 Nov. for operative treatment.

The abdomen was opened through a right paramedian incision. The stomach was found to be slightly dilated. The duodenum looked normal externally and, on palpation, the second part of the duodenum felt thick, giving the impression of something slipping in between the fingers. The liver, pancreas, and biliary apparatus were found to be normal and there was no evidence of other abnormality in the alimentary tract. The duodenum was mobilized by Kocher's manœuvre and the second part was opened anteriorly by a longitudinal incision. The intraluminal diverticulum was immediately apparent as a blind pouch (*Figs.* 3, 4) arising close to the ampulla of Vater and extending up to the middle of the third part of the duodenum. The intraluminal diverticulum, measuring 5 × 2 cm., was partially obstructing the lumen of the duodenum. The opening of the diverticulum was closely related to the ampulla of Vater and the blind end was lying in the transverse part of the duodenum. The diverticulum was removed entirely and the defect in the mucous membrane was sutured with fine atraumatic catgut. Before the duodenum was closed a small incision was made in the pyloric antrum and the pylorus was examined under direct vision and digitally to exclude the possibility of duodenal ulceration.

The histological examination was described as follows: 'Microscopically the wall consists of a thin layer of fibrous tissue covered on each side by intestinal type mucosa. No inflammatory or malignant changes were seen.' (*Fig.* 5.)

The follow-up, 21 months after operation, has been satisfactory and the patient reports complete relief of symptoms.

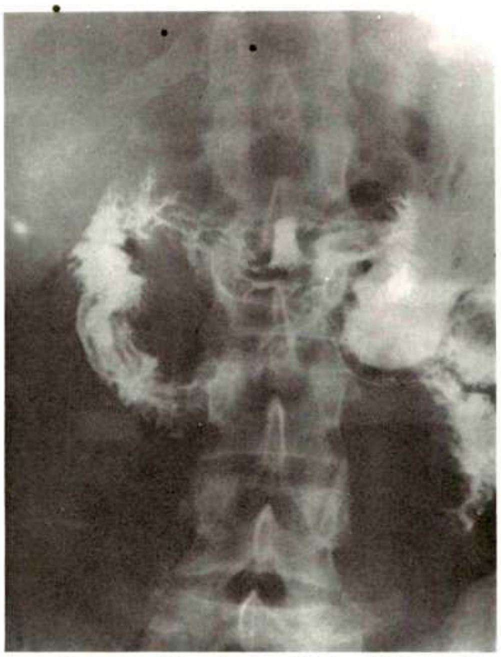

FIG. 1.—Barium-meal film, showing a blind-ended duplication of the gut lying in the descending part of the duodenum.

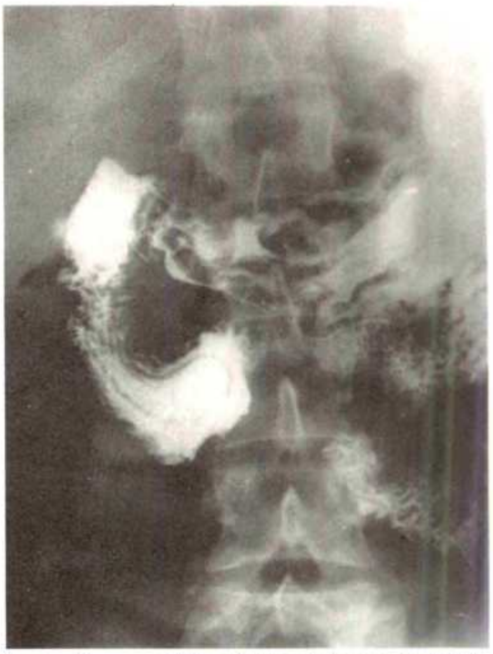

FIG. 2.—Barium-meal film, showing the barium-filled duplication extending into the middle third of the transverse part of the duodenum.

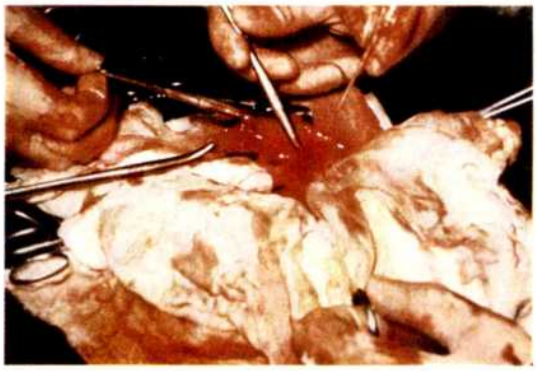

FIG. 3.—Operative appearances.

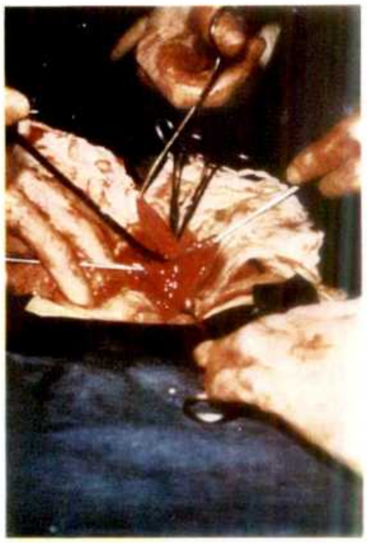

FIG. 4.—Operative appearances.

DISCUSSION

Very few similar cases have been reported in the world literature. In 1885 Silcock published the first pathological report of an intraluminal diverticulum of the duodenum. A very long period then elapsed in which no report of a similar anomaly can be found until 1949 when Kinzer published a radiological report of intraluminal diverticulum. Since then only 7 cases have been reported (Meyer and Edgren, 1956; Zatkin, Macy, and Kveton, 1959; Kohler, 1960; Coors and Mitchum, 1962; Kessler and Witmer, 1964; Petty and Mousley, 1966; Widmann, Schuman, and Poznanski, 1966).

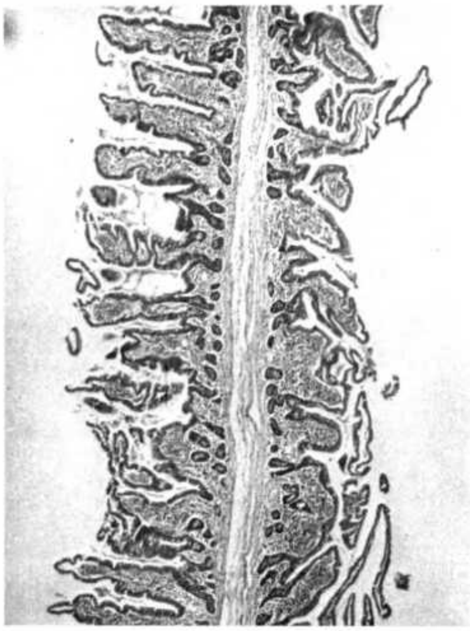

FIG. 5.—Section through the wall of the intraluminal diverticulum.

The aetiology of this lesion is unknown. It has been suggested that the anomaly represents true partial duodenal duplication. However, the facts that none of the reported cases was in babies or children and that a true duodenal duplication should contain all the layers of the duodenum while the intraluminal diverticulum has one layer of fibrous tissue which is covered on either side by intestinal epithelium do not support this theory.

Another theory is that the formation of the intraluminal diverticulum is caused by an incompletely developed duodenal diaphragm which sustains an almost continuous propulsive peristaltic force and forms an intraluminal sac which extends distally.

The third and most likely theory is that the folds of the mucosa in the second part of the duodenum which are transverse near to the ampulla of Vater are kept in almost continuous motion by peristaltic waves and gradually form an intraluminal sac.

All the previously reported cases have been found in adults aged from 22 to 71 years. The present case is in the youngest patient so far reported and has certain common features with other cases. The symptoms resemble those of peptic ulceration. Intermittent upper abdominal pain, discomfort, nausea, and vomiting were commonly found. Other symptoms included the invariable location of the intraluminal diverticulum in the second part of the duodenum with the opening lying proximally near to the ampulla of Vater and the blind end distally. The histological examination always shows epithelium on both sides of the diverticulum.

The diagnosis can be made only radiologically or at laparotomy. During screening peristaltic movements of the duodenum can be seen whilst the intraluminal diverticulum (translucent line) remains inert. Films should be taken in various positions in order to confirm that the diverticulum is intraluminal. The translucent line represents the thickness of the wall of the diverticulum.

Acknowledgement.—We should like to thank Dr. E. Rees, Department of Pathology, Royal Salop Infirmary, for the histological report and *Fig.* 5.

REVIEWS AND NOTICES OF BOOKS

Clinical Neurosurgery. Proceedings of the Congress of Neurological Surgeons, St. Louis, Missouri, 1970. Edited by GEORGE T. TINDALL, M.D. 9 × 6 in. Pp. 557 + xxxviii. Illustrated. 1971. Edinburgh: Churchill Livingstone. £8·25.

THIS volume is dedicated to Dr. Barnes Woodhall, guest and principal speaker at the Twentieth Annual Meeting of the Congress of Neurological Surgeons in October, 1970, at St. Louis, Missouri.

As one would expect, the majority of the contributors to this volume are from various surgical centres in America and Canada; there is one contributor from England, Mr. Walpole Lewin of Cambridge. He writes on 'Towards a Visual Prosthesis', and describes how an implant was inserted over the occipital cortex in a blind patient aged 47. Mr. Lewin has experimented on a series of baboons over the years and obtained some interesting results.

Dr. Barnes Woodhall contributes two interesting chapters on neurosurgical history. The first of these deals with 'Neurosurgery in the Past' and he concentrates mainly on the Dandy era, namely from 1926 to 1937. The second chapter is devoted to 'Neurosurgery of the Present', and Dr. Barnes Woodhall is of the opinion that neurosurgery came of age in the mid-trimester of this century.

The numerous contributors to this work cover every aspect of neurosurgical practice, such as neurogenic intermittent claudication, stenosis of the lumbar spinal canal, phantom limb pain, spontaneous intracerebral haemorrhage, cerebral ischaemia, brain scanning, stress ulceration, and the neurogenic bladder. The illustrations in this volume are very good.

At the end of each chapter there is a very complete list of references.

Every neurosurgeon will wish to possess this interesting book.

Year Book of Cardiovascular Medicine and Surgery. Edited by E. BRAUNWALD, M.D., San Diego; W. P. HARVEY, M.D., Georgetown; J. W. KIRKLIN, M.D., Alabama; A. S. NADAS, M.D., Boston; O. PAUL, M.D., Passavant; R. W. WILKINS, M.D., Boston; and I. S. WRIGHT, M.D., New York. 7½ × 5 in. Pp. 464. Illustrated. 1972. London: Lloyd-Luke. £6·80.

CARDIOVASCULAR medicine and surgery comprise a very active and progressive branch of medical science. *The Year Book of Cardiovascular Medicine and Surgery* helps to keep cardiologists and cardiac surgeons on their toes for it highlights all that is new during the year under review, namely 1971. The volume includes a considerable amount of research work on animals, such as the rat and the frog.

The normal and altered cardiovascular functions come under an extended review.

Cardiovascular disease in the infant and child is considered at some length and the result of surgical intervention assessed after some years.

Heart disease in adults, as one would expect, occupies a large section of this volume and articles on pacemakers are reviewed.

Angina pectoris and hypertension are considered at length.

Cardiovascular surgery, especially for ischaemic heart disease, is reviewed.

This is an excellent desk book for cardiologists and cardiac surgeons, and senior resident medical officers will find it of real value.

Les Tumeurs carcinoides du Tube digestif. By P. JOUANNEAU, Rouen, and M. MALAFOSSE, Paris. 9½ × 6½ in. Pp. 193. Illustrated. 1971. Paris: Masson et Cie, Editeurs. 45F.

OUR appreciation of carcinoid tumours of the digestive tract seems to have evolved from 'not very malignant, never giving metastases' to 'an affection that may have redoubtable endocrine and metabolic consequences'. The authors of the present book, setting out to provide an up-to-date and reasonably complete review of our knowledge, succeed to a very considerable extent. There is a general part dealing with important aspects, such as historical notes, pathology, diagnosis, applied physiology, and treatment. The fascinating biological features are amply discussed and explained. Armed with this knowledge, the reader can turn to the second half of the book, which deals with the various locations such as the small intestine, appendix, colon, etc. It is a pleasure to read this monograph, for in it we find a well-balanced blend of direct experience with the disease, based on 170 observations, and derived knowledge, obtained from the study of more than 500 papers. When treating a case of carcinoid tumour one will probably never turn in vain to this publication.

Curling's Ulcer. An Experiment of Nature. By STACEY B. DAY, BRUCE G. MACMILLAN, and WILLIAM A. ALTEMEIER, Cincinnati. 9 × 6 in. Pp. 286 + xxii. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $17.50.

ALTHOUGH some one hundred and thirty years have elapsed since Thomas Curling published his paper on the occurrence of duodenal ulcer after sustaining burns of the skin, little notice has been taken of this clinical observation, except for a passing notice in textbooks on surgery and pathology. With the establishment of burns centres at home and abroad following the Second World War a greater number of cases of Curling's ulcer has been collected.

The present monograph is published at an opportune time, for it gives a very comprehensive survey of the condition.

It is divided into three parts. Part 1 is concerned with the overall picture of post-burn gastro-intestinal ulceration as it has been explored by clinicians and research investigators over the years. The two World Wars presented a vast number of burn casualties and it was because of this that burn centres were introduced, especially in the Royal Air Force.

Part 2 is devoted to the clinical picture of Curling's ulcer and the accumulated clinical experience of the University of Cincinnati Medical Center General Hospital's Burns Unit and other burns units.

In Part 3 all the wide-ranging observations showing the multi-faceted nature of this condition are portrayed.

An excellent extensive bibliography can be found at the end of the book.

This is a worth-while guide for students and practitioners and as a reference book it could not be bettered.

In Appendix 1 there is a refreshing note on Thomas Blizard Curling, F.R.S., F.R.C.S., 1811–88.

Questions Colleagues Have Asked Me. By W. MELVILLE CAPPER, F.R.C.S., F.R.C.O.G., Bristol. Pp. 39. 1972. London: C.M.F. Publications. No price given.

THIS account is the substance of an address given at a meeting of the Christian Medical Fellowship on 15 March, 1961, in the hall of the Royal Commonwealth Society. Sir Clement Price Thomas, K.C.V.O., F.R.C.S., was in the chair.

This paper booklet has been published by the Christian Medical Fellowship in the belief that it will prove of inspiration and value to many surgeons both at home and abroad.

Sir Clement writes a foreword in which he speaks of Capper's influence and example.

A. S. Aldis of Cardiff contributes a tribute to a great Christian and a great surgeon. Melville Capper was a very active man and he examined in surgery at many universities and was on the Court of Examiners of the Royal College of Surgeons for several years.

Capper's experience as a devoted Christian is writ large in this excellent booklet, and surgeons far and wide will find much food for thought within its pages.

Die Inaktivitäts-Osteoporose. By J. MACH, Rostock. 8½ × 5¾ in. Pp. 207. Illustrated. 1971. Berlin: Verlag Volk und Gesundheit. 44.80 M.

DR. MACH has done a good job by writing a book about osteoporosis caused by inactivity, and it is probably the only complete survey of this subject. Osteoporosis is a symptom of diseases such as bone tuberculosis, Bechterew's disease, and rheumatic and neurological diseases.

Inactivity of the extremities because of bone lesions inevitably leads to osteoporosis, in the same way as muscle inactivity causes reduction of venous pumping, which can be demonstrated clearly in amputation stumps. Promoting muscular activity consequently is the logical method of preventing and healing osteoporosis; android steroids are perhaps the only other possibility. There are several methods of defining the degree of osteoporosis, for instance, by radiography, but a subtle technique is required to ensure that this is accurate.

Experiments have been performed on rabbits; on one leg the ischiatic nerve and the Achilles tendon were intersected, so that the breaking strength and elasticity of the legs could be measured. It was found that the breaking strength was significantly less on the artificially osteoporotic side.

Chemical tests showed that the calcium and phosphorus content did not decrease significantly in the artificially osteoporotic leg. The percentage of hydroxyproline, which is an important ingredient of collagen, appears to be lower than in healthy bone; this might prove to be one of the most reliable tests in determining osteoporosis.

Osteoporosis caused by weightlessness was discovered during the check-up of cosmonauts and this might be a warping for space flights in the future.

Advances in Surgery, Volume 5. Edited by CLAUDE E. WELCH, Boston, and JAMES D. HARDY, Jackson. 8¾ × 6 in. Pp. 354 + xiv. Illustrated. 1972. London: Lloyd-Luke. £8·65.

VOLUME 5 of *Advances in Surgery*, like the other volumes in this series, is devoted to a series of articles which covers certain aspects of surgery in which there has been significant progress within the past few years.

The best article in this book is that by Alan G. Parks dealing with all aspects of haemorrhoidectomy. The modern physiology of the rectum and anal canal is well set forth and the operative treatment of haemorrhoids is described in some detail. It is stimulating to see original line drawings which are easy to understand and which greatly enhance the written word.

Clinical diagnostic radiographs are described by Stuart S. Sagel and others, and they do demonstrate the great advances that have been made in current practices. New pharmacological agents have played their part in improving contrast media used in the chest, bile-ducts, and blood-vessels.

Insulinomas are considered in some detail by George L. Nardi, who records some 15 patients who were operated upon for hypoglycaemia. The pathology was found in the head of the pancreas in 5 cases, in the body in 4 cases, and in the tail in 6 cases.

The surgery of the parathyroid glands is dealt with by Chiu-an Wang, who considers that considerable progress has been made in the past decade in the diagnostic field of hyperparathyroidism.

The surgery of the adrenal glands is considered by John W. Raker, who advocates an arching, wide, transverse upper abdominal incision to explore the adrenal gland.

Diverticular disease of the colon is discussed in a lively and practical way by Richard and Robert Zollinger. Their article is illustrated by some very good line drawings.

Other subjects which come under critical review in this volume include the present status of tumour immunology, principles of tendon repair, and intra-abdominal sepsis.

This volume will be read with interest by all surgeons who wish to keep abreast of surgical advances.

A book for every surgeon's library because it is a useful reference volume.

Cancer do Pulmão. By JESSE P. TEISCEIRA, Rio de Janeiro. 8½ × 6 in. Pp. 197 + xiv. Illustrated. 1971. Rio de Janeiro: Editora Guanabara Koogan S.A. No price given.

THIS is a well-written, lucid textbook on carcinoma of the lung based largely on personal experience. The pathological, diagnostic, and therapeutic aspects are fully reviewed and are well illustrated. Although pre- and postoperative care and the techniques of thoracotomy and chest closure are well described, the resective procedures themselves are not discussed. Statistical data are presented based on 467 cases treated over 20 years, largely in one institution; the results conform with world-wide experience. A worth-while textbook for all doctors and particularly young general and thoracic surgeons.

Conduite thérapeutique d'Urgence chez les Polytraumatisés. By A. TRILLAT, Lyon, and A. PATEL, Garches. 9½ × 6¼ in. Pp. 118, with 16 illustrations. 1971. Paris: Masson et Cie, Editeurs. 28F.

THE paper which forms the major part of this book on the treatment of patients with multiple injuries was read at the annual meeting of the French Surgical College. To exclude minor problems the discussion was restricted to cases in which at least two serious injuries with repercussion on respiration or circulation were present. The treatment is discussed in relation to the first critical days and not to the late sequelae. The first part of the book analyses the different regions and tells us which conditions one should know and be aware of. The second part takes an integrated view and describes the types of patients one is likely to come across. The separate sections are very instructively summarized in small but most informative diagrams, and the whole subject-matter pertaining to the treatment is again condensed in one final 'master chart'. A very practical book that should find its way to all small hospitals and to the junior staff of the larger ones.

Cunningham's Textbook of Anatomy. Eleventh Edition. Edited by G. J. Romanes, C.B.E., B.A., Ph.D., M.B., Ch.B., F.R.C.S.Ed., F.R.S.E., Edinburgh. 10¾ × 8½ in. Pp. 996 + xv. Illustrated. 1972. London: Oxford University Press. £9.

Each of the systems in this, the fiftieth birthday or jubilee edition of a favourite, standard work has been revised by an expert anatomist or radiologist, and the length of the text has been kept down to the new, concise compass that so well fits the modified anatomical curricula found in many medical faculties today. Yet room has been found for good new material, especially in the sections on muscle action and on peripheral nerve injury. There is a new index which—so important in a work of this kind—gives the reader more than one chance of finding the fact he needs under headings of differing though equally familiar order. The diagrams and photographs are beautifully clear and the text is easy to read. The references have been brought up to date and include useful items on applied anatomy and radiology. It is a pity that space and other considerations have prevented the inclusion of more applied anatomy; those readers in the course of their surgical training would like to see this amended.

Gastroesophageal Reflux and Hiatal Hernia. Edited by David B. Skinner, M.D., Baltimore; Ronald H. R. Belsey, M.S., F.R.C.S., Bristol; Thomas R. Hendrix, M.D., Baltimore; and George D. Zuidema, M.D., Baltimore. 9 × 6 in. Pp. 208 + x. Illustrated. 1972. Edinburgh: Churchill Livingstone. £6.

This comprehensive review of the subject is a combined operation by members of the staffs of Johns Hopkins Hospital, Baltimore, and Frenchay Hospital, Bristol, in the proportion of 7 : 2, the majority dictating its transatlantic spelling and such inelegant neologisms as 'inapparent'.

After a short historical account the anatomy, physiology, and pathology of the lower oesophageal segment and of gastric reflux are described together with the symptoms of hiatus hernia. Then follows a description of modern investigations, the indications for medical and surgical treatment, the technical details of the surgical treatment, and finally two chapters on the management of recurrent hernia and of oesophageal strictures.

Oddly in so exhaustive a symposium nothing is said about aetiology, and the number of cooks involved leads to some disparity of view. For instance Dr. Hendrix in his chapter on the reflux barrier mechanism has little to say about the effect of the abdominothoracic pressure gradient which Mr. Belsey evidently (and this reviewer agrees) considers most important in preventing reflux; and the influence or very existence of that elusive lower oesophageal sphincter continues to be something of an embarrassment.

No distinction is made between para-oesophageal and 'rolling' hernias, although they are quite different, the former being congenital, the latter merely a radiological variant of an acquired sliding hernia. The diagrams illustrating them on p. 72 are misleading.

Mr. Belsey's account of the transthoracic technique of repair is excellent and is supported by an analysis of his own results. It is immediately followed by Dr. Zuidema's apologia for the abdominal approach, each of his arguments having been effectively demolished by Mr. Belsey. Dr. Zuidema reviews other authors' figures but gives none of his own.

The book is clear and readable and will be found useful by general surgeons and by Fellowship candidates who study it with a discriminating eye.

Coagulation Problems in Transplanted Organs. Edited by K. N. von Kaulla, M.D., Denver. 10 × 7 in. Pp. 190 + viii. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $16.50.

This book is the report of the proceedings of a symposium held in Germany in 1970. It has a number of contributions of high quality on the local coagulation occurring as a complication of rejection in transplanted organs. There are very adequate studies of the deposition of fibrin, fibrinolysis, and the production of fibrin-split products. With the exception of a contribution from Denver on hyper-acute rejection of renal allografts and xenografts there is very little on the nature of the initiating processes of coagulation. It is clear from this volume that studies on the ways in which an antibody combined with its antigen reacts to produce thrombosis and coagulation are needed. The role of platelets in the initiation of fibrin clot is not sufficiently discussed nor is the association between coagulation and complement activation. The conclusion that better anti-rejection drugs might be devised which interfere with coagulation as well as having an anti-complementary action is interesting, but, as in other situations of intravascular coagulation attacking the initiation processes, is more likely to be successful than trying to prevent the end-result of fibrin-stabilized intravascular thrombi. For those involved in the treatment of intravascular thrombosis there is much to stimulate in this book, as the changes in organ grafts provide such elegant experimental models for its study.

Innere Medizin, Parts 1 and 2. Third edition. Edited by Ludwig Heilmeyer, Freiburg, and Hans Adolf Kuhn, Wurzburg. 10½ × 7½ in. Pp. 1283 + xxxix. Illustrated. 1971. Berlin: Springer Verlag. DM.116.

This is the third and totally revised edition of a well-known textbook of general medicine aimed mainly at students. Increasing specialization in medicine has been dealt with by a large number of contributors, but the complete field of neurology has been omitted and paediatrics is excluded apart from infectious diseases. Illustrations are strictly limited but, on the other hand, the price of the two volumes is reasonable. The book is clearly written and contains an excellent subject index. It will certainly become popular with medical students in German-speaking countries.

Les Pièges de la Chirurgie vasculaire. By Jacques Dascotes, Lyon. 10 × 8 in. Pp. 168. Illustrated. 1972. Paris: L'Expansion Scientifique Française. 60F.

The title of this book—'Pitfalls in Vascular Surgery of the Limbs'—is certainly too modest. The authors mainly wished to point out the dangers that lie in wait in this field of surgery and how to avoid or to surmount them. They have, however, given much more; in fact a fairly complete handbook of operative surgery with an impressive amount of surgical pathology and some original alternatives to established methods. The first chapter describes the basic techniques in vascular operations and will provide anyone with a succinct introduction to this branch of surgery. The second chapter, rightly the longest one, discusses chronic obliterations with their topographical variations. The plea for using the extraperitoneal approach in aorto-iliac obliterations has a good case. The next chapter provides a fresh account of aneurysms and arteriovenous fistulae, while the fourth guides us through the dramatic world of the emergency cases. There are many clear line drawings, at which the French excel, and the reproduced roentgenograms are also amazingly informative. One has to admire the ease with which the authors find their way through this complicated field and can convey their acquisitions to others. The statement in the introduction that their experience is based on the treatment of 2600 patients certainly does not come as a surprise.

A Nurse's Guide to Anaesthetics, Resuscitation, and Intensive Care. By WALTER NORRIS, M.D., F.F.A.R.C.S., and DONALD CAMPBELL, M.B., Ch.B., F.F.A.R.C.S., D.A., Glasgow. 8½ × 5½ in. Pp. 181 + ix, with 112 illustrations. 1972. Edinburgh: Churchill Livingstone. £1·50.

THIS is a very interesting, easily understood, and well-written book. The photographs and diagrams are excellent and for the most part are self-explanatory. It is a book that should be purchased by consultants for the staff on their wards, as I am sure that it will be found useful for reference. My only criticism of the book is I feel that it should have a hard cover as reference books are handled so frequently.

Microbes in Action. Second edition. By HARRY W. SEELEY, jun., and PAUL J. VAN DEMARK, Cornell University. 11 × 8½ in. Pp. 361 + xii. Illustrated. 1972. San Francisco: W. H. Freeman and Company Ltd. £2·20.

THIS is a useful laboratory manual for students which aims at giving an appreciation of the basic characteristics of micro-organisms and their significance in disease, pollution, and other important factors affecting human life. The techniques of bacteriology are introduced by means of 90 experiments which include virus culture and serology. This up-to-date manual will be widely used in first-year university courses in microbiology.

Textbook of Surgery. Third edition. Edited by D. A. MACFARLANE B.Sc., M.Ch., F.R.C.S., London, and LEWIS P. THOMAS, B.Sc., M.Ch., F.R.C.S., Newport. 8½ × 5½ in. Pp. 796 + xi. Illustrated. 1972. Edinburgh: Churchill Livingstone. £4.

THE style of this textbook, in size, clarity of print, and layout of its sections, makes it a leader in sources of information for the undergraduate. The first chapters introducing the general principles of injury, repair, and infection supported by a short description of the relevant anatomy and physiology provide the essential base upon which the student can erect a well-understood picture of each clinical problem as it is approached. The text is written with a uniform lucidity from which it is easy to draw information with each subject covered evenly and very adequately. Line drawings embellish the text and tables help the reader to gather information without confusion.

That this textbook has reached its third edition already is sure proof of its value. The editors and contributors are to be congratulated on producing such an excellent book for the undergraduate on which to lay the foundations of surgical knowledge.

Das Ultrakurznarkoticum Methohexital. Edited by PROFESSOR DR. R. FREY, Mainz, DR. F. KERN, St Gallen, and PROFESSOR DR. O. MAYRHOFER, Wien 9 × 6 in. Pp. 188 + x. Illustrated. 1972. Berlin Springer Verlag. DM.28.

THIS paperback reports a symposium which was held in Frankfurt in December, 1970, on the short-acting anaesthetic agent, methohexital. The first five papers are devoted to the pharmacology of this drug and its effect on the body. The majority of the papers review different series of patients in whom this drug was used as an induction agent for various types of surgery. It would appear that Brietal Sodium (methohexital) is a satisfactory and widely used anaesthetic agent. This volume should be of interest to anaesthetists.

Selected Exercises from Microbes in Action. Second edition. By HARRY W. SEELEY, jun., and PAUL J. VAN DEMARK, Cornell University. 11 × 8½ in. Pp. 227 + xii. Illustrated. 1972. San Francisco: W. H. Freeman and Company Ltd. £1·80.

THIS book is a shortened form of the author's manual *Microbes in Action.* It comprises 57 of the 90 exercises that make up the full text and is designed for short courses in introductory microbiology. New exercises for the second edition deal with antimetabolite action, biochemical oxygen demand, precipitin reaction, and other current topics of interest.

Early Diagnosis of Human Genetic Defects. Edited by MAUREEN HARRIS, Ph.D., Bethesda, Maryland. 9 × 6 in. Pp. 229 + ix. Illustrated. 1972. Bethesda: National Institutes of Health. $2.50.

THIS book contains details of a symposium held at the National Institute of Health, Bethesda, Maryland, in 1970. It deals with the problems of detecting metabolic errors and evaluates the techniques of examinations performed on amniotic fluid and considers the problems of screening in relation to large populations. The risks of the techniques and their likely value are well discussed as are the problems of genetic counselling and the ethics involved in the screening programmes.

The book can be recommended strongly to all those with an interest in this field and the cost is very reasonable.

Allgemeine und spezielle Chirurgie. Edited by MARTIN ALGOWER, Basel. 9½ × 6½ in. Pp. 620 + xxii. Illustrated. 1971. Berlin: Springer-Verlag. DM.48.

THE advantage of this surgical textbook, to which several outstanding Swiss surgeons contributed, is that it is entirely up to date.

Recent developments and techniques are recorded, while the inheritance of the past, when only of historical interest, is either briefly mentioned or omitted completely.

The chapters dealing with orthopaedics, urology, and paediatric surgery give a schematic survey, though no essential problems are left out.

The book is to be recommended for students and general practitioners in particular since much advice for surgery in general practice is included.

Thoracic Surgical Management

J. R. BELCHER, MS, FRCS
Surgeon, London Chest Hospital, Thoracic Surgeon, Middlesex Hospital and

M. F. STURRIDGE, MS, FRCS
Surgeon, London Chest Hospital, Thoracic Surgeon, Middlesex Hospital

This newly revised edition is a clearly written, simply illustrated and thoroughly practical guide for those engaged in the day-to-day management of thoracic surgical patients. With the enormous increase in the scope of cardiac surgery has come a better understanding of the principles of resuscitation and supportive management. All members of the intensive care team, as well as surgeons, will find this book of considerable value. The authors are both well-known London chest surgeons. Mr Belcher is particularly interested in the growth of medical care in the developing countries in his own field, and has travelled widely in India, Malaysia and Indonesia on lecture and study tours.

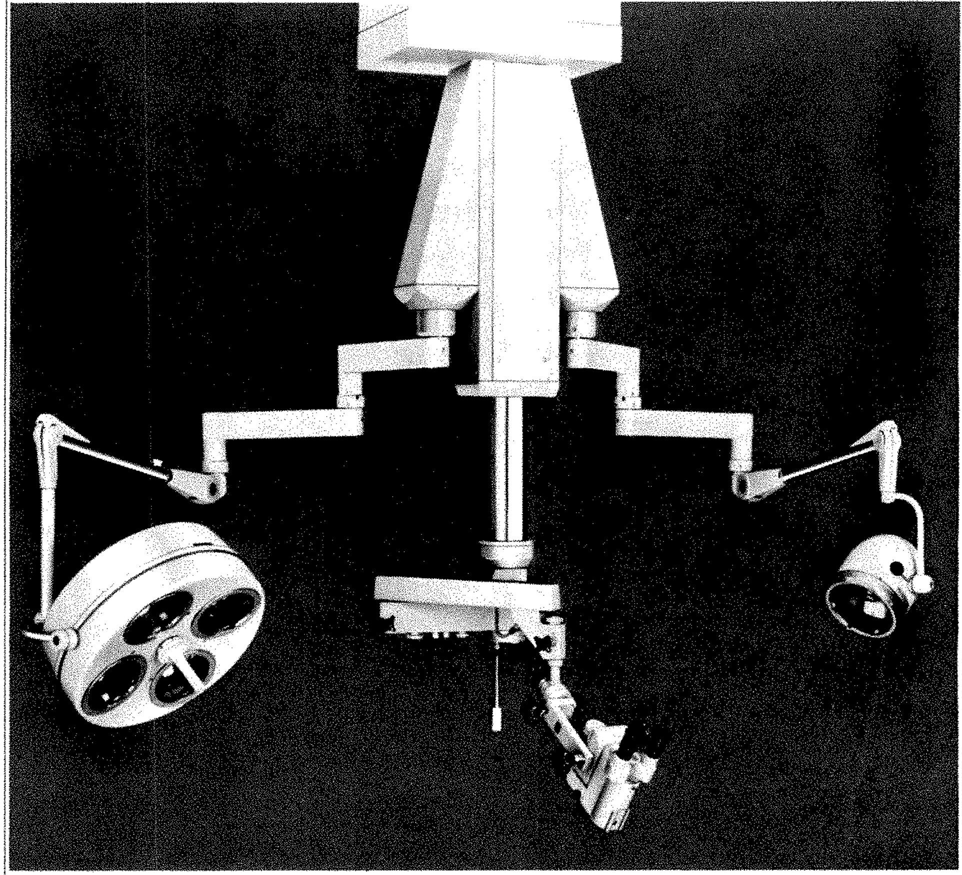
ZEISS

Ceiling
Suspension
Unit



for all Zeiss Operating Microscopes

Now available with a mounting for two Hanau Lamps providing complete flexibility of the positioning of either lamp. A choice of alternative Hanau Lamp models and combinations of lamps can be made.
The Zeiss Ceiling Suspension Unit is ideal for both existing as well as new surgical units. The microscope is lowered and raised by a hand or foot control and it can be kept in a complete assembled condition for maximum ease of setting-up by the surgeon and for reduction in wear and tear of the instrument.

Matburn M

*The supreme four section operation table**. . .

This is the supreme four-section operation table: grouped head-end control, the fullest range of positions and a series of over fifty accessories give the M the flexibility to meet the demands of any branch of surgery, and any procedure from routine examination under anaesthesia to advanced neurosurgical operations.

Built to the highest standards of engineering skill and precision, Matburn M combines absolute rigidity with easy mobility when required.

*More Matburn M Operation Tables are sold in this country every year than any other table.

RADIOTOM 619

for surgical diathermy

The *RADIOTOM 619 is a universal electrosurgical apparatus designed to meet all the clinical requirements of general surgery and the special requirements of neurosurgery.

The RADIOTOM 619 can be placed on a trolley. The small dimensions and the low weight of the unit also make it possible to mount it in a ceiling column, build it into a wall or to use it on a wall bracket or a floor column.

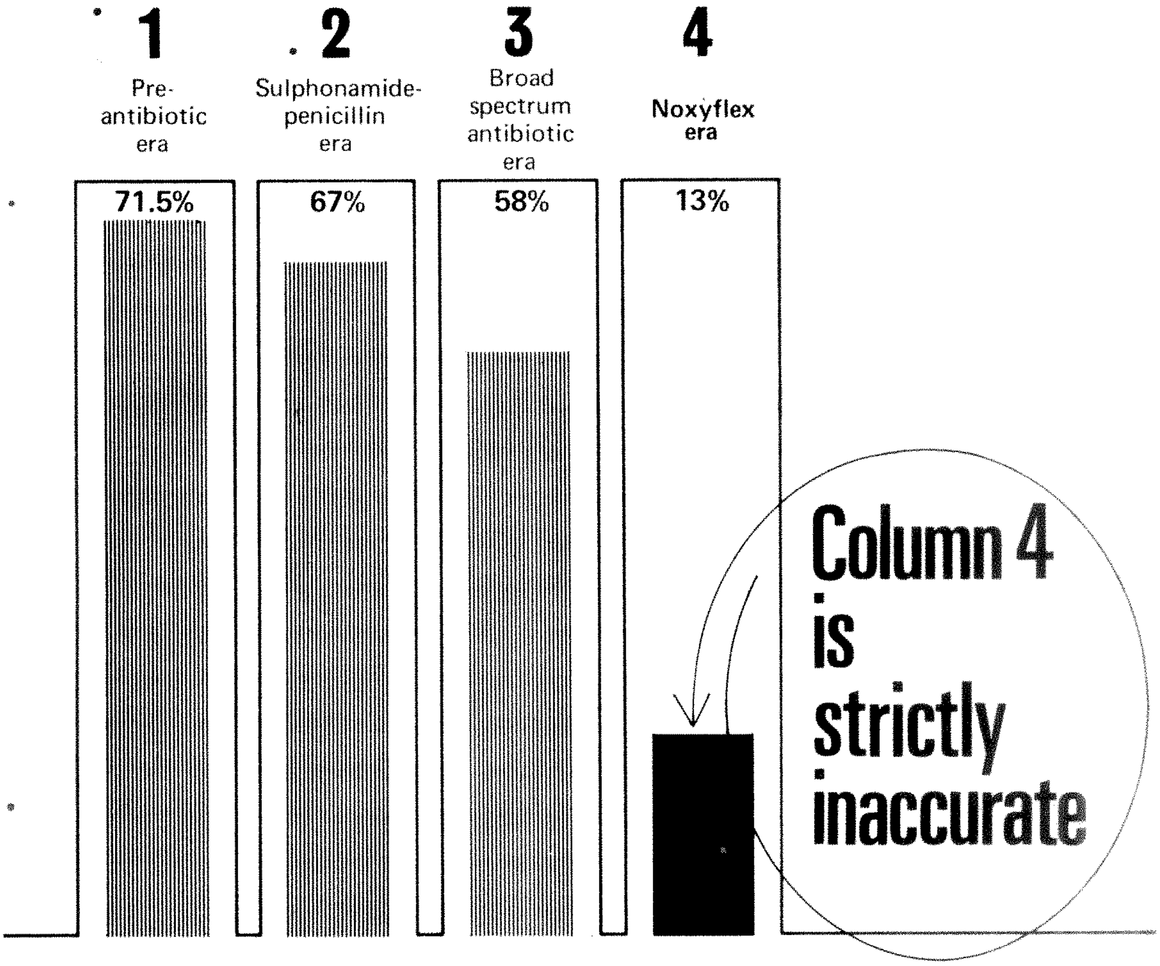
The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Column 4 is strictly inaccurate

Why inaccurate? Because column 4 refers to 23 cases of faecal peritonitis which were treated successfully with Noxyflex. But the *3 deaths which occurred were due to causes other than peritonitis – as post-mortem revealed. **The mortality rate due to peritonitis can therefore be regarded as zero.**

* The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

When bacterial contamination of the peritoneum is diagnosed or suspected: Noxyflex

John Wright ***SELECTED TITLES***

Emergency Surgery

Ninth edition. Edited by T. J. McNAIR, M.D., F.R.C.S. (EDIN.), F.R.C.S. (ENG.), Consultant Surgeon, Royal Infirmary of Edinburgh.
Extensively revised and with about 200 new illustrations, the theme of this book still remains: when to operate, when not to operate, and how to operate under emergency conditions.
998 *pages* 1155 *illustrations* **£12·50**

Fundamental Physics of Radiology

Second edition. W. J. MEREDITH, O.B.E., D.SC., F.INST.P., Director of Physics, Christie Hospital and Holt Radium Institute; and J. B. MASSIE, B.SC., F.INST.P., Physicist, Christie Hospital and Holt Radium Institute.
In the second edition a new chapter on the treatment prescription and an appendix on modulation transfer functions have been added.
674 *pages* 460 *illustrations* **£6·25**

The Arterial Anatomy of the Kidney

F. T. GRAVES, M.S., F.R.C.S., Urological and Senior Surgeon, Staffordshire General Infirmary, Stafford.
This book is a complete work of reference on the vascular and arterial systems of the kidney, based on investigations covering many years. With the ultimate aim of improving renal surgery, a complete chapter on surgical technique has been included.
116 *pages* 75 *illustrations* **£3·25**

Surgical Techniques

HERBERT HAXTON, B.SC., M.D., CH.M. (ST. ANDREWS), F.R.C.S., Senior Surgeon, Crumpsall Hospital; Manchester Northern Hospital; Royal Manchester Children's Hospital.
This book has been written in two parts covering surgical techniques in general and techniques in specific operations. During thirty years of surgical experience the author has modified his own surgical practise in many ways, and believes that other surgeons might benefit from a description of his methods, in particular the departures from the usual.
212 *pages* 158 *illustrations* **£2·50**

JOHN WRIGHT & SONS LTD, BRISTOL, ENGLAND BS8 1EX

Why Dexon*?

1. Easy to handle – similar to silk or linen thread
2. Packed dry – convenient to use
3. High tensile strength – excellent wound support
4. Smaller gauges needed for comparable strength compared with gut
5. Braided construction – secure knots – more security
6. Predictable absorption even in contaminated areas
7. Minimal tissue reaction and inflammatory response
8. Improved patient comfort
9. Permits undisturbed wound healing
10. Less painful wounds
11. Shorter hospitalization
12. Improved cosmetic results especially with subcuticular stitches
13. [illegible]here when it is needed, but has gone when it is not
14. Multi-uses means greater economy
15. May be removed as usual when used for skin sutures but may be left to absorb if preferred – e.g. paediatric surgery, under orthopaedic plaster casts, episiotomy repairs, circumcisions, etc.
16. Simplified stock holding, laying up for operations, nurse training
17. It is supplied on the best suture needles made

Why not?

1. The braided construction may mean an initial difficulty in tying knots
2. A slight increase in tissue-drag may be experienced. Can be improved by wetting
3. Absorption of blood and other body fluids may make Dexon more difficult to see
4. Suture for suture it appears to be more expensive than other materials – cost in use is probably less
5. It is different and you may need to especially ask for it

Dexon* the suture that supersedes catgut

ICI introduces the

AVLOX 18 SYSTEM

Trade Mark

The AVLOX 18 System from ICI provides a new and simple method of wound closure.

Simply hold the wound edges together with forceps and apply clips along the length of the wound.

Obviously this technique offers advantages. It is fast, easy to use and convenient. It reduces the risk of permanent marks because the clips hold and do not generally penetrate the skin.

The AVLOX REMOVER (also illustrated) has been specially designed to minimise discomfort during clip removal.

Both the AVLOX 18 and the AVLOX REMOVER are supplied sterile and ready for use.

Enables uterine contents to be removed by suction applied through a wide aperture, swivelling curette which can be rotated freely through 360°, without kinking the flexible suction tubing, to facilitate sweeping of the whole of the intra-uterine surface. A perforated basket within the suction bottle retains the aspirated tissues clear of blood to be immediately visible for identification. F171–03 Down's Intra-Uterine Suction device with pump for abortion by Intra-Uterine suction, as illustrated. F171–08 to F171–14 suction curette, 8 mm, 10 mm, 12 mm and 14 mm for use with above apparatus.

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·83	£3·70	£4·27	£5·70	£5·69	£6·32	£7·74	£8·99
4	3·58	5·19	6·09	7·12	8·07	9·09	10·97	12·97
6/8	5·94	7·62	9·27	10·84	12·59	14·09	17·47	20·72
10/12	9·32	12·72	15·09	17·72	20·34	22·97	28·40	33·05
14/16	10·37	14·34	17·47	20·59	23·72	27·03	33·18	39·55
18/20	14·62	19·47	23·47	27·47	31·78	35·93	44·05	50·89
COVERS	1·94	2·75	3·57	4·38	5·19	6·00	7·63	9·25

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 59. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St Martin's House,* 159 *Clapham High Street, London, SW4 7SU* (telephone 01-622 9225).

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

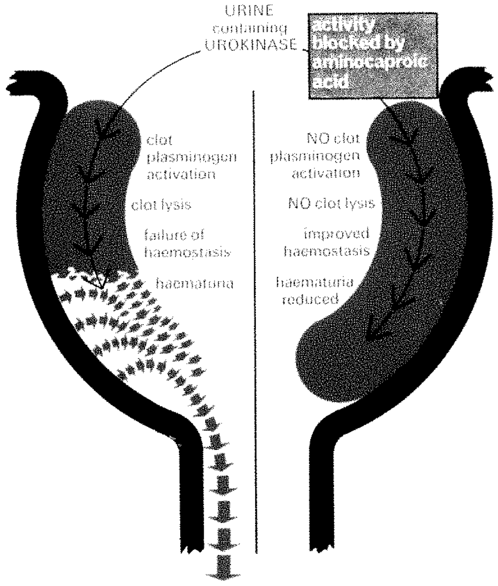
TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

The mechanism of post-prostatectomy bleeding and EPSIKAPRON® control



Epsikapron (aminocaproic acid) is rapidly excreted in the urine in high concentration; there it inhibits urokinase, the fibrinolytic enzyme in urine. With the haemorrhage-sustaining property of urine blocked, the haemostatic coagulum becomes adequate, and blood loss is diminished substantially.

Epsikapron makes your prostatectomy patient's post-operative course smoother by diminishing:

- the need for post-operative blood transfusion
- clot retention
- catheterization
- the risk of infection
- the period of hospitalization

Presentation

Epsikapron Solution for Injection 0.4 g/ml Box of 6 ampoules of 10 ml, each containing 4.0g aminocaproic acid (0022/5003) Epsikapron Effervescent Powder 50% Box of 30 sachets, each containing 3.0g aminocaproic acid (0022/5004) Epsikapron Syrup 0.3g/ml Bottle of 250ml (0022/5005)

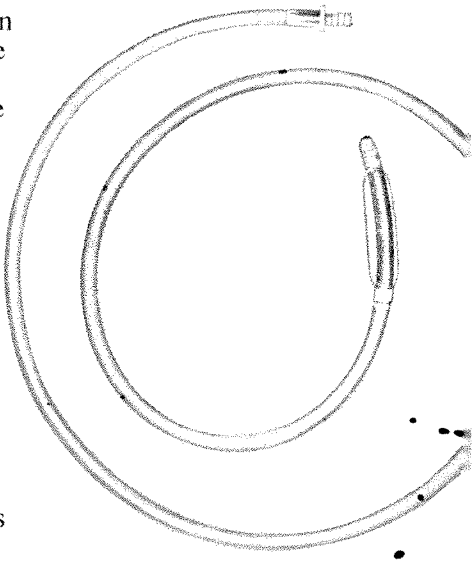
Our research is done in close consultation with the medical profession, and as a result we have devised equipment and test procedures where none previously existed. One such is the Portex Flex Test for Intravenous cannulae.

Our new product development programme has made possible significant advances in medical techniques. Like the Atrial Cannula. Like the Salpekar Tracheostomy Tube. Like the Cholangiogram Cannula. And more.

We are also in the forefront of the development of disposable products. This has entailed still further expertise and leadership in sterility procedures, biocompatibility testing, raw materials standards, identity and containment of microbial contaminant levels.

We like to feel that our research supports your search for greater medical advances.



)ur research sheds a little
light on your problems

sophageal Stethoscope
This is a new product which
vides a simple, yet highly
cient method of monitoring
rt sounds. It is particularly
ful during paediatric and
rosurgical procedures.
ilable in three sizes, all double
pped and sterile.

e Line Tracheostomy Tube
The new Portex tracheostomy
e has an extra smooth
-irritant finish designed to
w easier suction catheterisation.
strong inert floppy cuff allows
er inflation pressures.
h tube is supplied with a one
valve and its own spool
eck tapes.

Cuffed Blue Line Endotracheal Tube Designed with a new thin wall to give up to $\frac{1}{5}$ mm larger lumen than before and with even better slip properties. The cuff is inflated symmetrically via the airline which is incorporated into the wall without reduction of lumen.

BRITAIN'S LIFE LINE TO THE WORLD

PROLENE*

Monofilament Polypropylene

the most inert suture known

PROLENE provokes the minimum possible tissue reaction and combines improvements in tensile strength and smoothness over monofilament nylon with vastly superior knotting and handling qualities.

PROLENE suture may be used wherever a non-absorbable surgical suture is recommended.

ETHICON*

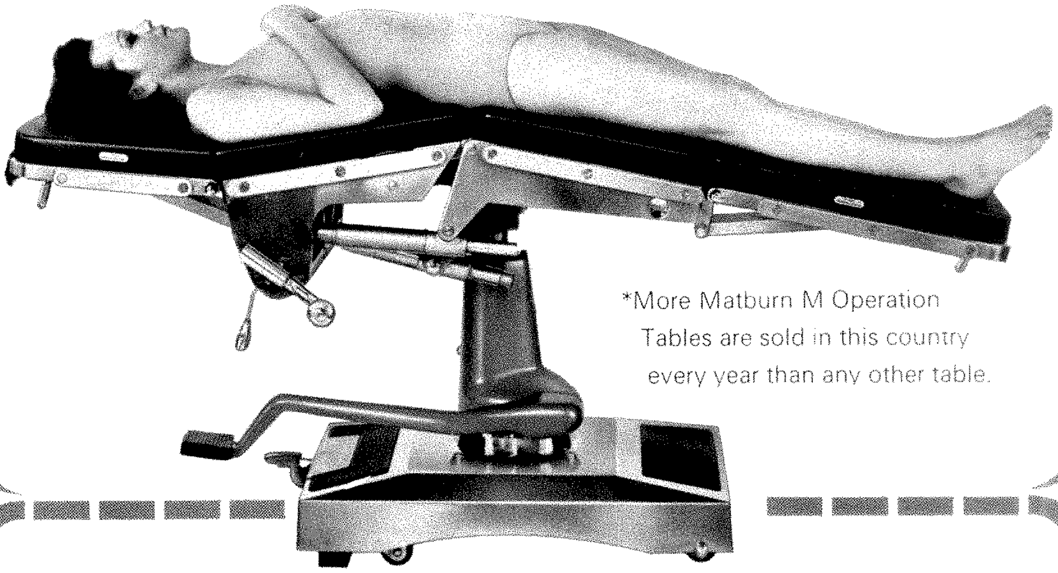
. . . leadership in wound repair

Matburn M

The supreme four section operation table*. . .

This is the supreme four-section operation table: grouped head-end control, the fullest range of positions and a series of over fifty accessories give the M the flexibility to meet the demands of any branch of surgery, and any procedure from routine examination under anaesthesia to advanced neurosurgical operations.

Built to the highest standards of engineering skill and precision, Matburn M combines absolute rigidity with easy mobility when required.



*More Matburn M Operation Tables are sold in this country every year than any other table.

ESCHMANN

. . . . there's no reason why anyone should be able to tell. There's no reason why a patient with a colostomy and those around him should be embarrassed by odours and tell-tale noises.

Celevac (a special grade of methylcellulose) enables the patient to control his bowel action—absorbs, and holds in loose chemical bondage, both H_2O and H_2S. Your patient can live with his colostomy—and others can live with your patient.

Give him Celevac—and a copy of our booklet "The Home Management of a Colostomy"—and he will be doubly grateful.

ORIGINAL PAPERS

CARCINOMA INVOLVING THE LOWER ALVEOLUS

AN APPRAISAL OF PAST RESULTS AND AN ACCOUNT OF CURRENT MANAGEMENT

By E. STANLEY LEE
CONSULTING SURGEON, WESTMINSTER HOSPITAL GROUP

AND J. S. P. WILSON
CONSULTANT PLASTIC SURGEON, WESTMINSTER HOSPITAL GROUP AND ST. GEORGE'S HOSPITAL GROUP

SUMMARY

Three hundred and fifty-six cases of carcinoma of the buccal mucosa, lower alveolus, and mouth floor treated under a policy of radiotherapy as the method of first choice are reviewed. Alveolar involvement, whether initial or by extension, greatly reduces the chance of radiotherapeutic success, and is more important in this respect than the exact site of origin of the tumour. A decision to switch to a trial of elective surgery in this group of cases with alveolar involvement was strengthened by major advances in surgical management, especially the evolution of satisfactory techniques of repair. A cardinal point is that tumour excision and closure of the mouth defect can now be accomplished reliably in one stage. The uses of the 'island' forehead flap and of Bakamjian's deltopectoral flap are discussed, as well as the methods of providing mandibular support when necessary. The authors' current techniques are described in detail on the basis of 82 consecutive radical procedures. A preliminary survey of the results suggests that surgery in this group may yield better results than radiotherapy.

In this paper based on the experience at Westminster Hospital the authors have endeavoured to set out a critical review of the treatment of mouth cancer, to focus attention on the mandible as an obstacle to successful radiotherapy, and to give an account of the current surgical procedures which now furnish an acceptable alternative.

THE HISTORICAL PERSPECTIVE

The history of the evolution of radical surgery for mouth cancer makes grim reading. Henry Butlin (1885, 1900), of St. Bartholomew's Hospital, traced it from the seventeenth century, noting such advances as the preliminary ligation of arteries, splitting of the cheek or division of the mandible to improve access, and the approach from the neck. In 1844 Sédillot had described midline splitting of the lip and mandible, and in 1858 Syme had used the method on two occasions, but both patients had died. A year later Fiddes (1859) reported a success, and Syme himself gave a dramatic account of a successful case in 1865. Kocher in 1880 recognized the implication of a metastatic node while removing a tumour of the tongue, and proceeded to excise the affected nodes through a Y-shaped neck incision. It was Kocher, too, who advocated tracheostomy for these operations. The first recorded in-continuity removal of a tumour of the central mandibular arch, mouth floor, and tongue was performed by Heath in 1875 (published in 1899). Gardham (1953) has described this successful case in some detail.

In a series of communications between 1894 and 1909 Butlin recorded his successes and failures in a series of over 200 excisions. In 5 patients with involvement of the mandible he established a technique for resecting the mouth floor, mandible, and nodes in continuity. Sound though the principles were, however, all 5 patients developed infection of the deep fascial planes of the neck, leading to fatal mediastinitis. Despite such setbacks surgeons continued to increase the scope of their operations. In 1906 Crile published a series of 132 radical neck dissections. Trotter (1913) stressed that a wide margin of macroscopically normal tissue around the growth was essential if surgical cure was to be hoped for. Modern concepts of *en bloc* resection of tumour, mandible, and nodes were evolved by Martin (1941, 1948), Sugarbaker and Gilford (1946), Conley and Pack (1949), Edgerton (1951), Ward and Robben (1951), Slaughter and Southwick (1952), and many others.

By this time, however, the ambitious scope of the excisions had outstripped the possibilities of repair.

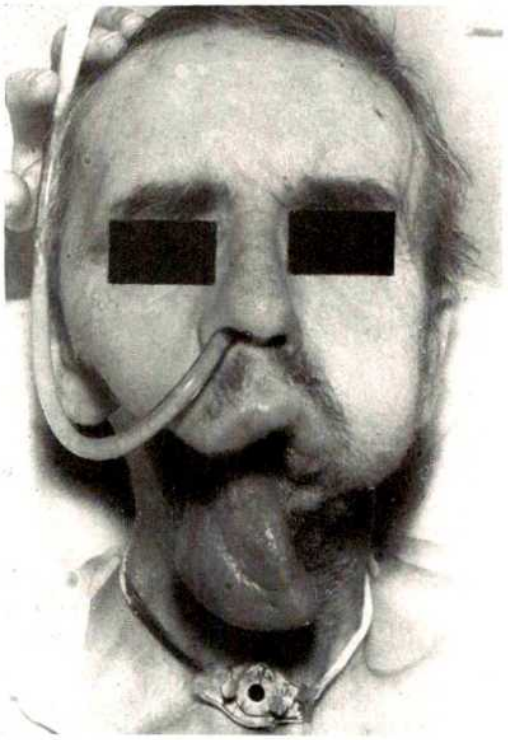

FIG. 1.—Failure of repair after excision of a carcinoma.

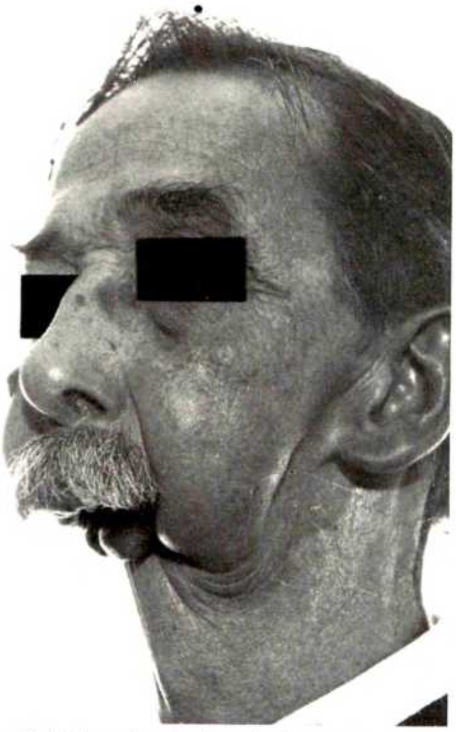

FIG. 2.—Unsightly end-result due to inadequate techniques of repair.

If the mortality was reduced by better anaesthesia and supportive methods, the morbidity and disablement were depressing. A main difficulty was the long interval which inevitably elapsed between the resection and the successful closure of the defect. During this time the often elderly and debilitated patients had to sustain all the miseries of a large oral fistula which were demoralizing to the patient, the nurses, and the rest of the ward (*Fig.* 1). All too frequently, eventual closure was obtained only at the cost of a tethered tongue and distorted facial soft tissues, leaving the patient after his long ordeal with a hideous and permanent deformity (*Fig.* 2).

Against this gloomy background, the possibilities of radium and radiotherapy had meanwhile gained increasing recognition as a welcome alternative. By the 1920's interstitial radium implantation was becoming standardized (Régaud, 1920, 1925; Lacassagne, 1921), giving good curative and palliative results with far less distress and mutilation to the patient. External irradiation (teletherapy), too, though at first crude and unsatisfactory, made phenomenal strides to become the sophisticated weapon that it is today, capable of excellent results and particularly useful in cases where radium implantation is impossible. At the Westminster Hospital radiotherapy was championed by Cade (1929), himself a surgeon, and for nearly 50 years it has been the agreed method of choice in treating primary mouth cancer. For the nodes, surgery has always been preferred.

Statistically satisfying comparison of the results of radiotherapy with those of surgery has always been difficult. Various large-scale reports have been published (Ledlie and Harmer, 1950; Ward, Edgerton, Chambers, and McKee, 1959; Ash, 1962; Frazell and Lucas, 1962), but the sources of the material and the degree of selection of the cases are often obscure and there is sometimes obvious disparity between surgical and radiotherapeutic series. Alford and Klopp (1958), writing of their surgical experience, admit: 'The present series included those patients in whom it was deemed possible to remove all visible and palpable cancer. Most of the lesions in these patients would have been classified as relatively early cancer . . .', yet later they claim: 'The results compare favourably with those obtained with radiation therapy.' The experience at the Memorial Center, New York, has been reviewed in an important series of papers (O'Brien and Catlin, 1965; Cady and Catlin, 1969; Harrold, 1971), but the comparisons are between modern radical surgery and obsolete radiotherapy. Binnie, Cawson, Hill, and Soaper (1972) have reviewed the *collected* nation-wide material from England and Wales made available by the National Cancer Registration Scheme begun in 1962, and they believe that the cases registered now include perhaps 90 per cent of the whole mouth cancer incidence. The figures demonstrate an apparent superiority of surgical over radiotherapeutic results, but the authors point out the invalidity of the comparison since the worst lesions and the poorest-risk patients were usually treated by radiotherapy.

We have always felt that the Westminster Hospital mouth cancer results in general (Cade, 1940) have compared favourably with those of radical surgery. In a study of 653 consecutive cases of tongue carcinoma (Cade and Lee, 1957) the over-all 5-year absolute cure rate for tumours of the anterior two-thirds of the tongue was found to be 35 per cent, and for lesions 2 cm. or less in diameter, 60 per cent. It must be stressed that the series included every case seen at a hospital which offers both irradiation and surgical treatment. Moreover, these results were obtained by the relatively minor procedures of radium implantation or teletherapy and minor diathermy, with neck dissection where necessary. The function of the healed tongue was in general far better than is usual after extensive glossectomy.

Table I.—Sex Distribution and Number of Cases treated from 1949 to 1965

Site of Lesion	No. of Males	No. of Females	Total No. of Cases
Buccal mucosa	74	47	121
Lower alveolus	63	30	93
Mouth floor	110	25	135
Total	247	102	349*

* There were also 2 patients with diffuse unclassifiable lesions, and 5 patients with multiple lesions not in same site.

Table II.—Age Distribution and Sex Ratios

Site of Lesion	Average Age (years)	Male Patients (per cent)
Buccal mucosa	64·5	61
Lower alveolus	65	68
Mouth floor	66	81

We have been increasingly aware, however, that radiotherapy has not been equally successful for all parts of the oral cavity and that failure is often seen in lesions close to bone. This feature tends to be concealed by the customary site classification so that for the present review we have grouped these three sites together as one continuous mucosal surface. In this way the effect of alveolar involvement on the results of treatment can be studied.

The appraisal has been made timely by the development of newer surgical techniques which are proving very successful in overcoming the former problems of resection and reconstruction, as described later in this paper.

I. REVIEW OF RESULTS 1950–65

Material.—From 1950 to 1965, 356 patients with carcinoma of the buccal mucosa, lower alveolus, and mouth floor were treated at the Westminster Hospital, London, and the Regional Radiotherapy Centre, Guildford, Surrey. Fifty of these cases had already received some treatment elsewhere and came with either persistent disease or major or minor recurrence of some kind. For the purpose of this review there seemed no point in separating these patients from the new cases. Nineteen patients had multiple lesions, and a total of 371 lesions was treated, including 13 adenocarcinomas. In *Tables I* and *II* the cases are analysed as to sex and age and location of the tumour. It should be noted that 133 patients (37 per cent) were between 70 and 79 years old, 38 (11 per cent) were between 80 and 89, and 6 patients were over 90 years old. Accurate T.N.M. staging (U.I.C.C. Geneva, 1968) has proved difficult in retrospect and the nearest approximation has been to divide the primary tumours into three groups according to whether the maximum diameter of the tumour was up to 2 cm., 2–5 cm., or more than 5 cm. (*Table III*). The tables comprise all the cases which were seen, including advanced lesions suitable for palliation only. Clinical node involvement as is shown in *Table IV* and those patients with no involved nodes at presentation have been subdivided into those who did and those who did not later develop malignant nodes. The clinical assessment of lymph-node involvement is notoriously inaccurate, and in the case of the mouth floor specially so because of the frequent enlargement and induration of the salivary gland owing to blockage of the duct.

Table III.—Staging of the Primary Lesion

Site of Lesion	Size of Lesion		
	2 cm. and less	2–5 cm.	5 cm. and more
Buccal mucosa	19	66	15
Lower alveolus	30	57	13
Mouth floor	25	68	7

All figures are percentages.

Table IV.—Degree of Lymph-node Involvement

Site of Lesion	No Involved Nodes at Presentation		Nodes Clinically Malignant at Presentation
	None at Any Time	Developed Later	
Buccal mucosa	42	28	30
Lower alveolus	40	14	46
Mouth floor	27*	26*	47*

* Salivary-gland enlargement due to duct involvement makes figures unreliable.

All figures are percentages.

Treatment.—The policy has remained remarkably constant for over 30 years.

Primary Tumour.—First preference, as already stated, was for interstitial radium therapy when possible, to a dose which was seldom less than 6000 rad and sometimes as high as 8000 or 9000 rad in about 7 days in small lesions (*Fig.* 3). If implantation was not possible teletherapy with cobalt or megavoltage X-rays was used, generally with multiple fields or a rotating source. In this way it was usually possible to achieve tumour doses of 6000 rad in 6 weeks without serious damage to the rest of the mouth.

The proximity of the mandible has always posed a problem because the bone, especially if it is exposed by ulceration or involved in the disease, is very vulnerable, and some risk of necrosis has to be accepted. When sequestration follows the insertion of radium needles very close to the bone, the resultant sequestrum is usually superficial and flake-like, separates cleanly if given time, and often heals soundly (*Fig.* 4), but in some advanced lesions with gross bone involvement treated by teletherapy more extensive necrosis is inevitable (*Fig.* 5). In suitable cases this has been dealt with by subsequent surgical ablation (*Fig.* 6); in a few others good palliation has been obtained by per-oral extraction of the dead bone with nibbling forceps.

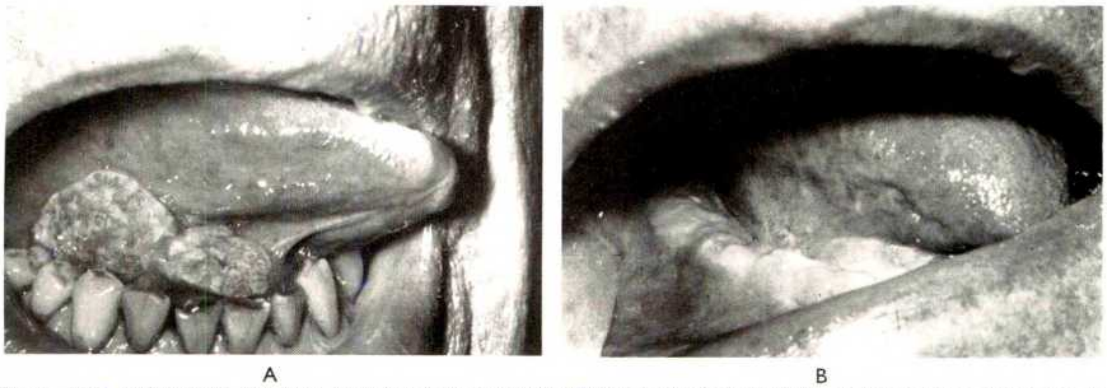

FIG. 3.—Male, aged 62 years. Squamous carcinoma of the mouth floor (A) before and (B) 8 years after a radium implant. Patient remains well after 10 years.

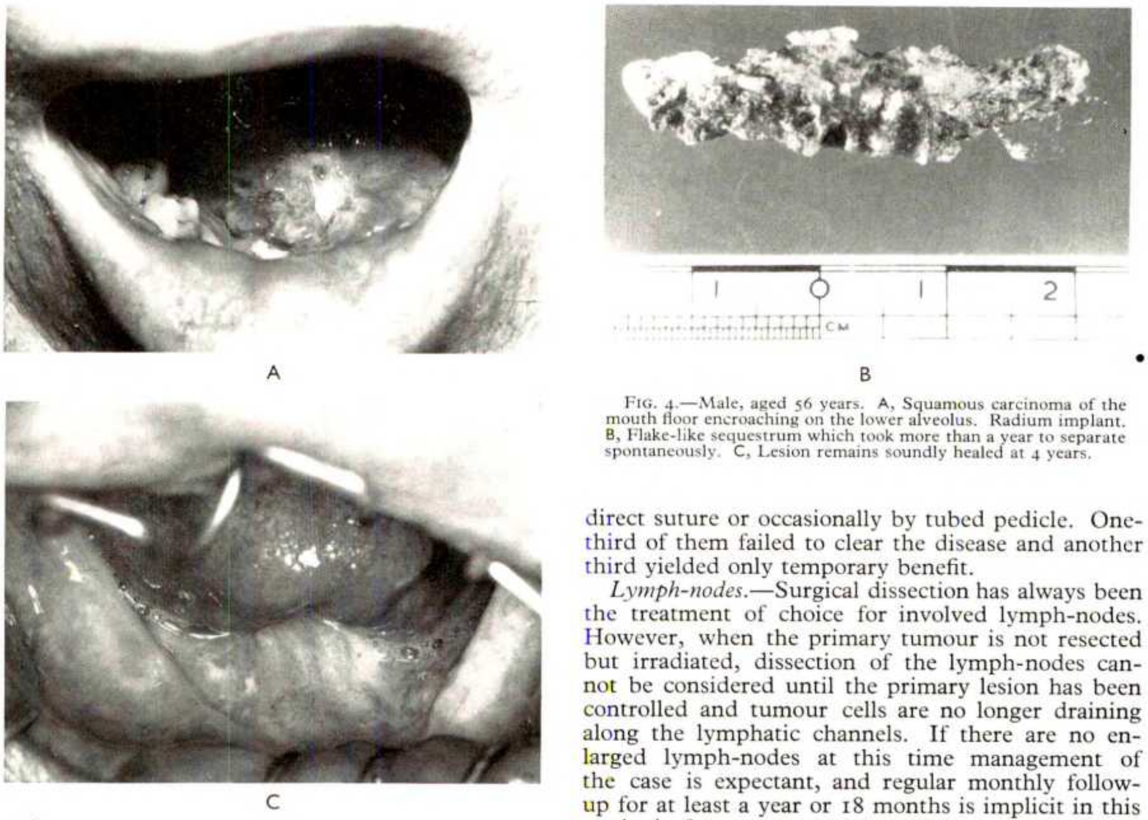

FIG. 4.—Male, aged 56 years. A, Squamous carcinoma of the mouth floor encroaching on the lower alveolus. Radium implant. B, Flake-like sequestrum which took more than a year to separate spontaneously. C, Lesion remains soundly healed at 4 years.

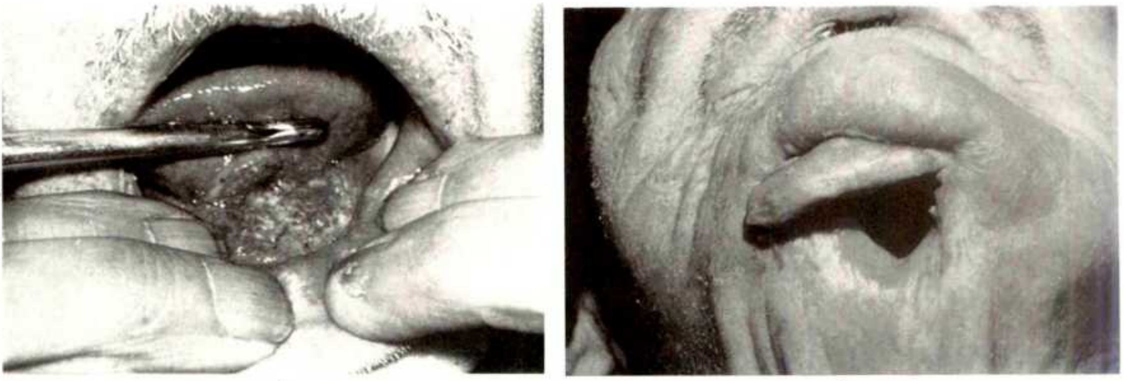
During the period under review only 68 resections of mandible were carried out and, of these, only 4 were elective. The rest were for persistent or recurrent tumour after teletherapy or radium implantation, sometimes with bony necrosis. Most were in the nature of palliative procedures, closure being by direct suture or occasionally by tubed pedicle. One-third of them failed to clear the disease and another third yielded only temporary benefit.

Lymph-nodes.—Surgical dissection has always been the treatment of choice for involved lymph-nodes. However, when the primary tumour is not resected but irradiated, dissection of the lymph-nodes cannot be considered until the primary lesion has been controlled and tumour cells are no longer draining along the lymphatic channels. If there are no enlarged lymph-nodes at this time management of the case is expectant, and regular monthly follow-up for at least a year or 18 months is implicit in this method of management. Any patient who for some reason cannot attend for follow-up provides one of the exceptional indications for elective block dissection. In cases presenting with the lymph-nodes already involved the nodes may be given holding teletherapy as soon as the radium needles have been removed from the primary site, and block dissection then follows as soon as the primary tumour is healed. When massive and perhaps inoperable nodes are



A B

FIG. 5.—Male, aged 74 years. A, Large midline carcinoma of the mouth floor and alveolus. This was treated by cobalt teletherapy and radium implant. B, The tumour was destroyed, but sequestration of the entire midarch of the mandible occurred. The fistula eventually closed with minimal surgery, and the patient died 4 years later without local recurrence or involved nodes.

Table V.—FIVE-YEAR SURVIVAL RATE RELATED TO THE SITE OF THE LESION

SITE OF LESION	5-YEAR SURVIVAL RATE (per cent)		
	Male	Female	Total
Buccal mucosa	47	42	45
Lower alveolus	30	40	33
Mouth floor	26	36	27

Table VI.—FIVE-YEAR SURVIVAL RATE RELATED TO ALVEOLAR INVOLVEMENT

ALVEOLAR INVOLVEMENT	NO. OF CASES	SURVIVORS	
		No.	Percentage
Alveolar mucosa free	114	55	48
Alveolar mucosa involved	230	67	29

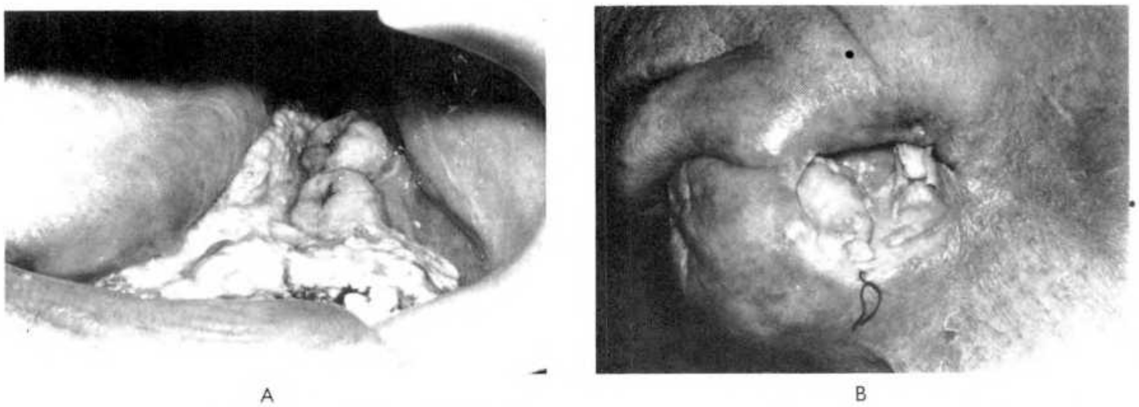
present from the start, treatment is usually by teletherapy to both the primary tumour and the nodes, and the tendency in these cases with a poor prognosis is to concentrate a high dosage on the involved nodes, giving less regard to the rest of the neck. Occasionally, inoperable node masses have been implanted with radium. Operable nodes are always dissected for choice, and if histology confirms the presence of metastases radiotherapy to the neck is usually given postoperatively.

Neck dissection was carried out in 58 of our 356 cases, but in the earlier years of the review many of these were partial (suprahyoid dissections). The effect of this conservative policy towards the lymph-nodes upon the 5-year cure rate is considered below.

Results and Discussion.—The results of therapy in this series of cases are analysed in *Tables V* and *VI*. Despite its limitations the 5-year survival rate has been taken as the index of success and all patients dying within this period are assumed to have died from the disease. In view of the high average age of the patients this assumption does, of course, give a pessimistic picture of the results of therapy. Nevertheless, we feel that it affords a more direct means of comparison than do other devices which seek to make actuarial allowance for the short life expectancy of patients of this seniority. The overall 5-year survival figure for the group works out at 34 per cent. In *Table V* the results are given according to the location of the tumour.

It is impossible to tabulate a satisfactory comparison between the results of interstitial therapy and those of teletherapy. The cases with the best prognosis were on the whole selected for implantation, and teletherapy was very much a second choice, used mostly for advanced or inaccessible lesions and for poor-risk patients. Radium implantation and radical surgery can, in fact, be applied to much the same range of cases; where one modality is possible, so in general is the other. If the gum is involved, however, the generalization obviously breaks down, for such tumours cannot be implanted. Thus, radium implantation was used in 65 per cent of tumours involving only the soft tissues, whereas of lesions spreading to the alveolus, only 20 per cent could be so treated and these were obviously cases where the encroachment was relatively slight. Clearly, by reducing the available treatment alternatives the proximity of the mandible could affect the prognosis, and *Table VI* divides the whole material into two groups: those where the tumour did and those where it did not encroach upon the gum. The difference in the cure rate is striking—a reduction from about 50 per cent in patients with no involvement of the alveolus to less than 30 per cent in patients in whom the alveolus was affected. It is true that there is a certain bias, for the second group contains fewer small lesions. Breakdown into stages makes some of the groups very small, but the diminished cure rate when alveolar involvement occurred seems to be present at all stages.

Lymph-nodes.—In an attempt to assess the importance of the lymph-nodes to success or failure we have reviewed the fatal cases, subdividing them according to whether the patient died with the primary tumour active, with a healed primary but active lymph-nodes, or with both the tumour and the nodes active. Only 21 patients, or about 6 per cent of the whole material, fell into the second group and it therefore appears that if the primary disease is controlled the nodes can usually be successfully dealt with also. Of the 21 patients, 7 had inoperable nodes when first seen, 2 were unsuitable for block dissection (extreme age in 1, simultaneous reticulum-cell sarcoma in the other), 4 had inadequate surgery (resection without block or suprahyoid block dissection), and in 7 there was failure of follow-up. At best, therefore, 11 patients *might* have been saved by elective block dissection, no more than 5 per cent of the patients dying of the disease or 3 per cent of the whole material. This must be set against the morbidity and possible mortality associated with a policy of routine elective block dissection applied to all the remaining cases (Martin, 1951, Jesse, Barkley, Lindberg, and Fletcher, 1970).



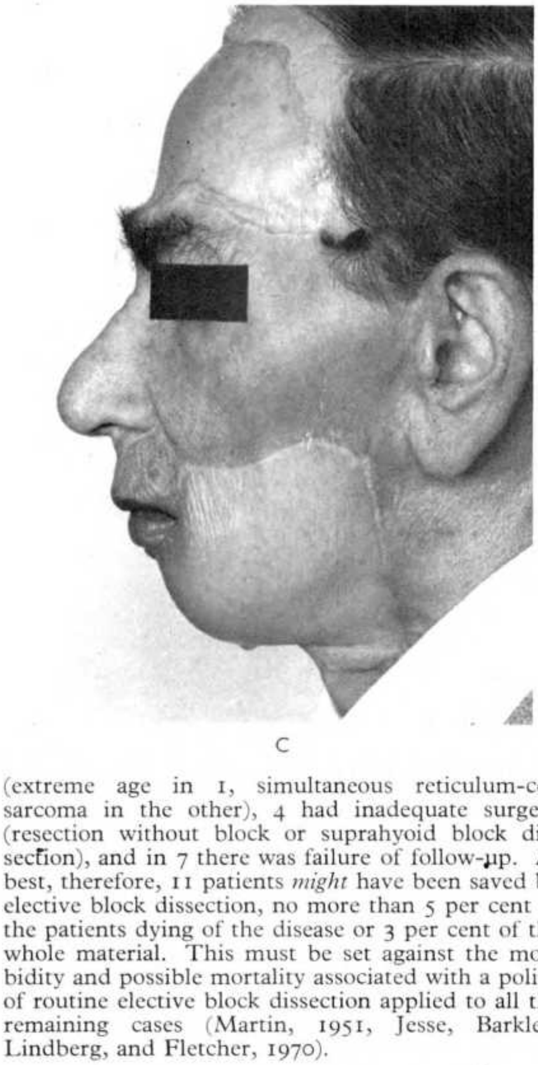


FIG. 6.—Male, aged 65 years. A, Very extensive carcinoma of the mouth floor, alveolus, and buccal mucosa, with submandibular infiltration. The lesion healed completely after treatment with high-energy electrons, but at 3 years the patient developed a large fistula exposing a necrotic mandible (B), necessitating hemiresection of the mandible with the whole thickness of the cheek and mouth floor. The histology was entirely negative for tumour. Repair with forehead and deltopectoral flaps was carried out. The patient remains well (C) at 5 years after therapy.

A purely statistical survey of the material is of limited value when discussing the place of block-dissection. Closer individual study of the cases suggested that certain groups can be distinguished. We have already alluded to patients unable to attend for follow-up. For patients presenting with manageable primaries but considerable node involvement there is much to be said for immediate radical monobloc surgery as the treatment of choice. Patients who present with a moderately large or a very anaplastic primary lesion well away from the midline and who respond well to irradiation should perhaps be given the benefit of an elective block dissection even if no nodes are palpable.

Conclusion.—Our main conclusion and the chief reason for Part II of this paper is that *for tumours involving the lower alveolus* radiotherapy is less effective than for other mouth sites, and the results may well be inferior to those of radical surgery. During the past 5 years we have made a gradual transition to surgical management of this particular group, and the techniques employed are set out in Part II. A provisional assessment will be made, but it is of course too early to know whether our hopes of improved results will be fulfilled.

II. PRINCIPLES AND EVOLUTION OF SURGICAL MANAGEMENT

Most patients with mouth cancer are elderly and many are enfeebled. The overriding need to achieve resection and reliable closure in one stage has already been stressed. In the following section we outline the search for techniques which can accomplish this aim without loss of their radical nature.

Requirements of Curative Resection.—

Primary Tumour.—The importance of wide soft-tissue clearance of the growth was stressed by Trotter (1913), and Gardham (1953) emphasized that this wide clearance must be in depth as well as surface extent. Lederman (1964) pointed out that growths of the posterior part of the mouth floor may penetrate direct to the submandibular triangle behind the free edge of the mylohyoid diaphragm (*Fig.* 7).

If the alveolus is involved two new routes of spread are opened up. Spread along the fascial planes of the periosteum has long been recognized (Polya and Navrath, 1903). Moreover, in the elderly edentulous patient the alveolar bone is absorbed and the inferior dental canal is no longer sited deeply in the mandibular body but comes to lie directly beneath the alveolar mucosa (*Fig.* 8). Consequently the perineural lymphatics of the inferior dental nerve readily become involved by the tumour. Southam (1970) recently confirmed these findings in 4 out of 15 cases where the nerve was submitted to histological examination. Thus when the alveolus is involved by growth extensive resection of the mandible becomes mandatory and excision must include at least the whole length of the inferior dental canal (*Fig.* 9).

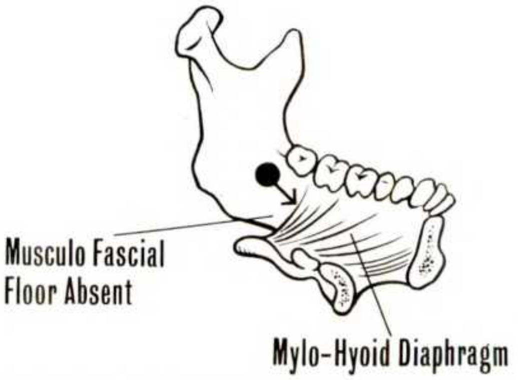

FIG. 7.—Direct spread of tumour involving the palatoglossal sulcus.

Nodes.—Since the radical procedures to be described necessarily enter the neck it is usually desirable to include neck dissection in the operation. The cervical nodes must be excised in continuity with the specimen to avoid rupturing the fascial planes and lymph-channels and so spilling tumour cells. It is therefore essential that the neck dissection, which is usually done at the start of the operation, should enter the correct muscle plane in the submental and submandibular regions, as will later be described.

In general surgeons have become disenchanted with the suprahyoid and other partial neck dissections, both as methods of exposure and as curative procedures. Complete block dissection of the affected side, including the whole submental triangle, has become the accepted operation. Although some surgeons have not hesitated to perform simultaneous bilateral block dissections (Frazell and Moore, 1961; Spiro and Frazell, 1968), there is no strong case for prophylactic dissection on the contralateral side unless both sides of the neck have to be opened up for the resection of the primary lesion. If enlarged nodes are present bilaterally an acceptable modification is to preserve the internal jugular vein on the less affected side (*Fig.* 10). In other cases it may be possible to delay the contralateral dissection for 3 weeks and thus avoid the undoubted risks of a simultaneous double dissection, for staged bilateral dissection with removal of both jugular veins (*Fig.* 11) has been shown to be a safe and worth-while procedure (Frazell and Moore, 1961). Undoubtedly there is a strong stimulus to strive for a complete clearance of these mouth tumours in that the disease seldom extends below the clavicle and definitive cure is a reasonable hope.

Reconstruction: 1. Soft-tissue Closure.—Radical resection with wide clearance of the tumour has been made safe by modern anaesthetic and supportive techniques, but the daunting size of the resulting defect presents great problems and the techniques of reconstruction have lagged behind. The evolution of our current solutions is summarized in the following paragraphs.

Attempts at Direct Suture.—

Local flaps: In the past intra-oral closure was often attempted by mobilization and suture of the surrounding mucous membrane. However, there is rarely enough mucosa to carry out direct suture, or to allow closure by a transposition flap, without producing unacceptable tension and distortion.

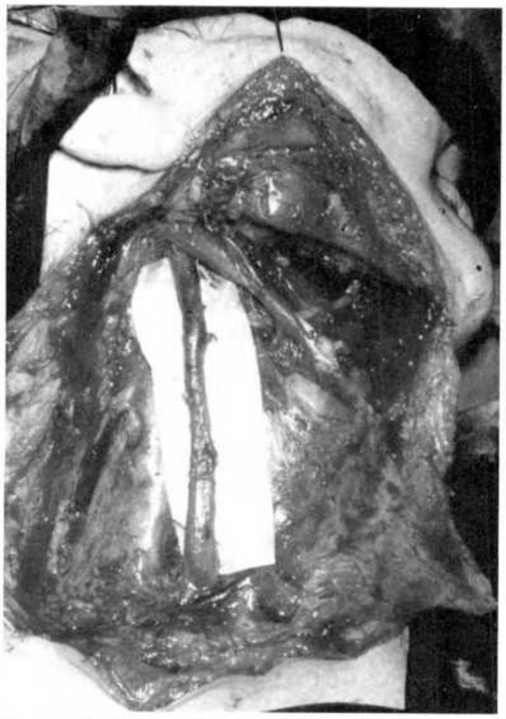

FIG. 10.—Simultaneous bilateral neck dissection. Conservation of the internal jugular vein on the less affected side.

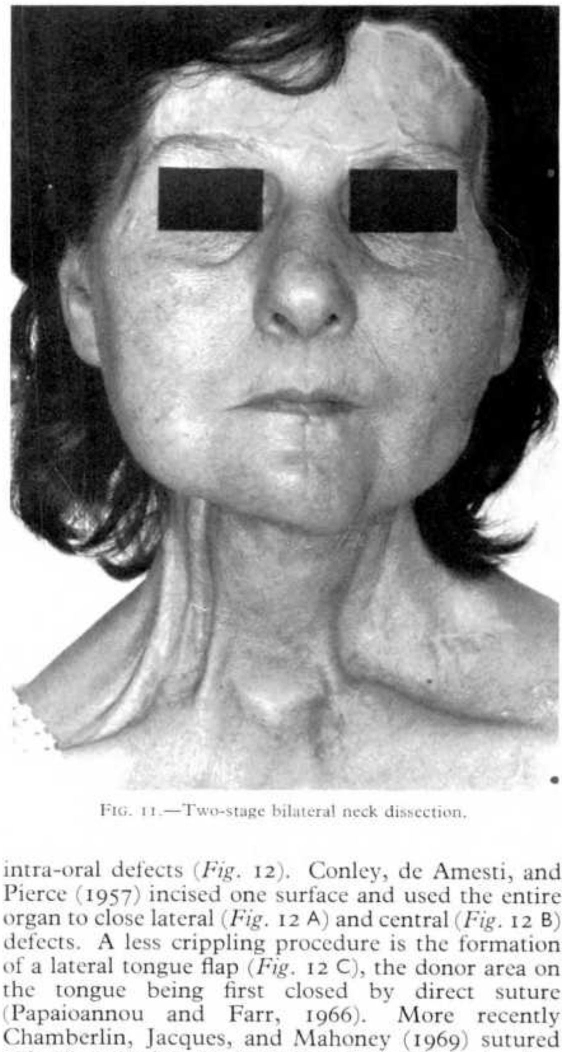

FIG. 11.—Two-stage bilateral neck dissection.

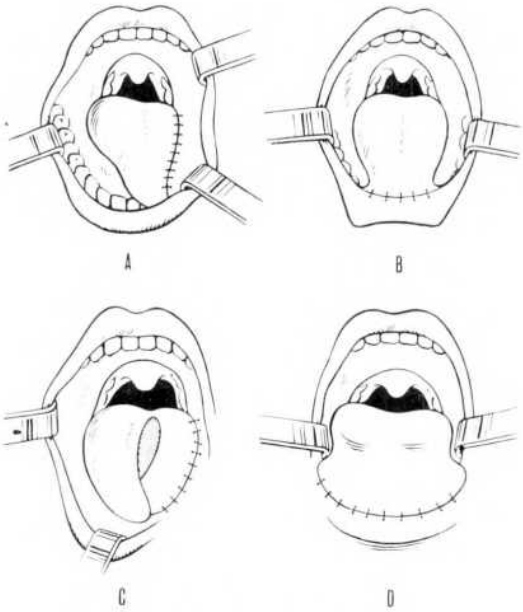

FIG. 12.—Use of the tongue in repair (*see* text).

Tongue flaps: The tongue is a highly mobile structure and it is therefore not surprising that numerous techniques have been described for using it to cloak intra-oral defects (*Fig.* 12). Conley, de Amesti, and Pierce (1957) incised one surface and used the entire organ to close lateral (*Fig.* 12 A) and central (*Fig.* 12 B) defects. A less crippling procedure is the formation of a lateral tongue flap (*Fig.* 12 C), the donor area on the tongue being first closed by direct suture (Papaioannou and Farr, 1966). More recently Chamberlin, Jacques, and Mahoney (1969) sutured only the anterior third of the defect and used a free skin-graft to close the posterior defect. Alternatively they cauterized the area to prevent adhesion of the remaining mobile tongue. In the case of very large defects or for dehiscence of a wound (provided that the tongue has not been exposed to a high dose of radiation), the entire organ can be split and unfolded to provide a large musculomucosal flap to close the defect (*Fig.* 12 D). These methods, however, lead to great difficulties in swallowing and speech owing to distortion of the tongue which interferes grossly with oral mechanics even when healing takes place by first intention. Worse, primary closure often fails and large salivary fistulae with their attendant miseries are not uncommon.

Free grafting: The possibilities of skin-grafting of mucosal defects had been realized by Schnitzler and

Ewald as long ago as 1894, but the inlay technique was first used by Moszkowicz in 1917 and developed by Esser in 1917. Pickerill in 1918 and Blair in 1925 extended its use. This technique became the standard method of repair in the fifties for post-excisional mucosal defects. Edgerton (1951), Figi and Masson (1953), Conway and Murray (1953), and Coleman (1958) developed these techniques, but Fister and Sharp (1963) described peripheral loss of these grafts and Edgerton and Desprez (1957) described total loss.

Many modifications of techniques were explored. Ward and Robben (1951) sutured a free graft under the overlying skin some 10 days before excisional surgery. Corso and Gerold (1962) buried a rubber tube covered by a free graft at the time of operation and 8 days later incised the area, exposing the new sulcus. This method, however, has greater application in the construction of a sulcus or mobilization of the tongue as a secondary procedure. It is now accepted that, even with the addition of muscular flap supports, the take of these grafts cannot be guaranteed, especially if preoperative radiation has been given. Even if an adequate take of the graft is achieved the skin has limited elasticity and will tend to contract (Fister and Sharp, 1963).

Causes of Failure.—Complications such as wound infection, fistulae, and strictures were common. Attempts at closure were often abandoned and skin-to-mucosa suture was performed, leaving a large fistula. The unfortunate patient was then sentenced to a lengthy follow-up period for the tissues to recover and to see if there was any recurrence of the tumour before definitive reconstruction was commenced. This commonly consisted of various forms of tube pedicles of abdominal skin laboriously conveyed to the defect, using the wrist as a temporary host. Meanwhile, with the passage of time secondary contracture of the edges of the defect had taken place, tissues had become distorted, the tongue had become fixed or prolapsed through the wound, and the remaining mandibular fragments had been dragged into malposition by the unopposed action of the pterygoid muscles and the contracting scars. Over the surface of these thick scar bands at the edges of the defect the skin was chronically infected and sodden from constant contact with saliva, rendering the area unsuitable for the reception of skin-flaps. The dire need became apparent for reliable techniques of immediate primary closure of the post-excision defect if patients were to have a reasonable quality of life postoperatively.

The Search for Safe Regional Flaps for Immediate Closure.—The use of *regional flaps*, as against flaps from distant areas, for repair promised an obvious advantage, namely, the importing of well-vascularized tissue, which is of special value when irradiation has been the primary method of treatment. The adjacent skin of the neck seemed the obvious choice, and a succession of different neck flaps has been described (*Fig.* 13). These may be conveniently grouped as follows:—

Group I: Simple skin-flaps either based laterally to form a transverse flap (*Fig.* 13 A), superolaterally to give an oblique flap (*Fig.* 13 B), or superiorly to give a vertical flap (*Fig.* 13 C).

Group II (*Fig.* 13 D): The broad-based vertical flap resulting in a large skin defect in the neck. Bakamjian and Littlewood (1964) closed this by a second skin-flap from the chest.

Group III (*Fig.* 13 E): Conley (1960) used a flap based posteriorly on the region of the nuchal line to produce a 'nape of the neck flap' but found it difficult to mobilize.

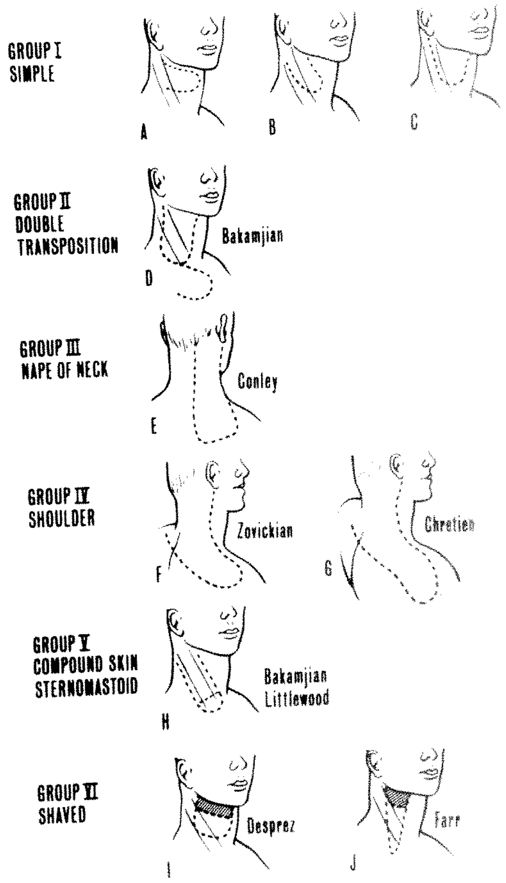

FIG. 13.—Neck flaps used for intra-oral repair.

Group IV: Zovickian (1957a, b) after a preliminary undermining procedure raised a flap of shoulder skin (*Fig.* 13 F). Chretien, Ketcham, Hoye, and Gertner (1969) used an even longer more mobile flap but numerous delay procedures were required (*Fig.* 13 G).

Group V: Bakamjian and Marshall (1963) described the use of a strap flap, based superiorly on the occipital and posterior auricular arteries and including the sternomastoid muscle, to close palatal defects. Littlewood (1967) adapted this technique to the closure of intra-oral defects (*Fig.* 13 H). (The skin in this composite flap procedure is 4 cm. wider than the muscle and extends distally on to the chest.) Unfortunately, preserving the vessels and the muscle may compromise the neck clearance.

Group VI: In order that primary intra-oral closure could be accomplished Desprez and Kiehn (1959) used a broad, superiorly based flap (*Fig.* 13 I) which they turned in below the mandible, removing enough of its epithelium to allow suture. However, the large defect in the neck needed a skin-graft for closure.

Farr, Jean-Gilles, and Die (1969) modified the technique and used a smaller, wedge-shaped flap (*Fig.* 13 J) which allowed immediate closure of the neck skin. The failure rate with this flap has proved unacceptably high (30 per cent in Farr's (1970) cases) unless there is a preliminary delay procedure.

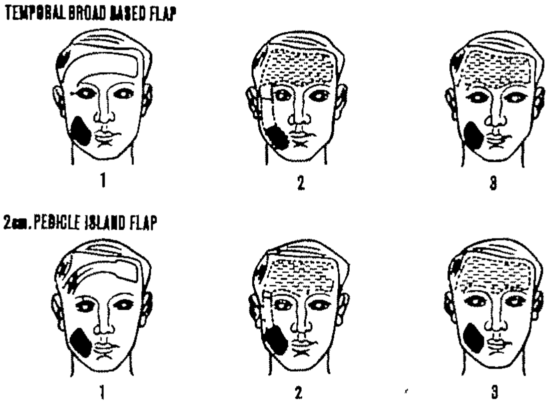

FIG. 14.—Forehead flaps based on the superficial temporal artery for replacement of intra-oral lining. 1, Mucosal defect. 2, Forehead flap turned down and passed into mouth. Split skin to forehead. 3, Pedicle returned to forehead.

For midline resections (central arch carcinomas) a submental flap based on the lower border of the mandible has been used. The flap was passed under the skin adjacent to the proposed defect, thus producing a lined flap to be used some 15 days later in the reconstruction (Edgerton, 1951; Ward and Robben, 1951; Zovickian, 1957a, b).

All these flaps have serious drawbacks. The skin of the neck is often hair-bearing, it may have been irradiated, and, as Ward and others (1959) have pointed out, such skin may slough if merely raised, let alone transposed. Moreover, all these techniques leave a temporary salivary fistula, the closure of which is not always the simple out-patient procedure that some authors have suggested it is. The greatest objection of all, however, to the use of cervical skin is the difficulty in providing really safe cover for the carotid system exposed by the neck dissection.

Development of the Island Forehead Flap.—Blair (1925), Conway and Murray (1953), Ward and others (1959), and McGregor (1963a, b) made a positive advance by establishing the value of a flap of forehead skin with a broad-based lateral pedicle (*Fig.* 14). This flap is passed through a surgically produced fistula into the oral cavity, with a suture line above the level of the salivary reservoir, thus giving complete salivary seal. Polya (1926) used the 'biological' flap of Monks (1898) and Esser (1917) to carry forehead skin to line the oral cavity on a vascular pedicle, consisting of only the anterior superficial temporal vessels. Kernahan and Littlewood (1961) demonstrated the possibilities of a narrow flap with a 2-cm. pedicle based on the course of the anterior branch of the superficial temporal artery to close skin defects. These techniques have now been combined and adapted for intra-oral closure (Wilson, 1967) (*Fig.* 14 B). The narrow pedicle provides a wide yet freely mobile flap which can be made to reach any required intra-oral site, allowing definitiv suture of nine-tenths of its perimeter at the primar operation. If desired the pedicle of the flap may b shaved of its epithelium so that it heals into the chee 'tunnel'. This avoids, with some cosmetic loss, second operation to divide and return the pedicle and may be useful in the elderly poor-risk patient.

FIG. 15.—Central arch carcinoma; mucosal replacement by deltopectoral flap.

The flap is well vascularized, with an excellen anastomosis across the midline (Corso and Gerold 1962), so that the entire forehead may safely be used giving ample tissue to close either a central, lateral, o posterior defect. Delaying, as suggested by Millar (1964), is quite unnecessary and is unwise, for th flap may then become stiff and oedematous and mor difficult to handle.

Some advanced tumours require a wide *en blo* resection including the overlying skin, creating whole-thickness defect. To close such a gap in on stage, skin cover, as well as the forehead flap fo lining, must be provided. Edgerton (1951) use free skin-grafts. Others have resorted to local flaps the drawbacks of which have already been described The large cervical-pectoral flap of Garrett, Giblin and Hoffman (1966) supplies enough tissue but it to may necrose as it is based on the anterior border of th trapezius where the platysma is deficient and vascularization poor (McGregor and Reid, 1966).

Delto-pectoral Flap (Bakamjian).—The delto-pectoral flap of Bakamjian and Marshall (1963) ha proved a satisfactory solution of this problem. I provides almost unlimited skin, and is a significan advance in the management of these cases. It can b used, alternatively, to provide mucosal lining; thi spares the forehead skin but leaves a temporar salivary fistula (*Figs.* 15, 16). However, by shavin a strip of dermis to allow complete closure we have successfully obtained salivary seal with this flap. We have found that the most valuable use of the Bakamjian flap is to close the skin defect in the face (and upper neck) after the mucosal defect has been closed by inserting a forehead flap (*Fig.* 17).

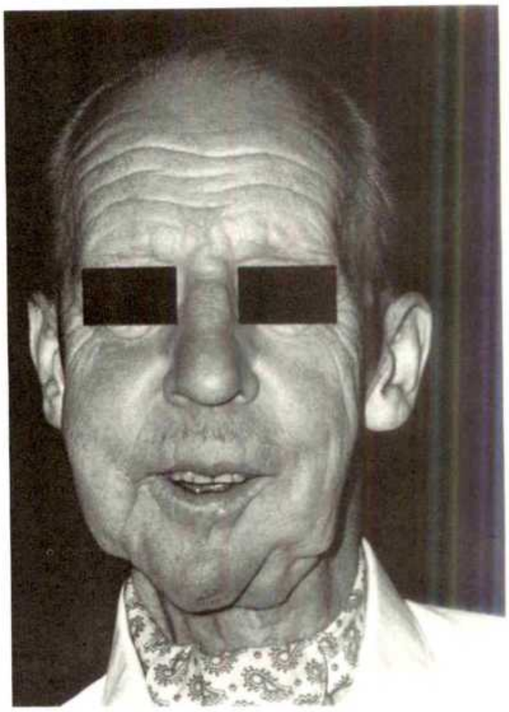
B



C

FIG. 16.—Male, aged 70 years. A, Central carcinoma. B, Use of a deltopectoral flap for mucosal replacement. C, The patient well 2 years after surgery.

If the lower lip with its vermilion border has to be sacrificed it can be replaced by using the Abbé procedure to switch a flap containing the required tissue from the upper lip and incorporating this in the repair. When and how to provide support, e.g., for the chin, are discussed under 'Current Surgical Management'.

Reconstruction: 2. The Mandible.—

Extent of the Problem.—Marginal resections of the mandible do not require any replacement (*Figs.* 18, 19). When, however, the continuity of the mandibular arch is destroyed by segmental resection or hemimandibulectomy the soft tissues collapse inwards, resulting in loss of contour. The lateral (posterior) mandibular segment, if there is one, is pulled upwards and inwards by the unopposed action of the temporalis–pterygoid sling, and the soft tissues contract to produce a deformity which becomes almost impossible to correct. The introduction of a skin-pedicle lining flap helps to prevent gross distortion by interposing a bulk of soft tissue and prevents the formation of tight scar bands between the bone ends. Even so, the loss of mandibular stability inevitably downgrades the functions of speech and mastication (Conley, 1962). Anaesthesia of the lower lip owing to loss of the mental nerve may in some cases interfere with 'lip-seal' and contribute to drooling of saliva. Hence, in these cases, though immediate mandibular support is not essential, an eventual bone-graft is often very desirable.

When the central mandibular arch is removed immediate stable support is vital (*Fig.* 19), otherwise there is no fixed point for a suture to support the tongue and larynx, so that funnelling of the oro-pharynx with dysphagia and perhaps respiratory obstruction will result. Immediate reposition of the excised bone segment seemed an ideal solution. Reposition of the bone, after removing the tumour and exposing the bone to boiling, was described by Orell in 1937. The technique was modified by Harding (1957), who cleared the segment of soft tissue and autoclaved it before reimplanting. The procedure has fallen into disrepute as no bony union takes place and many of the grafts are absorbed. Gaisford, Hanna, and Gutman (1961) had to remove the bone in 3 out of 4 cases in which they used this method.

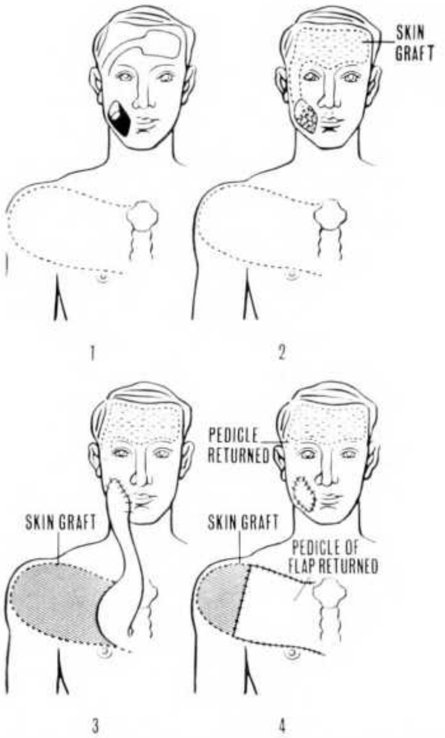


FIG. 17.—Use of an island forehead flap for lining, and a delto-pectoral flap for skin cover.

Immediate block-bone grafting of the defect seemed attractive and was advocated by Edgerton, Ward, and Sikes (1950) and Conley (1953, 1956). The technique was modified by Desprez and Kiehn (1959), who threaded blocks of bone on a Kirschner wire, improving the vascularization and allowing the implant to take up the correct curved form—the so-called 'shish-kebab' technique. Millard (1964, 1965, 1967), and Millard, Campbell, Syockley, and Garst (1969) threaded a Kirschner wire along the medulla of a section of rib, removed wedges of bone from the concave aspect to allow moulding, and slotted the ends into mortices cut in the remaining mandibular segments. This was the so-called 'pig-on-a-spit' method. Fleming and Morris (1969) used a simple bent-rib graft but supported the repair by an external acrylic splint. External splints, however, are ill tolerated by the patient. Cleanliness is difficult to maintain and there is increased risk of infection.

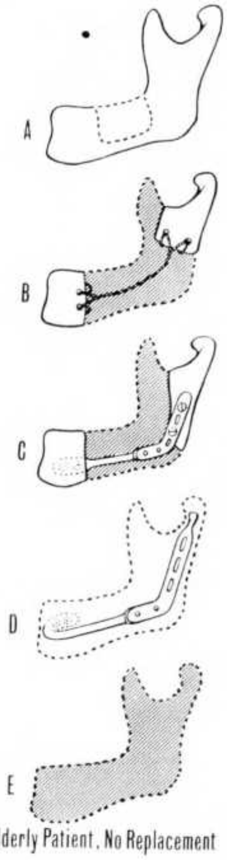

FIG. 18.—Mandibular resection and replacement (*see* text).

In our view, therefore, there are serious disadvantages in immediate bone-grafting in the type of case now under discussion. An immediate and lasting watertight intra-oral closure cannot always be guaranteed, especially if the tissues have been exposed to large doses of radiation. In these circumstances the avascular bone block is frequently lost. Millard (1971) reported a 30 per cent loss of grafts and now advocates a delayed bone-grafting procedure.

Because block-bone is so vulnerable to infection further trial is currently being made of the use of cancellous bone chips, pioneered by Mowlem (1963). These chips are rapidly vascularized even in the presence of infection and intra-oral sinuses. Yoel (1966) applied the chip-grafting technique to post-excisional mandibular defects. He used a perforated stainless-steel trough to support the chips and to give stability. Brånemark, Breine, Hallen, Hanson, and Lindström (1970) used a lighter, perforated, titanium frame filled with the chips, which are easily obtained with a gouge after a 2-cm. trapdoor of compact bone has been raised on the iliac crest. Fortunately, external fixation is not required, as it has been found that the support is adequate and limited stress increases the rate of vascularization of the bone.

Most workers have preferred not to use immediate bone-grafts. Various techniques have been employed to secure immediate stabilization, with the option of eventual substitution of a bone-graft.

Temporary fixation was first achieved by driving a Kirschner wire into the inferior dental canal in the cut end of the mandible (*Fig.* 19 B). Such wires were commonly extruded and postoperative pain from irritation of the inferior dental nerve frequently occurred. Byars (1946) suggested the use of metal bars. Many foreign substances have been used to maintain the position of the fragments and to replace the mandible. The use of stainless-steel plates was described by Edgerton and others (1950) and Philps (1967). Chrome-cobalt prostheses were advocated by Conley (1951) and Kleitsch (1951, 1952), and Ticonium was used by Walsh (1954). Acrylic resins were popularized by Niebel, Healey, Neenan, and Hoffman (1954) and Healy, Subdy, Niebel, Hoffman, and Duval (1954). Inert but weak replacements by Teflon or Silicone were tried by Brown, Fryer, Kollias, Oilwiler, and Templeton (1963) and Small, Brown, and Kobernick (1964).

Titanium now seems to be the material of choice (Cook, 1969, *Fig.* 19 D; Bowerman and Conroy, 1969, *Fig.* 19 E). Time has shown it to be non-irritant to the tissues and it is sufficiently malleable to allow bending to the required contour and fit. The prosthesis can be assembled as desired in the theatre from a kit of parts, which are easily and rapidly riveted together. Both the Bowerman and the Cook prostheses are currently used at Westminster Hospital.

Choice of Method.—The type of reconstruction, if any, to be used will depend, first, on the evaluation of the patient, paying particular attention to age, general condition, and the extent of the tumour. Secondly, it will depend on what sophisticated laboratory facilities and special skills are available to the operating team.

In the elderly poor-risk patient any form of implant is inadvisable. The adequate removal of the tumour with low morbidity is of paramount importance. Gaisford and others (1961) reported that in 89 cases where no reconstruction of the mandible was undertaken the patients willingly accepted their minor disabilities.

In the younger patient where fixation is necessary but metal implants are not available the mandibular ends may be temporarily stabilized quite simply by four strands of stainless-steel wire braided together for strength (*Fig.* 19 C). Fixation by passing each of the four filaments through oblique channels drilled in the outer cortex and twisting them together will give adequate stability and prevent torque. Three weeks later the wire can be replaced by a bone-graft, when the pedicle of the lining flap is returned.

In a carefully selected group of patients definitive bone replacement of a hemimandible can be undertaken as a primary procedure. In this case when the excision is undertaken the articular disk of the temporomandibular joint must be retained. The bone-graft, which is carved to pattern from the iliac crest, will then fuse with the undersurface of the disk, allowing movement in the upper compartment of the joint (Manchester, 1965) and preventing secondary ankylosis.

When the replacement demanded is greater than half of the mandible, the use of a permanent metal prosthesis is recommended as this is superior to multiple segments of bone wired together.

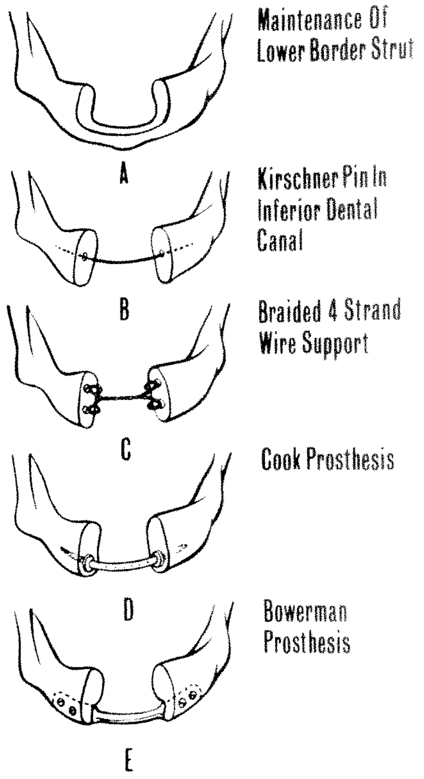

FIG. 19.—Central arch resection; immediate support.

In a few younger patients with firm remaining teeth a 'cosmetic' denture may be well tolerated and give great satisfaction (*Fig.* 20).

To sum up, therefore, a satisfactory routine for soft-tissue reconstruction has been found in the use of the forehead flap for lining and the deltopectoral flap for cover. Support is used only when essential, and, in general, temporary metal support is preferred to immediate bone-grafting.

III. CURRENT SURGICAL MANAGEMENT

In this final section the authors describe the fairly standardized procedure which is now their current practice.

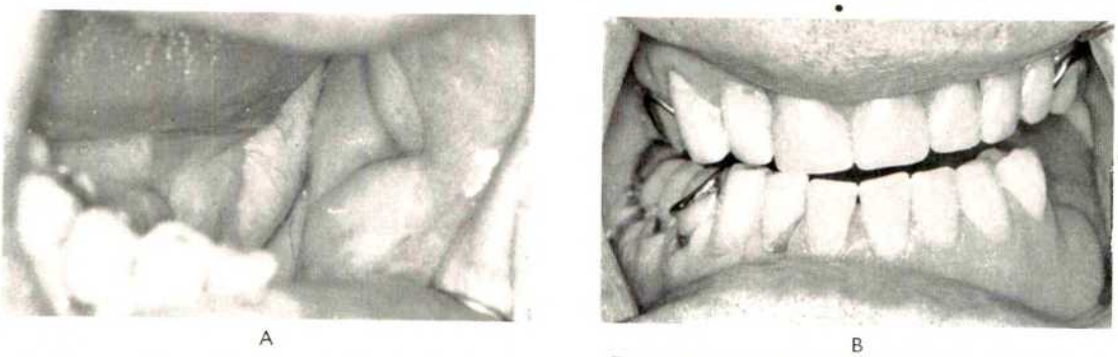
Operability and Planning.—Every effort is made to assess the individual tumour accurately. In addition to the anatomy of the tumour some idea of its malignancy may be gained from its histological picture, growth-rate, and relation of node involvement to primary size. Radiological examination, especially with dental occlusal films, may show destruction of bone, but this confirmatory evidence is often delayed long after clinical involvement of bone has become obvious. In cases with trismus tomography of the base of the skull and pterygoid region may be invaluable. Because distant metastases are occasionally seen, a routine radiograph of the chest is always performed.

Almost all the cases will repay preliminary examination under anaesthesia. At this time confirmatory biopsies of any suspicious areas may be useful, for sometimes this disease has a multifocal nature (the 'field cancerization' of Slaughter, Southwick, and Smejkal, 1953), when under-assessment is easy; and, conversely, some of the apparent surface extent may prove to be leucoplakic or premalignant only.

Extension backwards to the pharyngeal wall, or upwards to the base of the skull, may contra-indicate surgery; so may gross bilateral node involvement or fixity of nodes to the carotid vessels. All these factors must be weighed together, taking into account the age and condition of the patient and the extent to which the operation is likely to palliate if it does not cure. Dental treatment may be given at this preliminary session if desired and prosthetic requirements, if any, assessed.

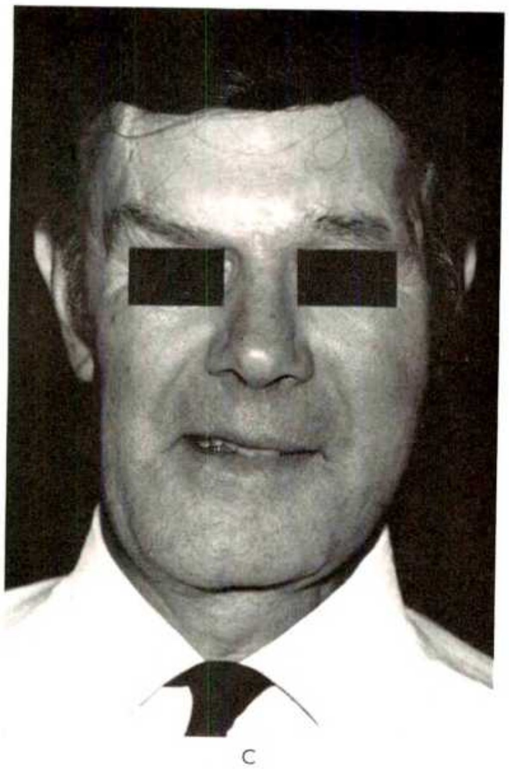
The superficial temporal artery should be checked for patency, and its course marked out preoperatively.

Preoperative Radiotherapy.—In the past, as recounted above, surgical resection was considered the second resort if full-dose radiotherapy failed. It is still our practice to give preoperative radiotherapy in the belief that it reduces the risk of operative implantation of viable tumour (Henschke, Frazell, Hilaris, Nickson, Tollefsen, and Strong, 1966). Our dose, however, is usually limited to about 4000 rad in 4 weeks and operation follows as soon as the visible reaction has subsided, whatever the response may have been. It is important to base the resection on the original assessment of the tumour, not on its reduced size after irradiation. Clinical photography is invaluable in this respect.



A

B



C

FIG. 20.—A, Left forehead flap after hemimandibulectomy. B, 'Cosmetic' denture in place. C, Final appearance.

Anaesthesia.—Age, cardiovascular state, and pulmonary function have nowadays receded in importance but they must be assessed by the anaesthetist, who will occasionally report that anaesthesia is absolutely contra-indicated.

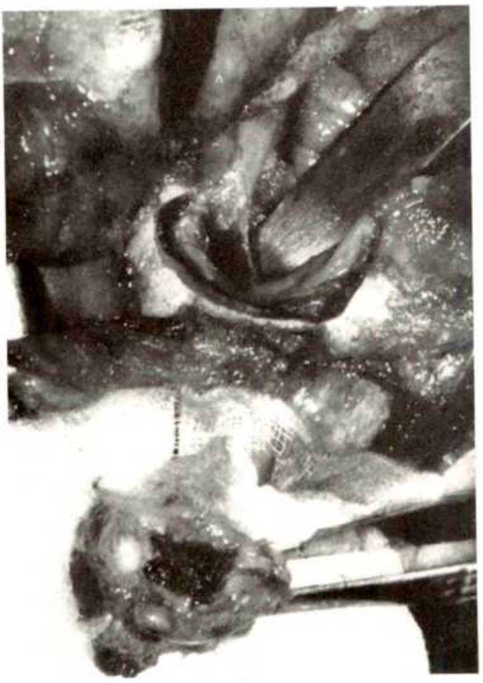
Intubation may present difficulties in patients with trismus and immobile cervical spines, and preliminary tracheostomy is sometimes inevitable. Otherwise, tracheostomy is almost invariably performed at the end of the operation. A simple technique without a Bjork flap is used to ensure rapid healing. An Intracath is inserted into an arm vein at the start of the procedure and pushed on into the innominate vein. This provides central venous pressure readings during the operation and a reliable drip for the vital postoperative days. Continuous electrocardiographic recording is used. Hypotension is almost always used but requires skill and care in elderly poor-risk patients.

General Considerations of Operative Technique.—

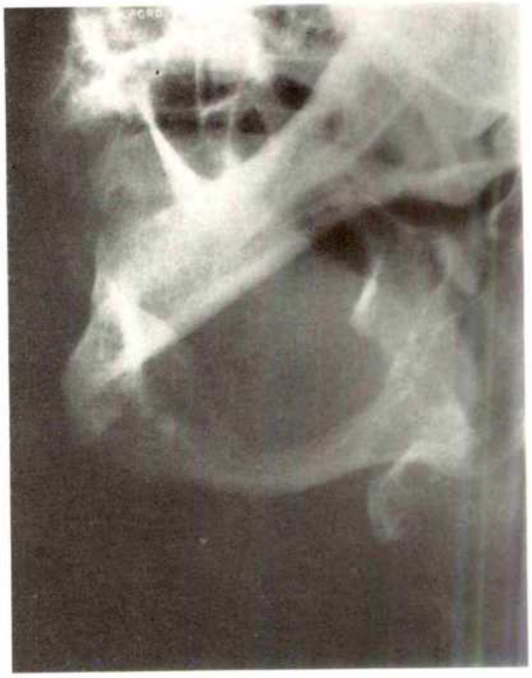
Frozen-section histology is used throughout the resection, as the aim is to obtain a clear margin of at least 3 cm., and if possible 4 cm., around the tumour. This certainty of clearance has obviously become more important now that immediate definitive closure is the routine.

Wound contamination: Fischer, Ketcham, Roxanc, and Malygreen (1967) reported that 13 per cent of washings from the neck wounds contained cancer cells. We take the following precautions. Ulcerated tumours are covered with a small wool pledget soaked in mercuric chloride, 1/500, and at the end of the resection the entire wound is either washed thoroughly with water or saline or exposed to half-strength Milton packs for 5 minutes.

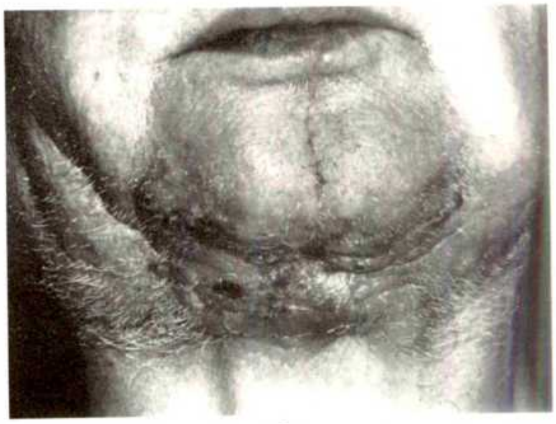
Premalignant lesions: Prophylactic excision of areas of mucosa known to be at risk is now both feasible and desirable (Helsper and Fister, 1967; Moore and Catlin, 1967). A free split-thickness skin-graft may be applied to the periosteum and held in position by a dental composition mould kept in place with a Gunning splint or denture fixed to the mandible.



A



B



C

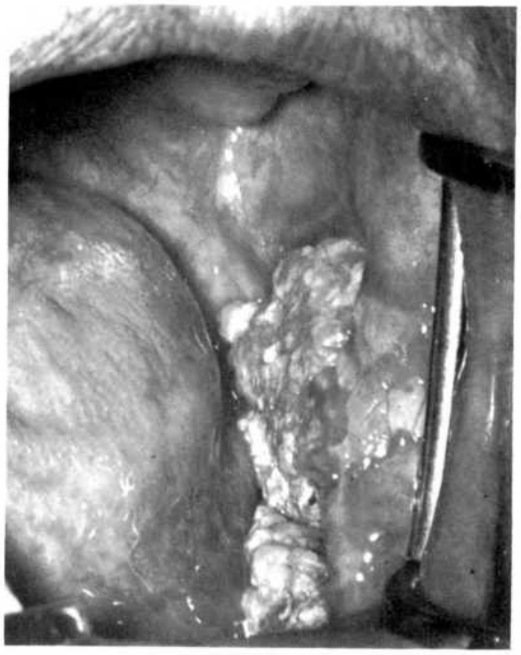
FIG. 21.—Local resection of a small alveolar tumour in an elderly patient. A, Resected tumour is seen above. B, Radiograph showing recurrence anterior to the defect. C, The clinical recurrence.

Local excision of small carcinomas: Local removal with an area of underlying alveolus was described by Rankow (1968). This procedure (*Fig.* 21) leaves the lower border of the mandible intact so that repair is simple, but it may well fail to allow an adequate clearance. We have seen recurrence of the tumour in the periosteum or along the inferior dental canal (*Fig.* 21 B) and we do not favour this procedure except for exceptionally early or border-line lesions or in extremely poor-risk patients.

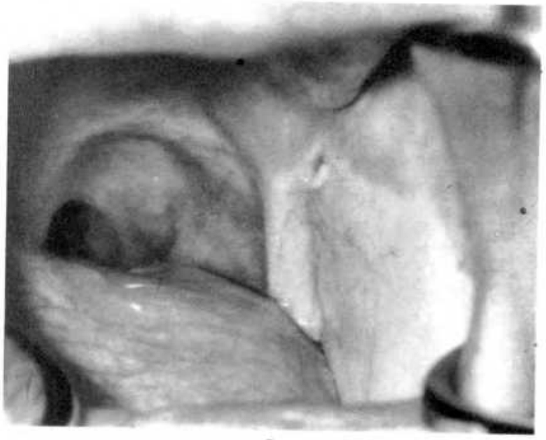
The Radical Resection.—This will be described under 'lateral arch tumours' and 'central arch tumours'. In each case extensions to include removal of the tongue and/or skin will be considered.

Lateral Arch Tumours (*Fig.* 22).—As has already been pointed out, the extent of the mandibular resection is never less than from the mental foramen to the inferior dental foramen, but in some cases part of the ramus may be left, though the coronoid process is usually removed (*Fig.* 18) to ensure ample room for the forehead flap as it passes into the mouth. For most tumours, other than small anteriorly situated ones, complete hemimandibulectomy is preferred.

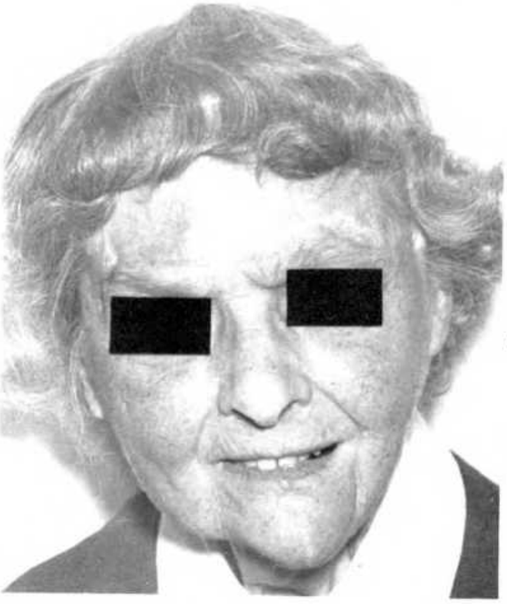
Any of the standard incisions for neck dissection may be used, and should be extended forwards to split the lip in the midline. The incision dividing the free margin of the lip should be V-shaped, otherwise postoperative contracture is liable to lead to unsightly 'notching' of the lip contour. If necessary, the vertical limb of the neck incision may be supplemented by the inferior extension of Martin (1951). If a deltopectoral flap is to be raised some modification may be needed (*see below*). The flaps normally include the platysma, for if the tumour is invading this layer skin resection and replacement are the proper procedures.



A



B



[redacted] [redacted]

C

FIG. 22.—Female, aged 68 years. A, Lateral carcinoma. B, Repair with a forehead flap. C, Final appearance of the patient alive and well after 4 years.

The operation begins with the neck clearance which is normally a total Crile dissection, working from below. The dissection is carried upwards, deep to the anterior belly of the digastric and the mylohyoid muscles, to include the affected area of the mandible and associated soft tissues. Division of the mandible 3 cm. anterior to the tumour permits the posterior segment to be rotated laterally, exposing the lingual sulcus and allowing a planned excision of the entire involved area. The mandible is sectioned posteriorly, preferably above the level of the lingula with its associated dental nerve and vessels. This completes the resection.

If the entire half mandible is to be resected the initial steps of the operation are as already described. However, when the stage of dividing the soft tissues posterior to the tumour is reached the masseter is sectioned to expose the ascending ramus of the mandible. A subperiosteal plane is then sought, stripping the soft tissue upwards to expose the entire bony ramus.

The coronoid process is now revealed with the insertion of the temporal muscle. This muscle is divided close to the bone by sharp dissection to free the coronoid process, and the vascular soft tissues are pushed away from the sigmoid notch. The condylar attachment is now fully in view. An incision is first made in the anterior capsule and, by a combination of pressure by an elevator thrust into the lower compartment of the joint and distraction of the mandible laterally, the mandibular condyle is dislocated. When this has been achieved the insertion of the lateral pterygoid muscle is revealed and is easily divided by sharp dissection. It is important that this dissection be kept close to the bone to avoid injury to the maxillary artery, which is in direct relationship with the posterior surface of the neck of the mandible. After dividing both the lateral and medial pterygoid muscles the specimen may be lifted clear. The cavity is now inspected and haemostasis secured. Irrigation with water or application of a Milton pack is carried out, as has been described.

A pattern is next made of the defect, marking on it the position of entrance of the narrow pedicle which will be on its posterosuperior aspect.

Attention is now directed to the forehead on which the course of the anterior branch of the superficial temporal artery has been marked out before the induction of hypotension. The necessary length of flap is assessed and checked by transposing a tape. The 2-cm.-wide pedicle can then be outlined on the temple and the pattern of the intra-oral defect marked out across the width of the forehead. The flap with its pedicle is then carefully raised to include the galea.

This ensures the continuity of the arterial system, leaving an intact pericranium as a good base for a split-thickness skin-graft. The entire forehead skin should be sacrificed to allow the edges of the repair to be concealed by the hairline, eyebrows, and glabellar crease. The defect is then covered by a single sheet of skin, preferably taken with a drum dermatome to give a graft of uniform thickness and including sufficient dermis to allow the best cosmetic appearance. The freed forehead flap is now folded on itself longitudinally and its folded distal end sutured together at two or three points with heavy black silk stitches, with the ends left long to be used as traction sutures.

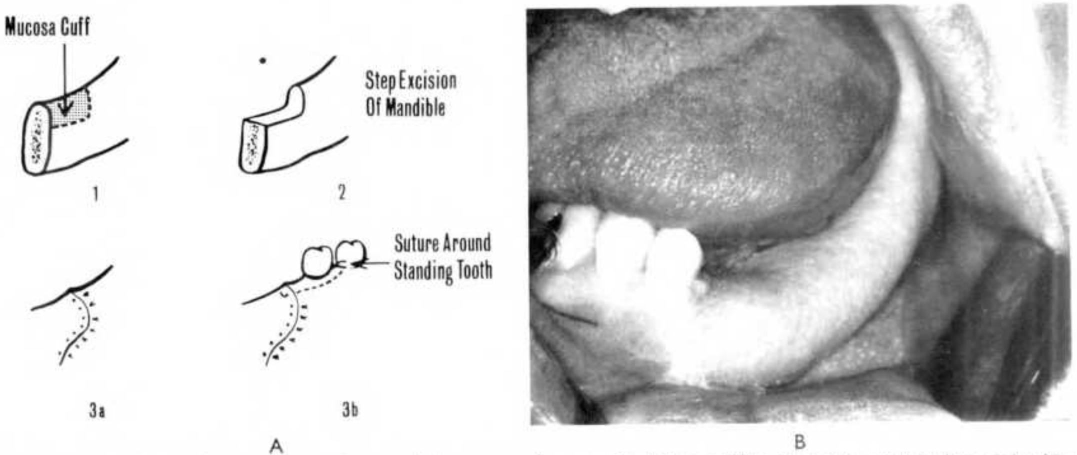


FIG. 23.—A, Technique for securing sound mucosal closure over the cut end of the mandible. B, Shows sound healing of the skin-flap over bone end.

In all females and some males the forehead is thin and the narrow-based flap may be passed easily through the space between the transected temporal muscle and its fascia, inside the zygomatic arch, and thus delivered into the mouth. In males with a bulkier flap a surgical fistula may have to be created around the external surface of the zygomatic arch into the oral cavity. This fistula is created by blunt dissection and stretching, keeping close to the bone to avoid the orbital branch of the facial nerve, the integrity of which must not be jeopardized. The flap is then unfolded and sutured to the defect, commencing posteriorly, using closely placed end-on mattress sutures of o silk, and working towards the midline. In this way the flap creates a new buccal sulcus as a salivary reservoir, above which the suture lines are relatively dry so that the risk of salivary leakage is minimal.

There is a weak point in the closure at the site where the flap is attached to the alveolar mucosa. A modified technique (*Fig.* 23), constructing a 1-cm. shelf of bone by sacrificing the intact alveolar margin, allows a valvular closure and provides bony support to the anterior edge of the flap, much reducing the risk of breakdown of the wound at this critical angle. The cut end of mandible should be smooth and rounded off carefully, using a bur in the Hall airdrill.

After hemiresection of the mandible an immediate prosthesis is not essential, but in the younger good-risk patient a Bowerman metal prosthesis may be inserted. The new half-mandible is constructed in the correct dimensions from a kit of parts. The upper end of the prosthesis carries a mandibular head which must be accurately fitted into the glenoid fossa. The weight and muscular pull transmitted to the prosthesis tend to dislocate it downwards and this is prevented by constructing a temporalis muscle sling, which is passed through a slot in the upper end of the prosthesis and sutured to the fascia of the pterygoid muscles.

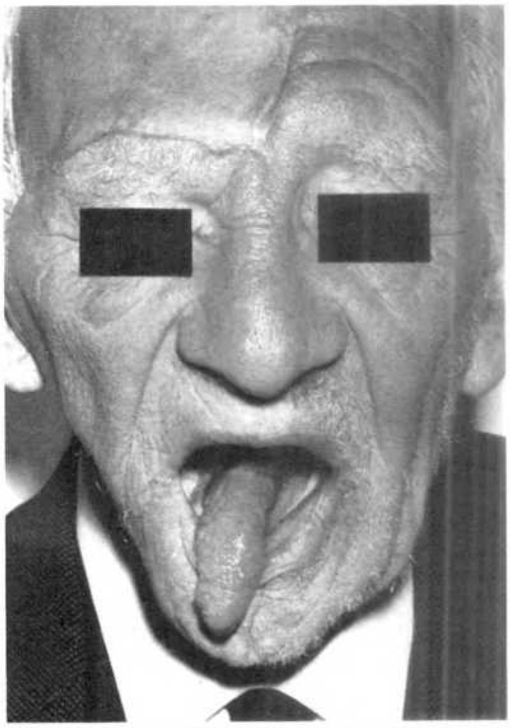

FIG. 24.—Mobile tongue after a right hemiglossectomy and hemiresection of the mandible. N.B. The appearance of the forehead is improved if the whole width of skin is taken. This is now our regular practice.

The lower end of the prosthesis is then bolted to a prepared flattened surface on the *lingual* aspect of the symphysial region of the mandible. The wounds are closed in layers. Suction drainage is provided.

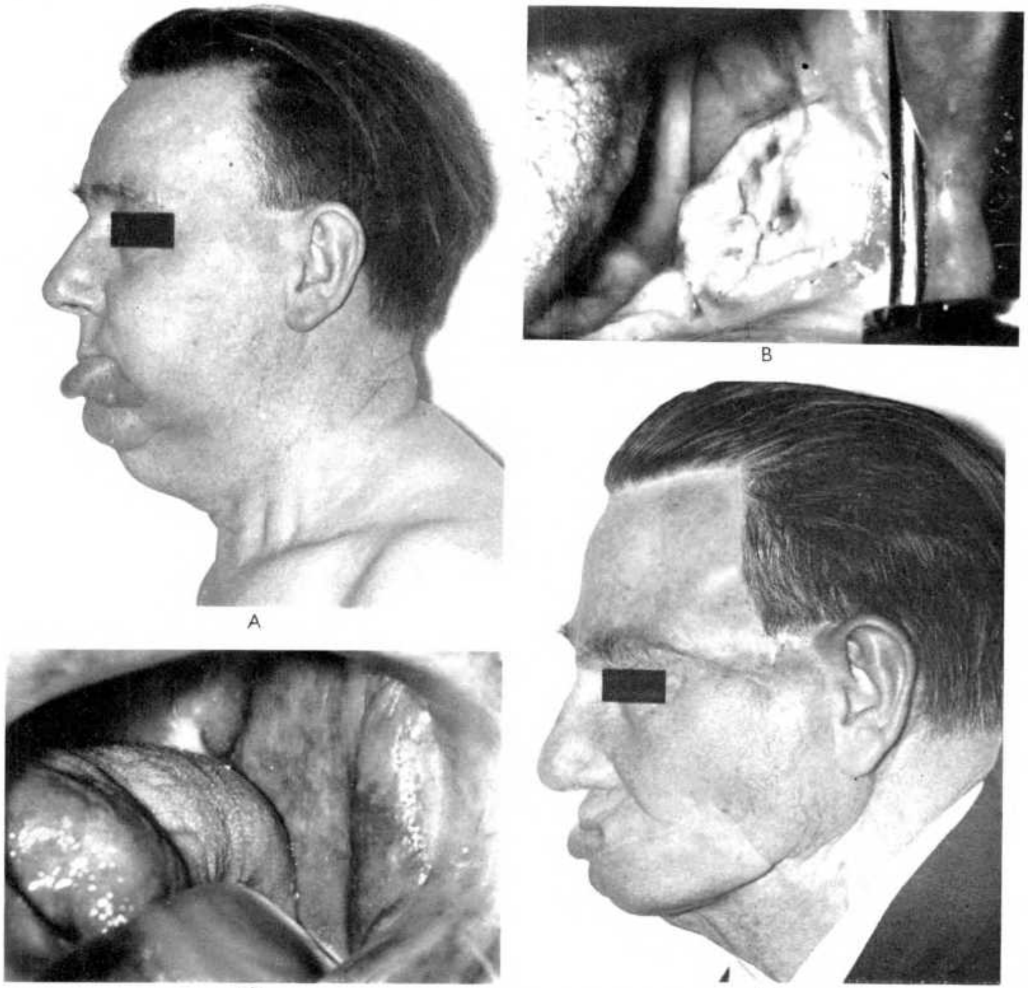

FIG. 25.—Male, aged 72 years. A, Lateral carcinoma involving the whole thickness of the cheek and lip. B, View of the lesion. C, Mucosal replacement by forehead flap; Bowerman prosthesis; deltopectoral flap for skin cover. D, The patient well 2½ years after surgery.

Hemimandibulectomy associated with hemiglossectomy: The half-tongue must be included in the resection in large tumours of the alveolus if they are found to trespass on the territory of the floor of the mouth within 1 cm. of the tongue. Only slight modification in surgical technique is required. The lingual artery is tied, as well as the facial artery, during the neck dissection, which is then carried upwards in a deeper plane, i.e., deep to the hyoglossus muscle, on the surface of the geniohyoid and geniohyoglossus. The lingual and hypoglossal nerves must, of course, be sacrificed. The tongue is split in its avascular midline plane, and the half-tongue becomes part of the *en bloc* resection.

In the reconstruction it is important to recreate a mobile tongue tip (*Fig.* 24) by suturing together the edges of the tongue wound for about 3 cm. backwards from the tip. Also, if the excision extends to the posterior third of the tongue some direct closure posteriorly may be obtained. The temporal flap can now be laid in to complete the reconstruction of the half-tongue and form a new floor to the mouth. This technique allows the formation of a mobile tongue which will not only play its part in speech and deglutition but also facilitate oral toilet. The importance of this aspect of tongue functions—to remove food débris from the mouth—was first emphasized by Aird (1958).

Carcinoma of the lateral alveolus involving the skin (*Fig.* 25): The resection in this case must include the involved skin along with at least a 2–3-cm. margin of healthy tissue, preferably checked by frozen section. The resultant defect constitutes a large fistula which must be closed by a pedicle skin-flap. In our hands, as has already been indicated, the island temporal flap supplies the best watertight lining to the mouth and the Bakamjian deltopectoral flap produces immediate unlimited skin cover. It will usually reach upwards to the level of the zygoma without difficulty. This flap (*Fig.* 17) is based on the lateral border of the sternum and in width extends from the clavicle to the nipple. It includes the upper three perforating branches of the internal mammary artery and, to accommodate shoulder abduction, it is highly elastic.

The flap is raised *to include the fascia of the pectoralis major*. It is then transposed to cover the defect as completely as possible and sutured in place. The intervening part of the flap is tubed to avoid a raw surface. The defect on the chest can be closed by an immediate or delayed free skin-graft. If neck skin has been sacrificed the flap can, to varying degrees, be set into the neck defect. It thus ensures secure cover for the exposed carotid vessels (*Fig.* 26).

Involvement of the posterior tongue and pharynx: The patient may experience difficulty in swallowing after extensive excisions of the tongue or pharynx necessitated by extension of the alveolar tumour. Cricopharyngeal myotomy at operation relaxes the sphincter-like action of the lower section of the inferior constrictor muscle, opening the upper end of the oesophagus to facilitate swallowing (Mladick, Horton, and Adamson, 1971).

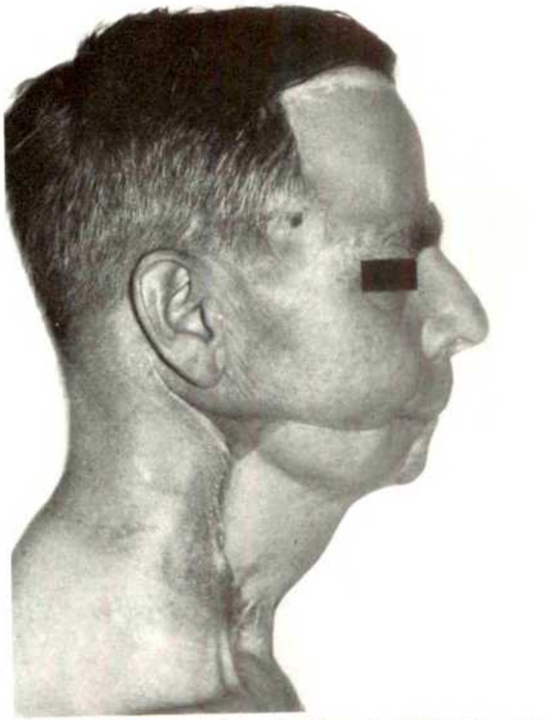
Central Arch Tumours.—Tumours involving the symphysial region of the mandible require special consideration. The defect produced is much more crippling. A totally anaesthetic lower lip is often unavoidable, and the two cut ends of bone, if left free, will be pulled upwards and inwards by the pterygoid muscles. Moreover, the tongue tends to fall back, obstructing the airway. Some form of fixation is therefore imperative, and a reliable skin-flap for lining, with if possible complete salivary seal, is vitally important.

Though a deltopectoral flap can be used to supply the lining it does produce a temporary fistula and its central position brings the pedicle over the tracheostome, interfering with the airway (cf. *Fig.* 16). The narrow-based forehead flap for lining is much to be preferred. Particular attention must be paid to a maximum insert of the flap to give a complete salivary seal.

It is our practice to insert an immediate metal spacer to maintain the position of the bony fragments and to support the anterior deep tissues of the neck and the tongue. If salivary seal cannot be guaranteed, or if the more refined prostheses are unavailable, the braided stainless-steel wire technique already described provides a simple method of obtaining at least a temporary fixation. When the pedicle of the flap is returned at 3 weeks the wire can, if desired, be replaced by a bone-graft, using a sheet-lead pattern taken from the operative specimen to ensure an exact replacement.

Better immediate fixation is obtained by a Cook or a Bowerman prosthesis (*Fig.* 27). The former (Cook, 1969, *Fig.* 19 D) screws into the cut ends of the bone by special swivelling screws; the latter (*Fig.* 19 E) is bolted to the *lingual* aspects of the two halves. Both types are made of titanium and may be bent to the required curve.

The excision in the region of the symphysis menti of necessity divides the genioglossus, geniohyoid, mylohyoid, and anterior belly of the digastric muscles—the central component of the so-called 'hyomandibular complex' of Edgerton and McKee (1959). The anterior support of the hyoid bone, larynx, and tongue is thus destroyed. If the larynx cannot rise the patient may be unable to open the upper end of the oesophagus to allow the swallowing of food. If the glottis cannot be closed owing to post-surgical glottic ptosis, aspiration of fluids will occur. Only minimal support is at first supplied by the skin-flaps, and therefore a temporary suture of catgut or silk from the mandible to the hyoid bone (*Fig.* 28 A) is essential (Jabaley and Hoopes, 1969). A more refined 'scaffolding' has been described by Desprez and Kiehn (1959), using fascial strips passing from the lateral border of the mandible, looped around the hyoid bone, and sutured to the central area of the mandible (*Fig.* 28 B) or mandibular prosthesis (*Fig.* 28 C). The creation of this double sling simulates the action of the mylohyoid diaphragm, combining vertical and forward traction. The procedures described allow adequate support of the tongue and prevent it from falling backwards, ensuring good airway after the tracheostomy tube has been removed. In our experience fascia is at risk from infection and should be used only if closure can be guaranteed (*Fig.* 29).



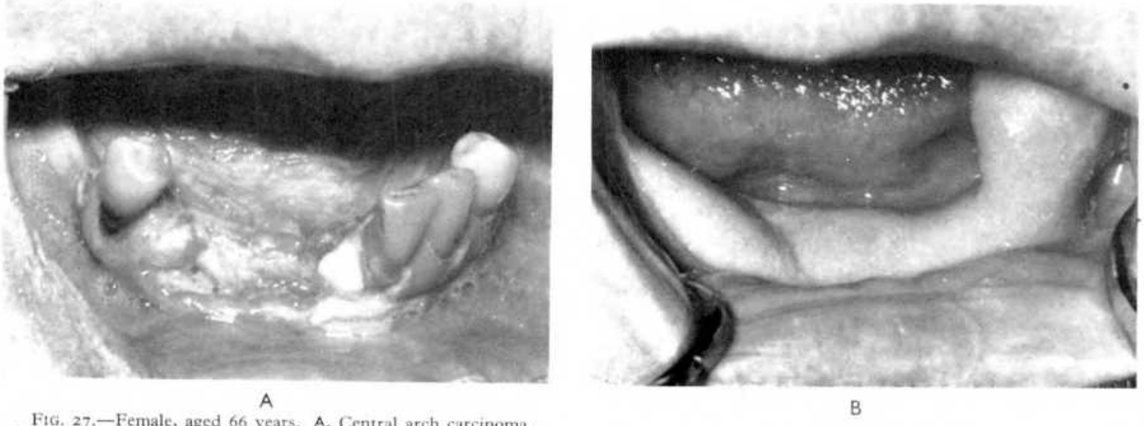
[redacted]

FIG. 26.—Deltopectoral flap set into the neck after skin resection to ensure good cover for the great vessels.

Central arch resection with anterior glossectomy: Extensive tumours in this region involve the mouth floor, which must be excised in continuity. Should the tumour extend to within 1 cm. of the anterior edge of the base of the tongue, the anterior tongue should be amputated and included in the specimen. The previously described methods of reconstruction allow repair of this defect and disablement is often surprisingly small.

Central arch tumour involving the skin: In advanced cases the tumour may ulcerate through the skin of the face. A wide monobloc resection of the involved area is performed. The defect in the facial skin is repaired by a deltopectoral flap, as already described.

Post-operative management: Bulky dressings of the wound are ill tolerated in this group of patients. The only pressure applied is a tie-over support of the forehead and deltoid skin-grafts.



A

B

C

FIG. 27.—Female, aged 66 years. A, Central arch carcinoma. B, Mucosal replacement by a forehead flap; Cook prosthesis. C, The patient well 2½ years after surgery.

Reliance is placed upon suction drainage. Two fenestrated wide-bore rubber tubes are carefully placed under the skin well clear of the carotid arteries, brought out through dependent stab incisions, and sutured firmly in place. These tubes should be connected without delay to two separate suction pumps.

In the elderly or poor-risk patient, continuous electrocardiographic monitoring is required for the first 3 days. A temporary defunctioning of the oropharynx by a nasopharyngeal tube is of great benefit, or occasionally gastrostomy may be preferable. A simple tracheostomy is routinely carried out. The tracheostomy is maintained for 5 days, preventing obstruction of the airway, reducing the dead space, aiding respiration, and facilitating bronchial toilet for the control of infection.

Many of the patients with advanced tumours have malnutrition, not necessarily obvious, from pain and trismus; hence postoperative nutrition may be a problem. Nothing can be given by mouth, although cleansing is essential, and feeding is by the intravenous route. Intravenous alimentation to ensure a calorie/nitrogen ratio sufficient to generate the protein required for the process of tissue repair is aimed at, and added vitamins, especially ascorbic acid, may be needed. The entire oropharyngeal cavity is at rest, healing is therefore rapid, and all tubes may be removed by the ninth postoperative day and a soft diet commenced. Most patients are allowed out of bed on the second day to sit in a chair, for early ambulation, especially in the elderly, is beneficial to the morale and reduces the complications. With good nursing care the morbidity of these admittedly major procedures can be kept to an acceptably low level.

RESULTS

We conclude with a brief report on 82 consecutive radical resections, all involving one or both of the pedicle flaps described in this paper. Lesser procedures are excluded from this review. Ages of the patients ranged from 34 to 85 years, but 40 patients were over 60 years old, including 12 over 70. More than half of the tumours were recurrent after radiotherapy or surgery and almost all were extensive and adherent to, or involving, bone. For most of these patients radical surgery remained the sole chance of survival.

In all the cases the diagnosis was histologically confirmed; there were 77 squamous carcinomas, 2 osteosarcomas of the mandible, 1 fibrosarcoma, 1 melanoma, and 1 adenoid cystic carcinoma arising in the midline mouth floor of a man with untreated tongue-tie, so that diagnosis had been delayed. The site of origin of the tumour was obscure in some of the advanced cases, and reliance had to be placed on the patient's recollection. The presumed locations are shown in *Table VII*.

The intra-oral defect was repaired in 78 cases by a forehead flap, and in the other 4 a deltopectoral flap was used. Of the forehead flaps, 74 were based on a narrow (2-cm.) arterial pedicle; a broad pedicle was used only if the artery was not palpable or had been sacrificed in the excision. There was major partial loss of the forehead flap in only 3 cases (1 of these was a haemophiliac) and minor marginal loss with delayed healing in a further 7, but no patient failed to obtain at least temporary intra-oral seal.

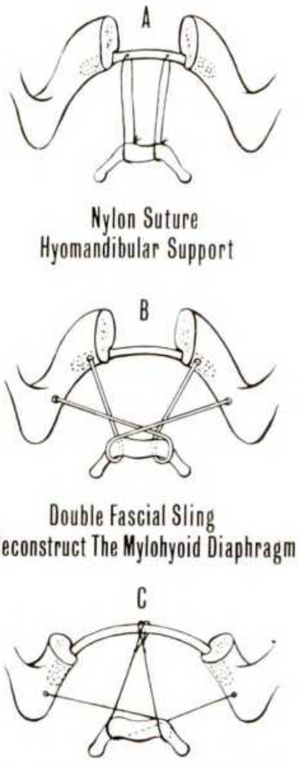


FIG. 28.—The hyomandibular sling.

Table VII.—SITES OF ORIGIN OF TUMOURS

Site of Origin	*No. of Cases*
Tonsillar area	4
Retromolar triangle	13
Lateral arch and mouth floor (includes 3 sarcomas)	34
Central arch and mouth floor	8
Buccal and labial mucosa	11
Tongue	12
	82

Resection of the full thickness of the cheek was needed in 17 advanced lesions. For these patients a deltopectoral flap was used to replace the skin, in addition to the forehead flap. In this group there was marginal necrosis of the deltopectoral flap in 2 patients and partial loss in 1 other patient whose flap was constructed on the ninth postoperative day to deal with secondary haemorrhage from a sloughing neck wound.

In all but 3 of the cases major mandibular resection was required. No immediate replacement was needed in 56 patients. No patient of over 60 years had any form of prosthesis after hemimandibulectomy. Where immediate support was essential, either a twisted wire or a Cook or Bowerman prosthesis was used. An immediate bone-graft was not required by any patient, but several cases have since received definitive iliac crest grafts.

Mortality.—No patient died during the operation or in the first 48 hours. Eight patients died in the later postoperative phase, the cause of death being as follows:—

1. Crusting of the trachea, leading to pulmonary collapse on the third day. Autopsy showed that excision of the tumour was complete.
2. Heart failure and pneumonia.
3. Cerebral damage following ligation of the common carotid artery which was involved by the tumour.
4. Coronary thrombosis.

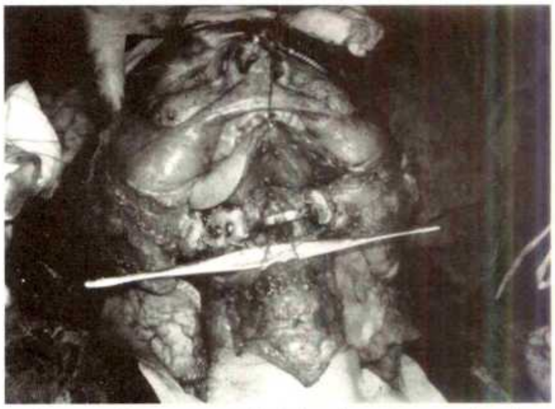

FIG. 29.—Bowerman prosthesis in place after central arch resection. The method of supporting the hyoid is also shown.

5. Coronary thrombosis and aspiration of food. This patient had had a posterior resection and had troublesome dysphagia. We regard this as a preventable death and in such cases, where initial dysphagia is likely, we would now tend to do a gastrostomy at operation.
6. Lung abscess due to aspiration.
7. Death on the fifteenth postoperative day. The cause was obscure but the patient had experienced difficulties with the double deltopectoral flap in relation to his tracheostome. Autopsy was refused.
8. A man of 84 years died of pneumonia after a secondary procedure to resuture his flap.

Status of Survivors and Conclusion.—Although 18 patients have been lost to follow-up and others have been operated on too recently for comment a cautious appraisal is possible. Thirty-nine patients are known to be living with no evidence of disease, including 11 who were operated on 3 or more years ago. This represents a considerable salvaging of patients with advanced disease and in our opinion justifies a continuing trial of radical surgery as the first choice of treatment for tumours involving the lower alveolus.

Acknowledgements.—The authors have the greatest pleasure in acknowledging their grateful thanks to all the other members of the tumour therapy teams at the Westminster Hospital and the Guildford Radiotherapy Centre. The case material presented here is in no sense our own. Patients were, of course, referred to individuals, but all the cases were discussed in joint clinics, where the policies of treatment that we have described were evolved in consultation.

All our colleagues made their cases freely available to us for this presentation. The surgeons include Mr. Gerald Westbury, whose patients contribute largely to this report, and Mr. Kingsley Robinson; the oral surgeons include Mr. John Bowerman and, in the earlier cases, Mr. Peter Cook. We have been fortunate in the high standard of anaesthesia and intensive care afforded by our colleagues of the Magill Department of Anaesthesia—particularly Drs. Wyman, Scurr, Feldman, and Conway, to whom our thanks are due. Almost all the histology has been the work of Professor D. H. Mackenzie, who also attended most of our joint clinics. The radiotherapists, especially Mr. T. M. Prossor and Dr. K. A. Newton at the Westminster Hospital, and Mr. J. J. Richmond and Dr. Helen Mellor at Guildford, merit our special thanks. We are fully aware of the superb quality of the radiotherapy practised at both centres, and are happy to express our sense of indebtedness to these colleagues.

It has been a matter of pride to us over the years that each patient's treatment has been decided by consultation and agreement, and has never been determined by the particular doorway through which the patient was referred to the hospital. For this tradition we owe an immense debt of gratitude to our former teacher and colleague, skilled both in surgery and radiotherapy, Sir Stanford Cade.

BACTERIAL FLORA IN THE DUODENUM OF PATIENTS AFTER BILIARY FENESTRATION

By E. THOMAS, A. KERR GRANT,* M. HOLFORD, D. RINGWOOD, A. W. DERRINGTON, and J. R. MAGAREY

GASTROENTEROLOGY UNIT, THE QUEEN ELIZABETH HOSPITAL, WOODVILLE, SOUTH AUSTRALIA

Summary

Fasting duodenal aspirates were studied in 15 patients with a biliary fenestration, 5 patients with a single duodenal diverticulum, 1 patient with a biliary fenestration and duodenal diverticulum, and 11 control subjects. A colonic type of bacterial flora, consisting of coliforms, *Clostridium welchii*, and *Streptococcus faecalis*, was found in 10 patients with biliary fenestration, 4 patients with a duodenal diverticulum, the patient with a fenestration and duodenal diverticulum, and in 1 of the control subjects. A high incidence of deconjugation of bile-salts (10 out of 15 patients) and of steatorrhoea (8 out of 15 patients) was noted in the patients with biliary fenestration, as well as in those with a duodenal diverticulum (5 and 3 patients out of 5 respectively). Above-normal serum-folate levels were observed in 3 subjects with coliform colonization.

It is possible that vague abdominal symptoms which may be experienced by patients after biliary fenestration, may be due to the presence of an abnormal bacterial flora in the duodenum.

Biliary fenestration is usually performed in an attempt to avoid postcholecystectomy complications. The operation involves an anastomosis between the common bile-duct and the first part of the duodenum (Magarey, 1966, 1971). It is possible that stasis in the portion of bile-duct distal to the anastomosis may result in the development, or perpetuation, of an abnormal bacterial flora.

---

* Requests for reprints to Dr. A. Kerr Grant, Director, Gastroenterology Unit, The Queen Elizabeth Hospital, Woodville, South Australia, 5011.

This study compares the bacterial flora in the duodenal aspirate of patients who had undergone biliary fenestration with the flora obtained from patients with a single duodenal diverticulum and with that of control subjects.

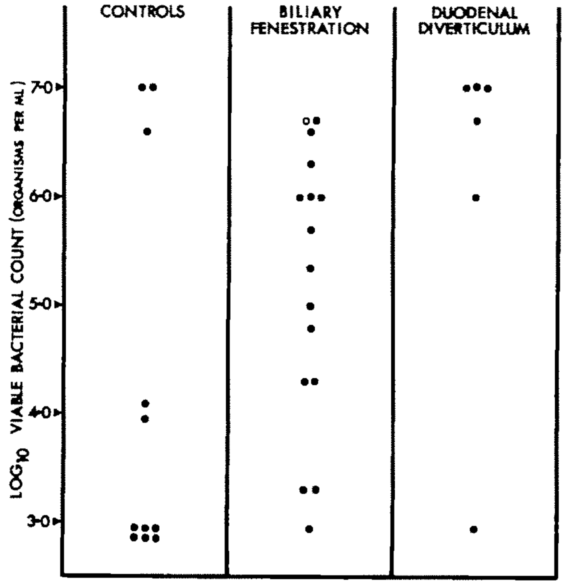

FIG. 1.—Concentration of bacteria in the duodenal aspirates plotted against a logarithmic scale. O, Biliary fenestration and duodenal diverticulum.

MATERIALS AND METHODS

Patients.—Fifteen patients with a biliary fenestration, 5 patients with a duodenal diverticulum, and 1 patient with both a duodenal diverticulum and biliary fenestration were studied.

Forty subjects were selected at random from a total of 448 subjects who had undergone biliary fenestration (Magarey, 1971). Of the 40 patients, 15 agreed to take part in the study. The 15 patients included 11 who complained of intermittent, mild, right hypochondrial pain, dyspepsia, malaise, and diarrhoea; the remaining 4 patients were asymptomatic. The mean age in this group was 55 years (range 40–73 years) and there were 4 males and 11 females. The mean period since operation was 7 years (range 6 months to 10 years).

The operative findings in the 15 patients were: proven cholecystitis (14), cholelithiasis (11), choledocholithiasis (3), and biliary cirrhosis (1). The common bile-duct was stated to have been dilated at laparotomy in 6 patients. There was macroscopic suggestion of pancreatitis in 2 patients. One patient in the series had no evidence of biliary-tract disease. Bacteriological studies were not performed on the gall-bladder or the bile-duct.

The 5 patients with a duodenal diverticulum included 3 who had mild upper abdominal discomfort and diarrhoea. In each case the diverticulum was situated on the pancreatic side of the second part of the duodenum and was approximately 3 cm. in diameter. The mean age of the 3 males and 2 female was 76 years (range 70–88 years).

The patient with biliary fenestration and duodenal diverticulum was a female aged 70 year who was investigated for intermittent diarrhoea.

The 11 control subjects (5 males and 6 females consisted of staff of the hospital. The mean age wa 28 years (range 18–41 years).

Methods.—A sample of duodenal aspirate wa obtained from fasting subjects through a steril open-ended tube which was positioned in th duodenum under fluoroscopic control.

Bacteriological Methods.—In all instance cultural studies were initiated within half an hour o obtaining the sample.

Culture.—Serial dilution of the aspirate was mad in thioglycollate broth. Blood-agar plates were the inoculated with 0·1 ml. of these dilutions an incubated aerobically and anaerobically at 37° C for 48 hours. Anaerobiosis was obtained b flushing with hydrogen in the presence of a col catalyst.

Another aliquot was centrifuged at 2500 r.p.m. fo 10–15 minutes, and the deposit was examined usin a Gram stain. The deposit was cultured on Mac Conkey plates and, where necessary, on anaerobi Nagler plates.

Bacteria were identified by colonial appearanc and biochemistry, and counts were given as th number of organisms per ml. of the aspirate.

Bile-salt Deconjugation.—Qualitative evidenc of bile-salt deconjugation was obtained by thin-laye chromatography on silicic acid using the solven system outlined by Hofmann (1962).

Serum Folate.—Serum folate was estimated b a modification of a microbiological assay usin *Lactobacillus casei* (Baker, Herbert, Frank, Parshe Hutner, Wasserman, and Sobotka, 1959).

Vitamin-B_{12} Studies.—Serum vitamin B_{12} wa estimated microbiologically, using *Euglena gracilis* i a modification of the method described by Hutne Bach, and Ross (1956). ^{57}Co vitamin B_{12} was used t study vitamin-B_{12} absorption; 8-hour plasma level and 48-hour urinary excretion values were estimate (Coupland, 1966).

Faecal Fat Excretion.—Seventy-two-hour faec fat excretion was estimated by the technique describe by Cammidge, using dried faeces (Varley, 1967).

RESULTS

The results of all the investigations are shown i *Table I.*

Bacteriological.—The bacteria isolated from th duodenal samples are listed in *Table II.* Culture wa sterile in 6 control subjects and in 2 patients: 1 wit biliary fenestration and the other with a diverticulum Coliform organisms were isolated in only 1 contr subject, but coliform bacilli (14 patients), *Cl. welch* (4 patients), and *Str. faecalis* (2 patients) wer predominant in patients (*Table I*). The concentra tion of bacteria in the duodenal aspirates has bee plotted against a logarithmic scale in *Fig.* 1. On patient (*Case* 23) had been treated 2 months befor investigation for acute cholangitis complicated b coliform septicaemia; duodenal intubation at th time showed 1×10^8 coliform organisms per m (*Table I*).

Bile-salt Deconjugation (*Table I*).—Thin-layer chromatography demonstrated unconjugated bile-salts in the duodenal juice of 10 patients who had undergone biliary fenestration. In this group duodenal aspirates grew coliform organisms (7 patients), *Streptococcus viridans* (3 patients), *Str. faecalis* (2 patients), and *Cl. welchii* (1 patient).

All 5 patients with a duodenal diverticulum were found to have deconjugated bile-salts in their duodenal aspirate. Coliform organisms were cultured from the duodenal aspirates of 4 patients and *Cl. welchii* from the aspirates of 2 patients; the aspirate from 1 patient was sterile. The patient with a biliary fenestration and a duodenal diverticulum had deconjugated bile-salts in her duodenal aspirate, and both coliform organisms and *Cl. welchii* were grown on culture.

Deconjugated bile-salts were not found in the duodenal aspirates from the control subjects.

Serum Folate.—The mean serum-folate level in patients with biliary fenestration or a duodenal diverticulum did not differ appreciably from that in the control group. However, all 3 patients with folate levels higher than those of the control subjects had coliform colonization of their duodenum.

Serum Vitamin B_{12} and Vitamin-B_{12} Absorption.—A low serum vitamin-B_{12} level and impaired absorption of vitamin B_{12} was found in an 88-year-old male, who had a duodenal diverticulum and a coliform

Staph. albus	2	0	0	0
Diphtheroids	1	0	0	0
Sterile	6	1	1	0

count of 1×10^7 organisms in his duodenal aspirate. Vitamin-B_{12} absorption was, however, corrected when the investigation was repeated with intrinsic factor, indicating that the deficiency was not related to the bacterial colonization. All the other patients exhibited normal vitamin-B_{12} absorption.

Faecal Fat Excretion.—Seventy-two-hour faecal fat excretion was above 22 g. in 8 patients with biliary fenestration, in 3 patients with a duodenal diverticulum, and in the patient with a biliary fenestration and a duodenal diverticulum. Faecal fat excretion was below 22 g. in all the control subjects.

DISCUSSION

The operation of biliary fenestration creates an anatomical abnormality of the biliary tract, resulting in a short-circuiting of bile into the duodenum. Stasis could occur in the portion of bile-duct between the anastomosis and the sphincter of Oddi. It is also possible that this stasis may result in persistence of preceding infection in the biliary tract secondary to past or persisting biliary obstruction (Scott and Khan, 1967) or choledocholithiasis (Elkeles and Mirizzi, 1942; Flemma, Flint, Osterhout, and Shingleton, 1967).

Fourteen out of 15 patients who had had biliary fenestration have been shown to have bacterial contamination of the duodenal content. In 10 of these patients the type of bacterial colonization of the duodenum (coliform organisms, *Cl. welchii*, and *Str. faecalis*) differed from that cultured from the control subjects, and resembled more closely the type of organisms found in the patients with a duodenal diverticulum. A similar colonic type of bacterial flora has been observed previously in duodenal diverticula (Goldstein, Cozzolino, and Wirts, 1963; Goldstein, Wirts, Salen, and Mandle, 1969; Gorbach and Tabaqchali, 1969; Drasar and Shiner, 1969), and in the blind-loop syndrome (Tabaqchali, Okubadejo, Neale, and Booth, 1966; Scott and Khan, 1968). This suggests that a situation similar to duodenal diverticulosis may occur after biliary fenestration. However, 3 patients with fenestration and 5 control subjects exhibited duodenal bacterial cultures of streptococci and staphylococci, as has been observed by Donaldson (1964), Kalser, Cohen, Arteaga, Yawn, Mayoral, Hoffert, and Frazier (1966), Donaldson, McConnell, and Deffner (1967), Gorbach, Plaut, Nahas, and Weinstein (1967), and Drasar, Shiner, and McLeod (1969).

There was a difference between the mean ages of the patients and the control group, but it seems to us unlikely that the older ages of the patients would be responsible for the abnormal bacterial colonization which was found in such a high proportion of the patient group (15 out of 21 patients).

Bacterial colonization with *Str. faecalis* or *Cl. welchii* may be responsible for the deconjugation of bile-salts found in the patients with biliary fenestration or a duodenal diverticulum. These organisms have been shown to be able to deconjugate bile-salts (Norman and Grubb, 1955; Maki, 1966; Midtvedt and Norman, 1967; Hill and Drasar, 1968; Shimada, Bricknell, and Finegold, 1969). Free bile-salts were observed in a few patients whose duodenal aspirate did not culture the organisms mentioned above. It is possible that our bacteriological techniques did not isolate an additional species (*Bacteroides*) which is capable of deconjugating bile-salts. The precautions in our modified method were not a strict as those advocated by Drasar (1967), but a rough correlation of the culture results with the Gram-stained smears did not indicate any significant numbers of unidentified organisms.

Biochemical steatorrhoea was found in 7 of the 1 patients who had deconjugated bile-salts in their duodenal aspirates. Bacterial deconjugation of bile-salts results in a lower concentration of conjugated bile-salts, interference with micelle formation, and malabsorption of fats (Tabaqchali, Hatzioannou and Booth, 1968).

No direct relationship was found between the duration of the postoperative period and the levels for bacterial concentration and type of colonization.

The high serum-folate levels found in 3 patients with coliform colonization of the duodenum confirms the observations of Hoffbrand, Tabaqchali, and Mollin (1966), and Hoffbrand, Tabaqchali, Booth and Mollin (1971), who suggested the possible synthesis of folic acid by these bacteria. On the other hand, other workers have found the folate levels to be normal (Mollin, Booth, and Baker, 1957), or low (Cooke, Cox, Fone, Meynell, and Gaddie, 1963) in such circumstances.

In a series reported by Magarey (1971) 105 of 448 patients who had had a biliary fenestration operation experienced subsequent abdominal symptoms. In only 12 of these patients were the symptoms shown to be related to the biliary tract. The 15 patients in the present series were selected 'at random' from the total of 448 patients on their willingness to volunteer for the investigation; it is possible that this willingness might have been influenced by the occurrence of intermittent symptoms.

Demonstration of an abnormal bacterial flora in the duodenum may be the only method of diagnosing infection in the biliary tree (Engstrom, Hellstrom, Hogman, and Lonnqvist, 1971). It is possible that the findings in the present study indicate that vague upper abdominal symptoms after biliary fenestration may, at times, be related to bacterial colonization of the duodenum. This is partly supported by the fact that 9 of the 10 patients with biliary fenestration and colonization of their duodenum with colonic types of bacterial flora suffered from upper abdominal symptoms (*Table I*). However, there were 2 patients with bacterial flora within 'normal limits' who had abdominal symptoms.

Similar colonization of the duodenum may follow other surgical procedures which are performed when the common bile-duct is explored. This possibility has not been assessed in the present study. Consequently, no comparison can be made between the possible effects of these alternative operations and biliary fenestration.

Acknowledgements.—The authors express their appreciation to the Board of the Queen Elizabeth Hospital for permission to publish this study. Dr. N. D. Hicks, Senior Clinical Pathologist, and his staff were responsible for the haematological studies. Dr. M. L. Wellby, Senior Medical Biochemist, and his staff were responsible for the faecal fat estimations.

This study would not have been possible without the co-operation of these two departments.

STARCH AND INTRAPERITONEAL ADHESION FORMATION

By D. G. JAGELMAN and H. ELLIS
THE WESTMINSTER HOSPITAL, LONDON

Summary

A series of experiments on surgical gloves, an animal model, and human biopsies is reported. These studies demonstrate that contamination of the peritoneal cavity is inevitable when starch-precoated gloves are used, and that small doses of starch contamination may be responsible for human intraperitoneal adhesion formation.

Previous publications are reviewed regarding the harmful effects of starch in humans.

In the past 18 months 3 proved cases of starch granulomatosis peritonei have been treated at the Westminster Hospital; 2 of these cases have been recently reported by Colin and Wastell (1971), and this coupled with the clinical interest in this problem has prompted our work on this subject.

Prior to the introduction of starch/magnesium oxide as a dusting powder for surgical gloves in the late 1940's various other substances had been used as glove lubricants and their harmful effects reported. Shattock (1916) reported a silica granuloma on the lip, and Antopol (1933), Germain (1943), Seelig, Verda, and Kidd (1943), Lichtman, McDonald, Dixon, and Mann (1946), Eiseman, Seelig, and Womack (1947), Saxen and Tuovinen (1947), Eberl, George, May, and Henderson (1948), and Seelig (1948), reported granuloma and adhesion formation in the peritoneal cavity caused by talc. It was therefore a relief when Lee and Lehman (1947) reported the development of a starch glove powder that was claimed to be completely absorbed from the peritoneal cavity without ill effect. This work was further substantiated by MacQuiddy and Tollman (1948) and Postlethwaite, McRae, Williams, Deaton, and Cornatzer (1949).

However, it was not long before reports began to appear of experimental studies and clinical observations suggesting that starch powder produced a granulomatous reaction similar to, but of less intensity than, talc.

In animal experiments granulomas have been produced in a variety of species including rabbits, hamsters, and mice (Willand, Masci and Craver, 1954; Ising, 1960; Myers, Deaver, and Brown, 1960; Myllarniemi, 1966). There have also been numerous reports of starch granulomas in humans, intraperitoneal granulomas having been reported by McAdams (1956), Hyden and McClellan (1959), Myers and others (1960), Blair and Blumenthal (1964), McNaught (1964), Bates (1965), Feegan and Beesley (1965), Cox (1970), Mitchell (1970), Colin and Wastell (1971), Nash (1971), and Neely and Davies (1971).

Three cases of intraperitoneal granulomas have been recorded in gynaecological patients not having undergone previous laparotomy (Paine and Smith, 1957; Saxen, Kassinen, and Saxen, 1963), and it is assumed that in these cases starch entered the peritoneal cavity by way of the Fallopian tubes following vaginal examination using starch-coated gloves.

The development of starch granulomas has not been restricted to the abdominal cavity. Ising (1960) reported finding granulomas in 4 E.N.T. cases, in a breast scar, and also following surgery to the leg and vas deferens. Rock (1967) reported starch granulomas in the middle ear and mastoid following stapedectomy.

There would seem to be two problems associated with the contamination of the peritoneal cavity with starch powder as used on surgical gloves. First, there is the development in the postoperative patient of a fever, abdominal pain and distension, ascites, and intestinal obstruction together with multiple granulomas throughout the abdominal cavity at subsequent laparotomy, the condition resembling carcinomatosis peritonei, as described by Bates (1965), Cox (1970), Mitchell (1970), and Nash (1971). Secondly, there is the less well-recognized presence of starch granules in intra-abdominal adhesions and the suggestion that they may be causative in the production of such adhesions (Myllarniemi, Frilander, Turunen, and Saxen, 1966; Sturdy, Baird, and Gerain, 1967).

The glove powder in general use in this country is Biosorb (Ethicon), which is a mixture of starch granules derived from corn starch pretreated with epichlorohydrin to which is added magnesium oxide to prevent clumping of the starch granules. Magnesium oxide alone has also been incriminated as a peritoneal irritant (Saxen and Saxen, 1965; Myllarniemi and others, 1966).

The dangers of starch granules in the peritoneal cavity are well defined but the exact frequency of the problem is uncertain. A series of experiments have been performed to determine whether starch contamination of the peritoneal cavity is inevitable when Biosorb is used as a surgical glove powder. The adhesion-producing effect of starch contamination of the peritoneal cavity alone and when coexistent with peritoneal trauma has been investigated in an animal model.

EXPERIMENTAL METHODS

Glove Experiments.—

1. Five pairs of standard size 6 surgical gloves precoated with Biosorb were taken. Each glove was slapped twice on to a standard 38-mm. laboratory glass slide. The slides were mounted with a cover-slip using XAM (G. T. Gurr) prefiltered through a Seitz filter to avoid contamination. Microscopic examination of the slides was performed using polarized light.

2. A further 5 pairs of similar gloves were washed in separate large bowls of water by sealing the open end of each glove and by immersion below the surface; each glove was then propelled backwards and forwards twenty times in the water. The gloves were allowed to dry and the next day slides were prepared in the same way as above.

3. Five pairs of gloves were washed twice and slides prepared in the same manner.

After preparing the slides, 2·5 ml. of Lugol's iodine were applied to each glove to confirm the presence of residual starch by blue discoloration.

Human Biopsies.—Omental biopsies measuring approximately 2·5 cm.^{2} were taken from 20 patients at the end of a variety of abdominal operations. The specimens were processed, sectioned, and examined under polarized light.

Animal Experiments.—Female Wistar rats were used throughout the study and were subjected to laparotomy via a 2·5-cm. midline abdominal incision. The animals were anaesthetized with ether and the abdominal incision was sutured using silk in all cases. The animals were sacrificed on the seventh day and autopsy specimens were stored in 10 per cent formol–saline. Surgical gloves were not used in the collection of specimens to avoid starch contamination. Specimens were processed, sectioned, and examined by routine microscopy with polarized light.

1. Six animals had 0·01 g. of Biosorb introduced into the abdominal cavity.
2. Six animals had 0·1 g. of Biosorb introduced into the abdominal cavity.
3. Six animals had 0·25 g. of Biosorb introduced into the abdominal cavity.
4. Six animals had 0·5 g. of Biosorb introduced into the abdominal cavity.
5. Six animals had 1·5 g. of Biosorb introduced into the abdominal cavity.
6. Six animals had a 1-cm.^{2} parietal peritoneal defect performed on the lateral abdominal wall and 0·01 g. of Biosorb introduced into the abdominal cavity.
7. Six animals were given a parietal peritoneal defect alone to act as controls.

RESULTS

Glove Experiments.—

1. Examination of the slides from the unwashed gloves showed the presence of multiple starch granules. The granules being birefringent showed the classic 'Maltese cross' appearance when viewed under polarized light. The starch granules were mainly discrete but there was the occasional clump of three to four granules (*Fig.* 1).

2. The gloves that had had one wash still showed the presence of multiple starch granules but there were slightly fewer than in the unwashed group. There were, however, several larger clumps of starch granules present on all the slides.

3. The gloves that had been subjected to two washings still showed multiple starch granules and even more and larger clumps than in the single-wash group (*Fig.* 2).

Human Biopsies.—Of the 20 omental biopsies examined, all showed the presence of starch-granule contamination.

Animal Experiments.—None of the animals that received 0·01 or 0·1 g. of Biosorb showed any evidence of adhesion formation and only 1 animal receiving 0·25 g. developed an adhesion, this being a small omental adhesion to the abdominal incision. However, all the animals receiving 0·5 and 1·5 g. developed a mass of adhesions involving the liver, omentum, and small and large intestines (*Fig.* 3).

The 6 animals with the peritoneal defect plus the introduction of 0·01 g. of Biosorb showed adhesion formation in each animal. The omentum was found to be adherent to the defect in each case and on microscopic examination a granuloma which included starch granules was demonstrated (*Fig.* 4).

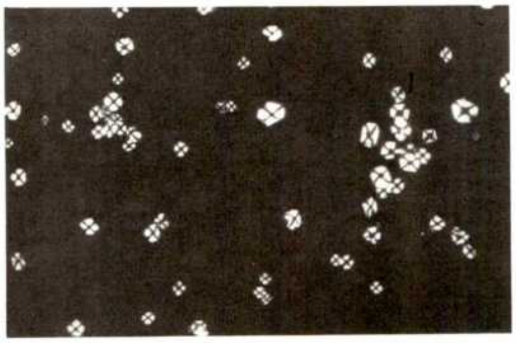

FIG. 1.—Starch granules from an unwashed surgical glove examined under polarized light.

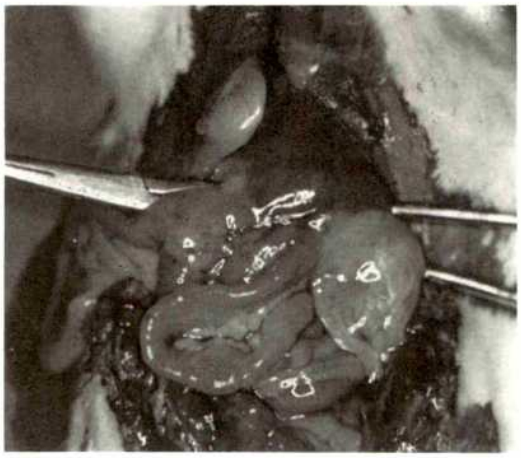

FIG. 3.—Mass of adhesions in an animal having received 1·5 g. of Biosorb intraperitoneally.

The six animals with a peritoneal defect alone showed no adhesion formation to the defect.

DISCUSSION

The standard surgical glove precoated with starch powder would seem inevitably to contaminate the peritoneal cavity with starch granules. Washing the gloves, although reducing the number of starch granules, does not free the outside of the glove from starch. (This finding was confirmed by the use of Lugol's iodine on each glove.) It did, however, cause some clumping of the remaining starch granules, presumably by removing the magnesium oxide in the glove powder. The human omental biopsies taken at the end of laparotomy in a series of patients undergoing abdominal operations also showed starch granules scattered on the serosal surface in every case. It would, therefore, seem to be impossible to avoid some degree of peritoneal contamination when using starch powder in spite of washing the gloves. Perforation of the glove also leads to further contamination and this occurs somewhat frequently; in a series reported by Postlethwaite, Howard, Schanher, and Durham (1949) there was a 16·7 per cent perforation rate in a total of 8893 gloves examined.

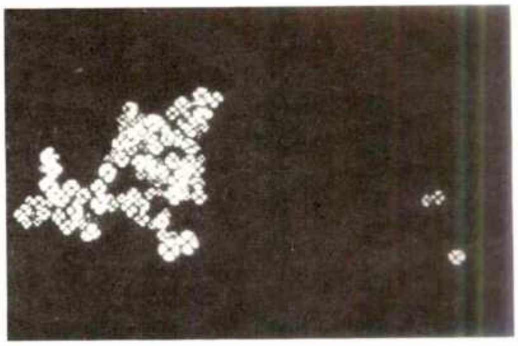

FIG. 2.—A clump of starch granules from a washed surgical glove.

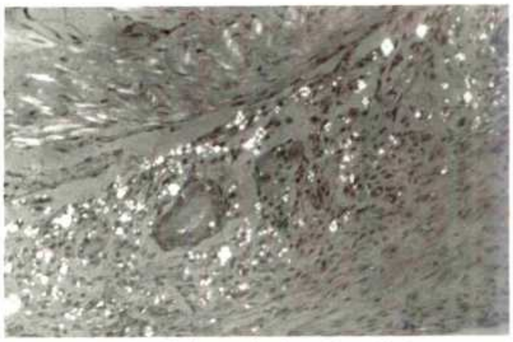

FIG. 4.—Polarized light examination of an adhesion to a peritoneal defect in a rat. Multiple starch granules and a foreign-body granuloma are demonstrated.

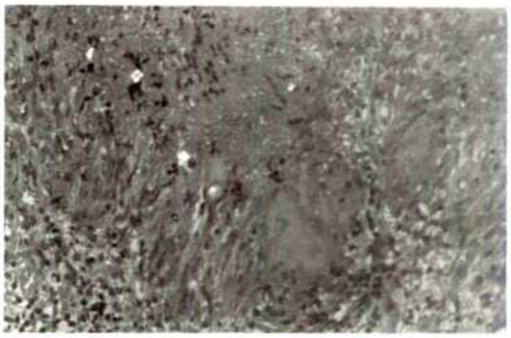

FIG. 5.—Human adhesion biopsy, showing a foreign-body granuloma and starch granules.

The significance of the clumping of the starch granules that occurred after washing is not clear, but it is conceivable that a clump of granules is less easily absorbed and possibly more likely to provoke a foreign-body-type reaction. Lee, Marchall, Collins, and Largen (1952) reported that when lumps of the starch powder were observed, absorption of the powder was delayed and the foreign-body reaction and the adhesions were irreversible. Not every patient develops the acute reaction of granulomatosis peritonei to starch in the postoperative period and the reason for this is not obvious. It has been suggested that a hypersensitivity reaction is to blame, but there is no definite proof of this hypothesis. Intraperitoneal adhesion formation is, however, a serious problem in abdominal surgery and foreign bodies including starch have been incriminated as causative factors in adhesion formation (Adams, 1913; Zachariae, 1954; Bridges, Johnson, and Whitting, 1965). The frequency of starch granulomas in intraperitoneal adhesions requires further investigation. Myllarniemi (1966) was able to show a correlation between dense adhesion formation and the presence of foreign-body granulomas in a series of human adhesion biopsies. We have recently been practising routine biopsy of adhesions and examination under polarized light, and several cases of granulomas in adhesions, with starch granules included, have been demonstrated (*Fig.* 5).

In the animal experiments in this study small amounts of Biosorb (0·01 and 0·1 g.) alone showed no harmful effects, whereas in larger amounts (0·5 and 1·5 g.) adhesion formation occurred in every case. This latter quantity is in excess of any contamination that could occur in a human situation, but nevertheless demonstrates that Biosorb is able to provoke adhesion formation at least in this quantity and in this animal model.

What was interesting was that adhesion formation occurred in all the animals with the small amount of Biosorb (0·01 g.) when coexistent with a peritoneal defect, whereas the defect or Biosorb alone at this dosage failed to produce adhesions. In the human situation injury to the peritoneum and contamination with starch are both inevitable in abdominal surgery, and the combination of these factors may be a more potent cause of intraperitoneal adhesion formation than is at present realized. Following abdominal surgery temporary fibrinous adhesions occur and resolve spontaneously. The presence of a foreign body and granuloma formation may prevent this natural resolution and promote the development of a permanent fibrous adhesion.

The frequency of reports on the harmful effects of starch in the abdominal cavity and the demonstration that contamination of the peritoneal cavity is inevitable when coupled with the high incidence of postoperative intraperitoneal adhesions leave us to question the advisability of using starch-precoated gloves in surgical practice.

Acknowledgements.—We wish to thank Mr. R. Thorley and Miss P. Brock for their technical assistance in the preparation of this article.

EXPERIMENTAL INVESTIGATION OF THE USE OF CYANO-ACRYLATE ADHESIVE TO PREVENT BILIARY LEAKAGE IN PERCUTANEOUS TRANSHEPATIC CHOLANGIOGRAPHY

By A. GEORGAKAKIS[*]
ST. GEORGE'S HOSPITAL, LONDON

SUMMARY

A simple modification of the technique of percutaneous transhepatic cholangiography to prevent leakage of bile or blood has been investigated.

Isobutyl 2-cyano-acrylate monomer has been used to obliterate and seal the tract left when the needle and polythene tube are withdrawn, thus effectively preventing leakage.

PERCUTANEOUS transhepatic cholangiography was first described in 1921 by Burkhardt and Muller in Germany. In 1937 Huard and Do-Xuan-Hop punctured the intrahepatic biliary tree and injected Lipiodol. Carter and Saypol in 1952 used a water-soluble contrast medium. Since then the method has been widely adopted, particularly in South America (Alvarez and Jensen, 1953; Sobredo and Garcia Siguero, 1954).

The number of different techniques described to date suggest that none has been entirely satisfactory, although the method is well established as a very valuable adjunct in the differential diagnosis of the jaundiced patient. All authors agree that the serious hazards in the procedure are bile leakage and biliary peritonitis. Haemorrhage is a secondary hazard. The reported incidence of complications from bile leakage varies from 5 to 50 per cent. The Shaldon modification (Shaldon, Barber, and Young, 1962), introducing a fine polythylene tube over an even finer needle, is regularly used at St. George's Hospital, London. The investigation is only

performed immediately before the operation. This principle is widely accepted because of the hazards mentioned above.

Experimental work has been carried out to test the possibility of using isobutyl-2-cyano-acrylate monomer (IBC-2) to obliterate completely the tract left behind by the introduction of the needle and catheter, thus totally preventing leakage of bile or blood.

MATERIALS AND METHODS

Twelve rabbits were operated upon and their common bile-ducts ligated. The rabbits weighed an average of 3 kg. General anaesthesia was used. At the end of the fourteenth postoperative day transhepatic cholangiography using Shaldon's modification (Shaldon and others, 1962) was performed either percutaneously (4 animals) or under direct vision (8 animals).

After the successful introduction of the catheter (*Fig.* 1) the needle is withdrawn and continuous aspiration of bile performed (*Fig.* 2); 8–10 ml. of 45 per cent Hypaque are introduced as the contrast medium. Aspiration of the Hypaque from the bile-duct system is not necessary, as more radiographs can be taken later on for further information if needed.

When the cholangiography is finished, a clean plastic syringe is attached to the end of the plastic catheter.

Stage A: A slight retraction of the polyethylene tube is made, thus removing the tube from the biliary-duct system. Aspiration with the clean syringe must show no trace of bile.

Stage B: Simultaneous withdrawal of the polyethylene tube and injection of the IBC-2 are performed (*Fig.* 3). The tract in the liver substance left behind by the tube is totally obliterated by the cyano-acrylate adhesive (*Fig.* 4).

RESULTS

No operative or postoperative complications occurred. In all 12 rabbits the method proved reliable and effective. The monomer satisfactorily obliterated the site of the needle puncture, and in no instance was there bile leakage, even with external pressure applied to the liver.

DISCUSSION

Cyano-acrylate monomers have been extensively investigated by several workers, and the tissue reaction to these substances has been studied. They have also been cautiously used in some surgical operations.

The response of liver tissue to cyano-acrylates is a localized acute inflammatory reaction. Degeneration or necrosis of the liver tissue in contact with the polymer is slight (Ota and others, 1968). Infiltrating cells are giant cells and lymphocytes. Within a wee after the application a fibrinous membrane is see covering the polymer, and 2 months afterwards thi membrane becomes fibrous.

The biodegradability of this polymer has bee studied with special staining techniques using oil re O, osmic acid, and Nile blue sulphate (Pani, Gladieux and Brandes, 1968). The removal of the polymer i very gradual. It has been reported to be still demonstrable in small amounts for up to 2 years.

The mild histotoxicity of cyano-acrylates is not very serious limitation to the proposed use of thi material since the polymer plug can be removed i those cases where operation is performed.

The factor of carcinogenicity must be borne i mind as no report of very long-term observation is ye available.

In the experiments reported the use of cyano acrylate monomer has proved an effective method o preventing bile leakage or haemorrhage. The metho itself has been shown to be experimentally saf provided that the polyethylene tube is withdraw from the bile-duct system (as shown by aspiration before the monomer is introduced.

Acknowledgements.—The continuous help an assistance of Professor David Slome, the Bernar Baron Professor of Applied Physiology of the Roya College of Surgeons of England, and Mr. Rodne Smith, Consultant Surgeon, St. George's Hospital London, are gratefully acknowledged.

UBRETID®
distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of **UBRETID** ampoules and tablets are available upon request.

KOCHER'S PERAMPULLARY APPROACH FOR COMMON BILE-DUCT CALCULI

BY A. E. CARTER
KING EDWARD MEMORIAL HOSPITAL, LONDON

SUMMARY

Supraduodenal choledochotomy for common bile-duct stones carries the risk of biliary leakage, a predilection to stricture, and no certainty that all the stones are removed. Stones left behind after the first exploration and new stones formed later require secondary surgery, which is often difficult and has an even greater risk of serious complications.

Perampullary exploration, on the other hand, does not carry an increased initial risk of death or of the complications of biliary fistulae and retained stones of which none occurred in this series. Late complications of stricture and secondary unpassable stones similarly did not occur.

Neither method is free from the risk of postoperative pancreatitis (1 per cent in this series), but there is no evidence that perampullary exploration carries a greater risk than supraduodenal exploration. Even so, it is considered wise to give propantheline for 72 hours after perampullary exploration to reduce this risk.

It has been suggested that a wide, poorly competent, distal common-duct orifice might predispose to ascending cholangitis. No case in this series developed such cholangitis, nor has any case developed stenosis at the sphincteroplasty which might encourage cholangitis. In fact, in the 3 cases that came to post-mortem examination at intervals of 2 and 3 years the sphincteroplasties were still widely patent. Boulter (1961) suggested that sphincterotomy increased the flow of bile in the physiological pressure range and thus might be an additional benefit from the procedure.

GALL-STONES in the common bile-duct as well as in the gall-bladder are not infrequent in gall-stone disease. Rains (1969) stated that between 4 and 7 per cent of all patients with gall-stone disease have stones in the common duct. In the present series almost 20 per cent had such stones. Their removal by standard methods is not always complete and Glenn (1952) cited a figure of 9·7 per cent of cases needing further surgery, while Hughes, Hannan, and Mulvey (1948) found an incidence of 24 per cent. A single exploration of the common bile-duct was stated by Glenn (1967) to carry a mortality of 6 per cent—a figure that is likely to be compounded if more than one exploration is necessary.

The approach to the common duct through its supraduodenal part is the recommended method in the United Kingdom (Rains, 1969). On the Continent of Europe an approach across the duodenum through the ampulla of Vater is popular. The supraduodenal common duct is prone to stenosis when injured, and, after being opened, frequently needs drainage to the exterior. Drainage of the common duct after perampullary exploration is naturally directly into the duodenum and requires no external drains.

Perampullary exploration would have much to recommend it, provided that it was not more dangerous, more liable to sequelae, or less efficient than the supraduodenal route. The procedure can, moreover, be so arranged that should any stones be left behind or new stones form they can discharge spontaneously into the duodenum without hazard to the patient or need for further surgery.

TECHNIQUE

The method used to explore the common-bile duct in this series is, in essence, that of Kocher (1911) with a sphincteroplasty at the end of the procedure, of the type recorded by Rothwell-Jackson (1968).

The abdomen is opened by any standard method, that of Kocher being used in this series. It is essential that the whole of the second and the beginning of the third parts of the duodenum are mobilized completely as the ampulla of Vater lies farther along the second part of the duodenum than is commonly thought (Cattell and Warren, 1956). If the gall-bladder has not been removed already the cystic duct is defined and ligated close to the gall-bladder. A cholangiogram is now performed by inserting a small catheter into the common duct through the cystic duct. Having proved the presence of stones and their number, the duodenum is opened over the ampulla, which often can be located by gentle palpation. Occasionally it is difficult to locate the ampulla when it is of the flat type. Then the passage of a fine bougie through the cystic duct and down the common duct to cause the ampulla to protrude into the duodenum aids the manœuvre. Of the alternative incisions into the duodenum, a single longitudinal incision along the border has been preferred in this series. A suitable probe is inserted into the ampulla and into the common bile-duct, taking care not to misdirect the probe into the pancreatic duct. The distal common duct is opened along its length, lying within the wall of the duodenum against the probe, with diathermy, to a size sufficient to allow mobile stones to fall into the duodenum and to accept Desjardin's forceps to remove any other stones. It is important to define the pancreatic duct at an early stage lest it be damaged by instruments or sutures placed at the sphincteroplasty. Irrigation of the common duct is performed to be sure that it is clear of stones and 'mud'. If there is doubt, a cholangiogram is made by inserting a fine catheter into the common duct through the ampulla. To prevent back-flow of the contrast medium the lips of the incision into the duct are held together over the catheter with non-toothed tissue forceps.

When the common duct is clear beyond doubt its incised wall is united to the cut duodenal mucosa to form a standard sphincteroplasty, using interrupted sutures of 00 chromic atraumatic catgut. The final opening into the duodenum must be equal in size to the widest part of the common duct so that any new stones which are formed can pass into the duodenum freely. It is not necessary to insert any drains into the common duct.

The duodenum is closed longitudinally in the line of the original incision in two layers; the inner of 0 chromic atraumatic catgut and the outer by 000 silk sutures placed singly close together. The operation is completed by cholecystectomy if the gall-bladder has not been removed previously, and the subhepatic space is drained as appropriate.

Postoperatively nasogastric suction is maintained until clear bile is withdrawn, usually for 48 hours. Propantheline, 30 mg., is given intramuscularly every 8 hours, starting at the end of the operation and continuing for 72 hours to reduce stimulation of the pancreas and to diminish the risk of pancreatitis.

Table I.—CAUSE OF POSTOPERATIVE DEATH IN 107 CASES UNDERGOING PERAMPULLARY EXPLORATION OF THE COMMON BILE-DUCT

Cause of Death	*No. of Cases*
Pancreatitis	1
Acute duodenal ulcer	1
Staphylococcal pneumonia	1
Pulmonary embolism	2
Cardiac infarction	3
Total	8

Table II.—COMPLICATIONS OCCURRING AFTER PERAMPULLARY EXPLORATION OF THE COMMON BILE-DUCT

Complication	*No. of Cases*
Early	
Subhepatic abscess	2
Late	
Recurrent stones	1

CLINICAL MATERIAL

Of 361 cases of gall-stone disease who were treated between 1958 and 1965, 107 (29 per cent) had stones in the common bile-duct; 5 of the 107 had previously had a cholecystectomy when no common-duct stones had been suspected. All the common-duct stones were removed by the perampullary route; 7 cases (6·5 per cent) died in hospital from causes associated with the operation in general (*Table I*).

The remaining 100 cases comprise 71 women aged 22–86 years and 29 men aged 27–78 years. Of these, 1 woman, aged 44, died on the second postoperative day from fulminating pancreatitis, which was proved at autopsy. This patient had had 11 months of recurrent biliary colic, frequently with transient jaundice and, on the occasion that brought her into hospital, pancreatitis. She recovered well from the pancreatitis, the jaundice, disappeared and, after intravenou cholangiography, she was explored 2 weeks afte admission. A single stone impacted in the ampull of Vater was removed. At operation the pancrea was indurated but not actively inflamed. Her initi recovery was uneventful until 48 hours after operation, when she developed fulminating pancreatiti from which she did not recover. It may be tha perampullary exploration of the common duct i inappropriate after pancreatitis. However, in thi series one 60-year-old woman had had precedin pancreatitis severe enough to produce anuria wit added obstructive jaundice and staphylococca pneumonia, yet she recovered from subsequen cholecystectomy and perampullary removal of he common-duct stones 19 days after admission withou event. Similarly 2 other women and 4 men had ha preceding pancreatitis and all recovered from operation without trouble.

Two cases developed subhepatic collections of pu without bile. Both required drainage and bot recovered slowly without subsequent biliary troubl (*Table II*). One woman, who had previously had colostomy after rectal excision, has passed gall-stone through her colostomy on three occasions; altogethe 11 stones were passed, the largest being 6 mm. i diameter. She is known to have a double-barrelle cystic duct–common duct junction and is, presumabl forming new stones in the cystic duct remnant. A the new stones have passed without discomfor jaundice, or pancreatitis. Another woman claims t have had jaundice and to have passed stones pe rectum. Neither her family doctor nor the hospita has seen her during one of these episodes and sh does not have the stones to prove the point. Moreover, intravenous cholangiography shows an apparently normal common bile-duct.

Two cases have had later laparotomies; 1 for diverticulitic stricture of the colon in a woman of 7 and the other a vagotomy for oesophagitis in woman of 65. In both cases examination of th common-duct area showed nothing abnormal.

Three cases have since died from other causes an at necropsy (at 2 years in 1 case and 3 years in th 2 cases) the common duct was found to be empty an to have a wide entrance into the duodenum.

Of the survivors, none has had further biliar disease over a minimum of 6 years and a maximu of 13 years.

TRAUMATIC RUPTURE OF THE ILEUM

By J. P. Evans
BASINGSTOKE DISTRICT HOSPITAL, HAMPSHIRE

Summary

Three cases of patients who sustained rupture of the ileum following blunt trauma to the abdomen are reported. The onset of symptoms was delayed for a period which varied between 5 and 12 hours after the injury.

As so many of these patients are either asymptomatic or have minimal symptoms for the first 6 hours after the injury it might be advisable to admit all cases of abdominal injury to hospital for observation.

Laboratory investigations of the haemoglobin, white-blood count, and serum amylase contributed nothing to the early diagnosis of the condition. Plain radiographs of the abdomen show gas under the diaphragm in only 34 per cent of cases of traumatic rupture of the ileum.

Needle aspiration of the abdomen for liberated intestinal contents was not carried out in this series. In other series this procedure was found to be accurate in 90 per cent of cases of traumatic rupture of the small bowel. This is the only investigation which can be regarded as making a useful contribution to the early diagnosis of the condition.

Laparotomy was carried out between 5 and 15 hours after the injury. There was gross contamination of the peritoneal cavity by intestinal contents. This was due in all 3 cases to a single laceration on the antimesenteric border of the bowel. The lacerations were situated at distances varying between 15 and 22·5 cm. from the ileocaecal valve and were between 1·3 and 2·5 cm. in diameter. These were closed using two layers of chromic catgut. The peritoneal cavity was washed out with saline and Noxyflex.

The death of 1 patient in the series occurred 13 hours after the injury and was due to a myocardial infarct. The mortality-rate of 33 per cent for the series is similar to that described in other reports.

ABDOMINAL injuries due to blunt trauma to the abdomen are increasing in number. The majority of these injuries are the result of the large rise in the number of road-traffic accidents and are commonly associated with damage to solid organs such as the liver, spleen, kidney, and pancreas (Counsellor and McCormack, 1935; Hicken and Carlquist, 1944; Fitzgerald, Crawfurd, and DeBakey, 1960; Williams and Yurko, 1966; Hall and Angles, 1969).

The association between blunt trauma to the abdomen and rupture of the small bowel in patients with coexistent inguinal or femoral hernia is well recognized (Aird, 1937; McAdam and Maggregor, 1969). Rupture of the small bowel occurring as an isolated injury following abdominal trauma is extremely rare (Chambers and Card, 1961). Three cases of this type of injury are reported. Attention is drawn to the mortality-rate of 33 per cent which is due to the difficulty and delay in reaching the diagnosis (Hall and Angles, 1969).

CASE REPORTS

Case 1.—A 49-year-old woman tripped and fell on to her back while at home. A few minutes after the accident she began to complain of lower abdominal discomfort. She was seen within 1 hour of the accident by her family doctor. Apart from finding tenderness in both iliac fossae he could detect no other injuries. The patient was not shocked and bowel-sounds were present. The doctor attributed the abdominal discomfort to a possible crush fracture of a vertebra with girdle-type pain.

Twelve hours later the doctor was recalled to see the patient who was in severe pain. She had vomited several times since the accident and examination at this time revealed that she was shocked and had marked abdominal tenderness. The patient was admitted to hospital 14 hours after the accident.

CLINICAL EXAMINATION.—The patient was in severe pain, dehydrated, shocked, and lying motionless. Her temperature was 37° C., pulse 120 per minute, and blood-pressure 90/50 mm. Hg with cold cyanotic peripheries. The chest was clear. The neck and spine were not tender to palpation. There was no bruising of the abdominal wall. Bilateral scars of two previous inguinal herniorrhaphies were noted. The abdomen was distended with guarding and rebound tenderness in all areas. Bowel-sounds were absent. Rectal examination revealed tenderness in the pouch of Douglas. There were no other injuries.

INVESTIGATIONS.—The haemoglobin was 98 per cent, white-blood count 4500 per c.mm., and packed-cell volume 36 per cent. Electrolytes and urea were within normal limits. The serum amylase was less than 250 Somogyi units. A chest radiograph showed partial collapse of the right lower lobe. Supine and erect radiographs of the abdomen revealed no abnormality.

After resuscitation with intravenous saline, plasma, and blood the patient underwent laparotomy.

OPERATION.—The abdomen was opened using a right paramedian incision. The peritoneal cavity was grossly contaminated by intestinal contents. The liver and spleen were intact. The stomach and duodenum were normal. There was a laceration, 2·5 cm. in diameter, on the antimesenteric border of the ileum, 22·5 cm. above the ileocaecal valve. The perforation was sutured in the transverse axis using two layers of chromic catgut. The peritoneal cavity was washed out with saline and Noxyflex. Corrugated drains were inserted into both the upper and lower quadrants of the abdomen. The patient's postoperative recovery was uneventful.

Case 2.—A 51-year-old man, who had previously been well, was admitted to hospital complaining of abdominal pain and vomiting. Six hours prior to admission he had been assaulted after partaking of a large quantity of alcohol. He had been knocked to the ground and kicked several times in the face and abdomen. He had not lost consciousness. Five hours after the incident he began to vomit and complain of severe abdominal pain.

CLINICAL EXAMINATION.—The patient was in severe pain, lying motionless and sweating profusely. His temperature was 37° C., pulse 120 per minute, and blood-pressure 120/70 mm. Hg with cold cyanotic peripheries. The patient had a right periorbital haematoma and a right-sided epistaxis. The neck and spine were not tender to palpation. The chest was clear. There was no bruising of the abdominal wall and no evidence of an inguinal or femoral hernia. The abdomen was not distended, but there was rigidity and widespread rebound tenderness. Bowel-sounds were absent. Rectal examination revealed tenderness in the rectovesical pouch. There were no other injuries.

INVESTIGATIONS.—The haemoglobin was 88 per cent, white-blood count 5200 per c.mm., and packed-cell volume 43 per cent. Electrolytes and urea were within normal limits. The serum amylase was less than 250 Somogyi units. A chest radiograph revealed no abnormality. Supine and erect radiographs of the abdomen showed free gas under the diaphragm.

After resuscitation with intravenous saline, plasma, and blood the patient underwent laparotomy.

OPERATION.—The abdomen was opened using a right paramedian incision. There was gross contamination of the peritoneal cavity by intestinal contents. The stomach and duodenum were intact. There were no lacerations of the liver or spleen. There was a laceration, 2·5 cm. in diameter, on the antimesenteric border of the ileum, 15 cm. above the ileocaecal valve. This was closed in the transverse axis using two layers of chromic catgut. The peritoneal cavity was washed out with saline and Noxyflex. Corrugated drains were inserted into both the upper and lower quadrants of the abdomen.

In the postoperative period the patient was hypotensive and the blood-pressure could not be raised above 70/40 mm. Hg. The patient died 13 hours after the initial injury.

Post-mortem examination, revealed that death was due to a large anterior myocardial infarct.

Case 3.—A 15-year-old girl was referred to the Casualty Department of the Basingstoke District Hospital by her general practitioner. Two hours prior to being seen she had been kicked in the lower abdomen by a horse. Although she was asymptomatic it was decided to admit her for observation.

CLINICAL EXAMINATION.—The patient looked and felt well. Temperature was 37·2° C., pulse 120 per minute, blood-pressure 100/70 mm. Hg with warm peripheries. The chest was clear. There was no bruising of the abdominal wall and no sign of an inguinal or femoral hernia. There was slight tenderness in the right lower quadrant of the abdomen but no guarding or rebound tenderness. Bowel-sounds were present. Rectal examination revealed no abnormality.

INVESTIGATIONS.—The haemoglobin was 95 per cent, white-blood count 8500 per c.mm., packed-cell volume 42 per cent. Electrolytes and urea were within normal limits. The serum amylase was less than 250 Somogyi units. A chest radiograph and erect and supine radiographs of the abdomen revealed no abnormality.

The patient was admitted to the ward. Hourly observations of the pulse and blood-pressure together with 4-hourly observations of the temperature and respiration were carried out. Twelve hours after the original injury the patient began to complain of abdominal pain.

Examination at this time revealed no change in the vital signs. There was, however, widespread tenderness of the right side of the abdomen with guarding and rebound tenderness. Bowel-sounds were now absent and there was extreme tenderness on rectal examination. Laparotomy was therefore undertaken.

OPERATION.—The abdomen was opened using a right paramedian incision. There was slight contamination of the right lower quadrant by intestinal contents. There were no lacerations of the stomach or duodenum and the liver and spleen were intact. There was a large haematoma in the wall of the caecum. A laceration was found on the antimesenteric border of the ileum, 15 cm. above the ileocaecal valve. The perforation was 1·3 cm. in diameter. This was closed in the transverse axis using two layers of chromic catgut. The peritoneal cavity was washed out with saline and Noxyflex. The patient's postoperative recovery was uneventful.

DISCUSSION

The jejunum and ileum sustain damage at or ne
the points of fixation, such as the ligament of Treit
or the ileocaecal valve (Kennedy, 1952). The middl
4 m. of bowel descends vertically along the medi
border of the left psoas muscle into the depths of th
pelvis and is relatively immune to injury (Cottrel
1954).

Rupture of the bowel may be due to crushin
tearing, or bursting injuries. In a crush injury direc
force is applied perpendicularly to the abdomen. Th
bowel ruptures when it is trapped between th
distorted abdominal wall and fixed structures such a
the spine or pelvis. Tearing injuries occur whe
force is applied tangentially to the abdominal wal
The bowel is torn from its attachments and th
mesentery is frequently lacerated. Bursting of th
intestine is associated with an increase in the intra
luminal pressure exerted by fluid or gas caug
between the angulations of the bowel (Counsello
and McCormack, 1935).

The effects of pressure on isolated segments c
fresh human bowel have shown that the intestin
ruptures at a pressure of 7 or 8 lb. per sq. i
(Andrewes, 1911). It has also been shown that whe
the rate of distension was doubled the pressur
required to perforate the bowel was reduced to 4 l
per sq. in. (Burt, 1931). Further investigations hav
revealed that a low pressure acting suddenly on
loop of fluid-filled bowel will produce rupture, b
there will be no harmful effects when the sam
pressure acts on an empty bowel (Geoghegan an
Brush, 1956).

In the present series rupture of the bowel in *Cas*
1 and 3 was probably due to a crush injury. Th
bowel was lacerated when it was forced against th
spine or side-wall of the pelvis. In *Case* 2 the patie
had partaken of a large quantity of alcohol when th
injury was sustained. The laceration of the bow
was probably due to a combination of a crushing an
bursting injury.

When the bowel ruptures, the serosa splits fir
followed by the mucosa. The submucosa is the la
layer to give way (Hertle, 1907). Rupture of the sma
bowel occurs most frequently on the antimesenteri
border (Penberty and Reiners, 1953; McAdam an
Maggregor, 1969). Lacerations of the mesenteri
border occur much less frequently (Aird, 1937
Mufson, 1939; Payson and Mace, 1962). All th
patients in the present series had sustained laceration
on the antimesenteric border of the bowel.

The high mortality of traumatic rupture of th
ileum has been attributed to the difficulties and dela
in reaching the diagnosis. The majority of patient
are either asymptomatic or have minimal symptom
when first seen (Counsellor and McCormack, 1935
Jordan and McAfee, 1963). Two of the patients i
this series (*Cases* 1 and 3) were seen within 3 hours c
sustaining their injuries. One patient (*Case* 1) ha
minimal symptoms while the second patient (*Case*
was asymptomatic. Both patients were thought n
to have sustained serious injury, but after 12 hou
signs of peritoneal irritation were so advanced th
laparotomy was undertaken. The third patient (*Case*
was not seen until 5 hours after the assault. Sig
of shock and peritoneal irritation were by this time s
advanced that laparotomy was considered mandator

The delay in the onset of symptoms and signs is due to the sequence of events which occur following perforation of the bowel. Leakage of the intestinal contents is restricted by evertion of the mucous membrane through the laceration in the wall of the intestine. This has the effect of 'plugging' the hole in the bowel wall. Leakage is also thought to be curtailed by spasm of the circular muscle above and below the level of the perforation (Fraser and Drummond, 1917). The spasm passes off after 5 or 6 hours and peristalsis is resumed. Contamination of the peritoneal cavity then occurs owing to the effluence of intestinal contents through the perforation (Cope, 1914).

If a patient is asymptomatic or has minimal symptoms following trauma to the abdomen there is a danger that the injury might be regarded as being of no importance. This occurred in *Cases* 1 and 3 in the present series. Hall and Angles (1969) have stated that in cases of abdominal trauma with rupture of the bowel there is an immediate reduction or cessation of bowel-sounds. This sign was said to be present even if the patient was asymptomatic and was, by itself, an indication for admission to hospital for observation. In 2 of the patients in this series bowel-sounds were still present 1 and 3 hours after the intestine had been perforated. This sign is of no assistance in attempting to assess the severity of damage to the small bowel.

Laboratory investigations of the haemoglobin, white-blood count, and serum amylase in the present series were within normal limits. These findings are in accordance with those of Shaftan (1960) and confirm the fact that these procedures are of no value in establishing the diagnosis.

Erect and supine radiographs of the abdomen have shown gas under the diaphragm in only 34 per cent of patients with traumatic rupture of the ileum (Duncan, 1956; Williams and Zollinger, 1957). This sign was present in only 1 patient in the present series. These investigations are of limited value in confirming the presence of this condition.

Diagnostic needle aspiration of the abdomen for liberated intestinal contents has been found to be positive in up to 90 per cent of patients with traumatic rupture of the small bowel (Williams and Zollinger, 1957; Williams and Yurko, 1966). This procedure was not used in the present series. It could only have been used with benefit in *Case* 3. In the other 2 patients peritoneal irritation was so advanced that laparotomy was mandatory. This investigation, if used more often, might establish the diagnosis at an earlier stage of the post-injury phase with consequent improvement in the mortality-rate.

Laparotomy with suture of the perforation and peritoneal toilet must be carried out at an early stage if the patient is to survive. Small-bowel perforations have a mortality of 15 per cent when detected within 4 hours, 44 per cent when detected between 4 and 8 hours, and 70 per cent when detected at 12 hours (Wright, Prigot, and Stein, 1948).

The mortality-rate for traumatic rupture of the ileum has decreased over the past 30 years from 60 per cent (Counsellor and McCormack, 1935) to 33 per cent (Hall and Angles, 1969). A greater awareness of the condition together with earlier diagnosis is needed if the mortality-rate is to show further improvement.

Acknowledgements.—I should like to thank the consultant surgeons to the North Hampshire Group of Hospitals for allowing me to report on patients who were under their care. I should also like to thank Mr. J. F. Newcombe, Consultant Surgeon to the Central Middlesex Hospital, for his advice on the writing of this paper.

INTRAMUSCULAR MYXOMAS

BY R. D. ROSIN

THE WESTMINSTER HOSPITAL, LONDON

SUMMARY

Seven cases of intramuscular myxoma are presented. Although these lesions appear to be malignant macroscopically they are in fact benign tumours. They are well recognized and described in the pathology literature, but are not so readily recognized by surgeons.

A COMPREHENSIVE review of 34 cases of intramuscular myxoma was published by Enzinger in 1965. Over the past 2 years 9 cases have been discovered in patients in the Westminster Hospital group. Their presentations were varied and no tumour was diagnosed correctly prior to excision and histological examination. Three of the examples were in patients who did not present in the past 2 years but whose histological slides were reviewed in that time and the diagnosis changed. One of these cases has not been followed up and there are few historical facts available. This case and another which was a chance finding at post-mortem examination will not be described. The present report concerns the remaining 7 cases of intramuscular myxoma.

CASE REPORTS

Case 1.—*Site: Vastus medialis.*—A 63-year-old female presented in 1961 with a swelling in her right thigh which had been present for 18 months. It had not caused pain or limitation of movement. It felt firm and was fixed in the muscle. At operation the tumour was widely excised. Histology showed a spindle-cell tumour in which the cells were very loosely packed and the whole tumour had a myxomatous appearance. These appearances did not suggest aggressive behaviour but the tumour was infiltrating muscle. At the time it was regarded as a fibrosarcoma. Postoperatively the patient was treated with radiotherapy. Ten years after operation there were no signs of recurrence.

The histology has been reviewed within the past 2 years and the opinion is now that it was not a fibrosarcoma but an intramuscular myxoma.

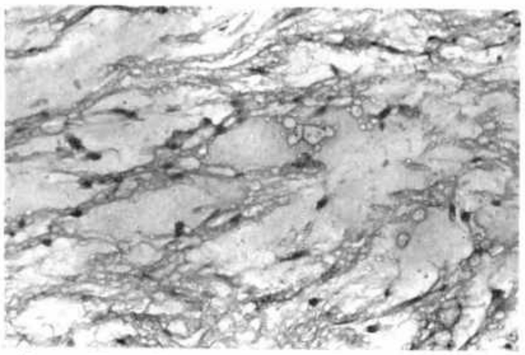

FIG. 1.—*Case* 3. Intramuscular myxoma, showing myxomatous tissue, scattered nuclei, and absence of blood-vessels. H. and E. (× 98.)

Case 2.—*Site: Latissimus dorsi.*—A 73-year-old female presented in 1962 with a swelling in the right side of her neck. On routine inquiry she revealed that she also had a small, painless swelling under her right arm which had been present for 9 months. On examination this second swelling proved to be a firm mass, 3 cm. in diameter, situated in the posterior fold of the right axilla. It was lobulated and had an indefinite margin.

At operation a myxomatous tumour was dissected out of the latissimus dorsi muscle and fat of the axillary fold. It was excised with a wide margin of normal-looking tissue. Histologically it was thought to be a myxomatous tumour, possibly with sarcomatous changes. The patient has been regularly followed up and at 9 years after operation there were no signs of recurrence.

The histology has been reviewed within the past 2 years and a definite diagnosis of an intramuscular myxoma made.

Case 3.—*Site: Gastrocnemius.*—A 65-year-old female presented with a 5-month history of a painless, hard swelling at the back of her right calf which had gradually increased in size. She was otherwise well except for being hypertensive. Clinically there was a well-circumscribed mobile swelling in the superficial muscle of the right calf, approximately 5 cm. in diameter.

At operation there was a swelling in the medial head of the gastrocnemius, measuring 5 × 3 cm. It was excised with a narrow rim of surrounding muscle. During removal the tumour burst and thick white fluid exuded. Histology proved it to be an example of an intramuscular myxoma (*Figs.* 1, 2). There were no signs of recurrence 2 years later.

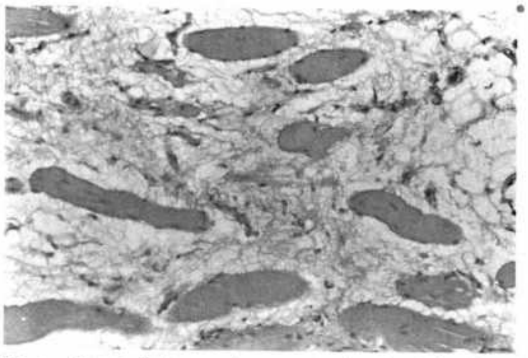

FIG. 2.—*Case* 3. Intramuscular myxoma, showing infiltration of muscle. H. and E. (× 62.)

Case 4.—*Site: Geniohyoid.*—A 44-year-old man presented with a small painless swelling under the chin in the midline, measuring 2 cm. in diameter. It had been present for 8 months and had been troublesome only inasmuch that it interfered with shaving.

At operation the lump was found to be surrounded intimately by muscle of normal appearance. It was excised with a rim of this muscle. Macroscopically it had the appearances of a desmoid tumour, but histology showed it to be an intramuscular myxoma.

The patient made an uneventful recovery and there were no signs of recurrence 18 months postoperatively.

Case 5.—*Site: Rectus abdominis.*—A 54-year-old man was admitted for removal of a small fatty hernia of the linea alba, 2 cm. below the umbilicus, which had been present for 4 months. At operation the lump was excised with a portion of the surrounding rectus sheath. Macroscopically, the lesion was suggestive of a desmoid tumour. Microscopically, it consisted of loose myxomatous tissue containing spindle-shaped and stellate cells. Numerous small blood-vessels were present coursing through the tissue. Mitotic activity was not seen.

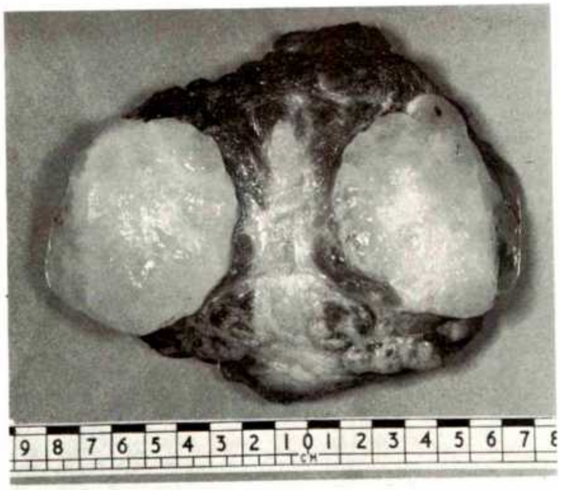

FIG. 3.—*Case* 6. Macroscopic appearance of the tumour.

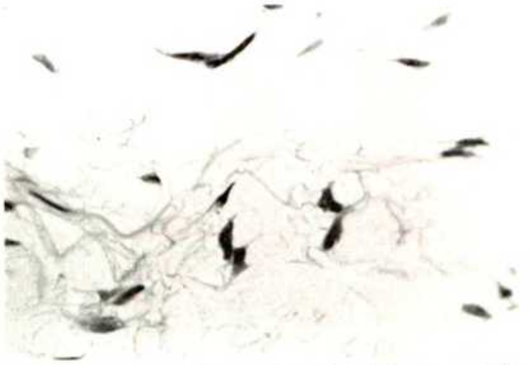

FIG. 5.—*Case* 6. High-power view of typical tumour cells. H. and E. (× 186.)

The tumour was thought to be an atypical intramuscular myxoma as the vascularity was greater than is usually seen. There were no signs of recurrence 2 years postoperatively.

Case 6.—*Site: Gluteus maximus.*—A 73-year-old woman was admitted for a left total hip replacement. Clinical examination revealed a large swelling in the muscles of the left buttock.

At operation through the routine posterolateral incision a large well-circumscribed tumour was discovered within the gluteus maximus muscle. It was 8 cm. in diameter and looked like a well-circumscribed fibrosarcoma (*Fig.* 3). A frozen section was taken and was equivocal, but it was thought that malignant cells were present. A wide excision of the tumour was performed and the wound was closed.

Paraffin sections (*Figs.* 4, 5) showed the lesion to be an intramuscular myxoma. The patient was discharged after 10 days and readmitted 3 months later when a McKee-Farrar arthroplasty was performed. There were no signs of recurrence 1 year later.

Case 7.—*Site: Adductor longus.*—A 45-year-old woman was seen by her general practitioner as she had a small painless swelling on the medial side of her left thigh. She thought that it had appeared after twisting her leg 2 months previously. The doctor diagnosed a haematoma, but as the lump enlarged over the next 4 weeks he referred her to hospital with a diagnosis of possible fibrosarcoma.

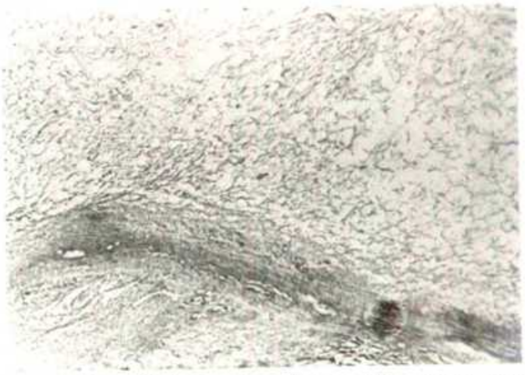

FIG. 4.—*Case* 6. Reticulin stain to show the delicate meshwork of reticulin fibres. H. and E. (× 53.)

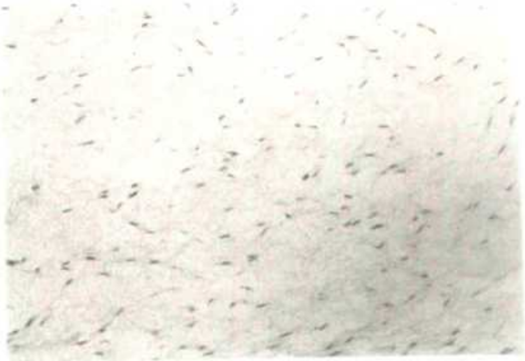

FIG. 6.—*Case* 7. Small numbers of inconspicuous cells scattered in a mucoid stroma. H. and E. (× 53.)

Clinically, there was a non-tender swelling, 4 cm. in diameter, in the left adductor longus which was mobile in the horizontal but not in the vertical plane. The inguinal lymph-nodes were not enlarged.

At operation a swelling within the substance of the adductor longus muscle was discovered. It appeared to infiltrate the muscle locally and it was excised with a rim of normal-looking muscle. Macroscopically, it was an oval cystic lesion measuring 4 cm. in diamater. Histology proved it to be an intramuscular myxoma (*Fig.* 6). There were no signs of recurrence 3 months later.

DISCUSSION

Clinical Presentation.—The sole presenting symptom in all the cases was a painless palpable mass. The interval between the appearance of the tumour and its excision was variable, the average time being 4 months. There was no history of trauma in any of the cases except for 1 patient who had received gold injections in the same area some years ago. All the lesions presented in adults, of whom two-thirds were female.

Pathology.—Macroscopically, the features varied only slightly from case to case. Most of the tumours were rounded masses with a glistening, mucoid, grey/white appearance. On casual examination all were well circumscribed, but closer examination showed them to have infiltrated the adjacent muscle. The size of the different tumours ranged from 2 to 12 cm. in diameter. They appeared in widely differing muscles, although half of them were in the lower limbs.

Microscopically, the tumours were characterized by a small number of scattered inconspicuous cells in abundant mucoid material and a meshwork of delicate reticulin fibres (McKenzie, 1969). In only 1 case was there more than just a sparse vascular network.

Treatment.—The treatment was confined to local excision except in 1 case where radiotherapy was given as the diagnosis was in doubt. There has been no recurrence or metastases in any of the cases, the longest follow-up period being 10 years.

A review of 9 myxomas, of which 7 cases are reported, shows that an intramuscular myxoma is a distinct tumour of benign behaviour. They may resemble mucoid sarcomas, myxoid liposarcomas, and fibrosarcomas. The surgeon must, therefore, be on his guard not to mistake this benign lesion for one o the others mentioned. Frozen sections may b misleading.

Histologically, Stout (1948), Enzinger (1965), an McKenzie (1969) have stated that the precise natur of myxomas is still a matter of controversy. McKenzi (1969) suggested that the myxoma cell may be a altered fibroblast and that transitional forms betwee myxomas and fasciitis may be encountered.

It has recently been reported (Wirth, Leavitt, an Enzinger, 1971) that intramuscular myxomas are a extraskeletal manifestation of fibrous dysplasia. Thi was not evident in any of the cases reported here.

Acknowledgements.—I should like to than Mr. R. Cox for his help with this paper and providin *Cases* 3 and 7; Mr. E. S. Lee for *Case* 2; Mr. B. G Andrews for *Case* 6; Mr. C. Westbury for *Case* 4 Mr. T. M. Prosser for *Cases* 1 and 5. Dr. D. H McKenzie and Dr. J. Earle helped with the patholog and provided the figures.

EMBRYONIC RHABDOMYOSARCOMA OF THE UROGENITAL TRAC

BY S. GHAZALI
THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET, LONDON

SUMMARY

Forty-two cases of embryonic rhabdomyosarcoma of the urogenital tract are reviewed. Their distribution, modes of presentation, clinical features, surgical management, and prognosis are discussed.

EMBRYONIC rhabdomyosarcoma is an extremely malignant tumour of the lower genito-urinary tract which arises from striated muscle. It characteristically presents as a lobular grape-like mass (sarcoma botryoides), an example of which is one of John Hunter's original specimens in the museum of the Royal College of Surgeons of England.

CLINICAL DETAILS

Between 1945 and 1971, 42 patients with embryonic rhabdomyosarcoma of the urogenital tract have been treated at the Hospital for Sick Children, London; 24 tumours arose in the bladder, 9 in the prostate, 3 in the spermatic cord, 4 in the vagina, and 2 in the broad ligament. The median age of the children with bladder tumours was 1 year 9 months, which was significantly lower than that of children with prostatic tumours—3 years and 6 months ($P < 0.05$, Rank sum test)—and also less than that of children with the other types of rhabdomyosarcoma of the urogenital tract (*Fig.* 1). There was no differenc between the sexes in age of presentation.

1. Rhabdomyosarcoma of the Bladder.—O the 24 children with rhabdomyosarcoma of th bladder, 14 were boys and more than 85 per cent wer less than 3 years of age at the time of operation. Th most common first symptom was urinary retentio with strangury due to tumour lobules being pushe down into the posterior urethra. Constipatio occurred in a third of the patients and, in these, recta mucosal prolapse was common. Polyps were passe per urethram in only 2 children and macroscopi haematuria was rare. A baby who was born with th tumour had a distended abdomen, a large tumou arising out of the pelvis, and gross pitting oedema o the lower half of the abdomen and of the right labia The diagnosis could usually be made on clinica grounds when a palpable bladder swelling did no disappear on urethral catheterization. An abdomina tumour was palpable in 22 of the 24 patients afte catheterization. Intravenous pyelography invariabl displayed a dilated upper urinary tract with displacement of the bladder, which contained the characteristic lobulated filling defects (*Fig.* 2).

All the patients were treated by cystectomy wit excision of the posterior urethra in the male and th whole of the urethra in the female, with ileal loo urinary diversion in the later patients in the series. Ureterosigmoid diversion for rhabdomyosarcoma has been disappointing and in the survivors it was later converted to ileal loop diversion. One patient died of cardiac arrest on the operating table; at autopsy a tumour embolus was found occupying the right ventricle and there was tumour thrombus in the inferior vena cava and its pelvic tributaries.

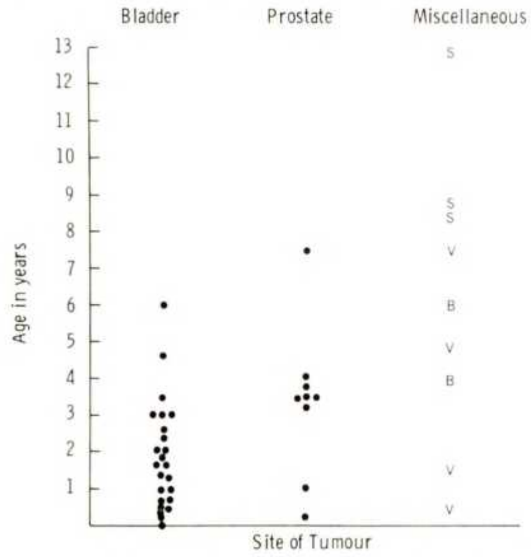

FIG. 1.—Age distribution of children with embryonic rhabdomyosarcoma of the urogenital tract. B, Broad ligament. S, Spermatic cord. V, Vagina.

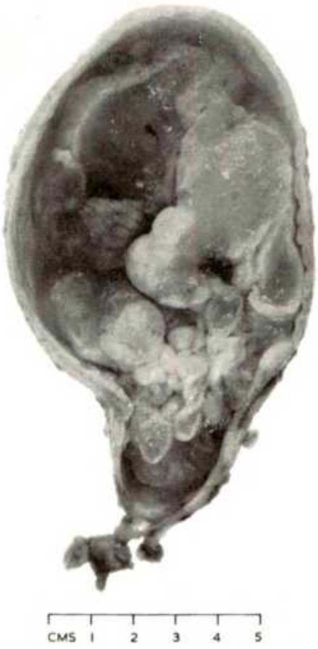

FIG. 3.—Cut section of an embryonic rhabdomyosarcoma of the bladder of the polypoidal type, showing the characteristic polypoidal protuberances in the bladder whose walls are of a normal thickness.

Rhabdomyosarcoma of the bladder has been classified as a polypoid or solid tumour according to the macroscopic appearance at operation or after histological examination. Polypoid tumours (*Fig.* 3) grew principally into the bladder lumen, producing a mass of pearly-grey lobules similar to those which, in the case of rhabdomyosarcoma of the vagina, have been likened to a bunch of grapes (sarcoma botryoides), whereas the solid tumours (*Fig.* 4) grew mainly by extending into the bladder wall, involving the adjacent organs, and, in their late stages of growth, producing a few excrescences into the bladder lumen. There was no significant difference in the age distribution between the polypoid and solid tumours. Seven of the 15 solid tumours occurred in boys as did 7 of the 11 polypoid tumours. Dysuria, pain in

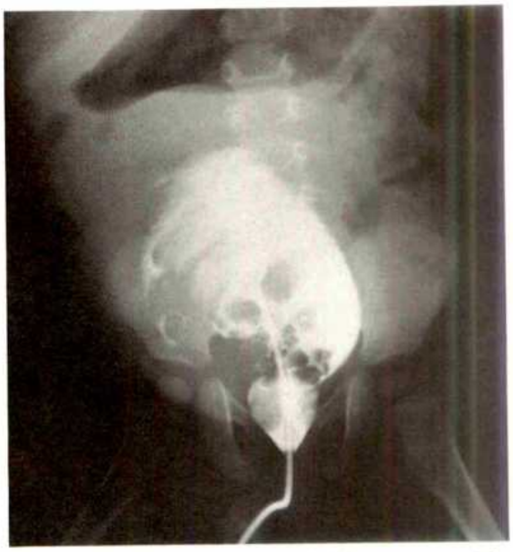

FIG. 2.—Cystogram of an embryonic rhabdomyosarcoma of the bladder, showing the characteristic filling defects in the bladder.

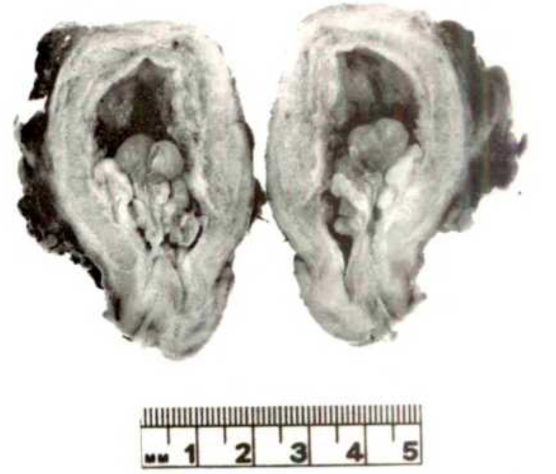

FIG. 4.—Cut section of an embryonic rhabdomyosarcoma of the bladder of the solid type, showing a thick-walled bladder which is involved by the tumour with very few broad-based excrescences.

the lower abdomen, frequency of micturition, and constipation with rectal mucosal prolapse occurred in both varieties, but urinary retention was more common with the polypoid type of tumour. Local recurrence was a constant feature in the patients who died, associated with pulmonary and distant metastases. Of the 24 patients with rhabdomyosarcoma of the bladder who have been operated on since 1945, 11 have survived (for periods of 22, 20, 14, 13, 12, 10, 9, and 5 years, 1 year, and 6 and 3 months, respectively), and in all 11, the tumours were of the polypoid type.

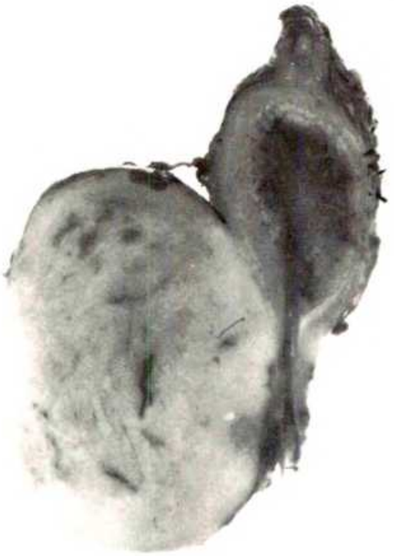

FIG. 5.—Cut section of an embryonic rhabdomyosarcoma of the prostate.

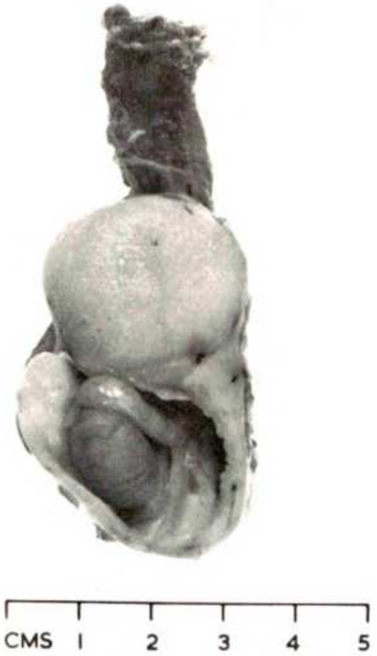

FIG. 6.—Cut section of an embryonic rhabdomyosarcoma of the spermatic cord. There was no involvement of the testis or epididymis by the tumour.

2. Rhabdomyosarcoma of the Prostate (*Fig.* 5).—This tumour usually causes urinary retention at a later age than rhabdomyosarcoma of the bladder, and is accompanied by dysuria, straining on micturition, and dribbling. The median age at the time of presentation was 3 years and 6 months, the youngest patient being 3 months and the oldest 7 years 6 months. The tumour was palpable on rectal examination. Cysto-urethrography helped in revealing the diagnosis, confirmation of which was usually obtained at the time of operation.

Up to 1963, excision of the bladder, prostate, and the posterior urethra was possible in only 3 of the 6 cases and in 2 of these partial excision had been performed at the referring hospital. None of the 6 survived, all having local recurrence followed by distant metastases. Of 3 subsequent patients, suprapubic cystostomy had been performed before referral in 2 as a means of drainage and biopsy. The first child initially did well after excision of the tumour but died 18 months later of local recurrence and distant spread. It is less than a year since the other 2 children had their tumours resected, but at the present time they are thriving and there are no signs of metastases. In both of the longest survivors the tumour recurred 29 months after operation.

3. Rhabdomyosarcoma of the Spermatic Cord.—The common presentation was of a painless lump or lumps in the scrotum, two on the left and one on the right, present for periods of 1 day, 1 month, and 4 months respectively (*Fig.* 6). The lumps were hard or cystic. Orchidectomy with excision of the spermatic cord was performed but lymph-node clearance was not undertaken. In 1 child, because tumour cells were found on histological examination of the veins of the spermatic cord, the testicular vessels were excised up to the level of the renal vein. The para-aortic lymph-nodes were not enlarged. The tunica vaginalis was thickened in all 3 cases, but it was not possible to decide from which para-testicular layer the tumour arose, although it appeared to arise from the tunica in 1 case. One child died within a year of operation without responding to actinomycin D or to radiotherapy, but the other 2 are alive and well 10 years since the time of operation. Both children were given actinomycin D for 10 days postoperatively, and in 1 the course was repeated. These 2 children are probably the longest survivors of this disease.

4. Rhabdomyosarcoma of the Broad Ligament.—Both patients presented with large pelvic lumps. The older girl had severe dysuria and constipation whereas the other had pain in her groin. Intravenous pyelography demonstrated pressure effects of the tumour on the upper urinary tract and a cystogram revealed indentation of the bladder and displacement of the ureters. At operation in both cases a large cystic, very friable, and extremely vascular mass was found arising from the broad ligament. In 1 case this was surgically inoperable and in the other the mass was ruptured on manipulation and was incompletely excised. Postoperative vincristine and radiotherapy did not make any impression on the tumour. Both children died of uraemia within 1 year.

5. Rhabdomyosarcoma of the Vagina.—One 5-month-old child showed typical grape-like masses protruding from the vaginal introitus (*Fig.* 7). The other 3 patients had vulval masses with severe dysuria and considerable vaginal discharge. Two had been treated as vaginitis for prolonged periods of time before a diagnosis was made. The diagnosis of this tumour is based on the demonstration by cystographic and postoperative macroscopic examination of the surgical specimen that the urinary bladder is not involved in the disease. In the youngest child at the time of operation, after the uterus and vagina had been mobilized and the vagina had been opened, it was demonstrated that the tumour was localized to the lower part of the vagina and there was no apparent spread to any other organ. Hence, only vaginectomy was performed and a split-skin graft was applied to the excised defect. In the 6 years since this operation there has been no obvious recurrence of the tumour. In 2 other patients cystectomy, hysterosalpingectomy, and vaginectomy were performed, 1 case also having block dissection of both inguinal lymph-nodes and also removal of the lymph-nodes along the iliac veins. In both patients ileal loop urinary diversion was done. In the fourth patient only biopsy of the tumour was possible as the tumour had metastasized to the lungs. The last 3 patients all died 3 and 2 years and 1 year after operation or biopsy, respectively. There was no response to radiotherapy.

DISCUSSION

There is no agreement about the possible site or sites of origin of rhabdomyosarcoma of the urogenital tract but the following structures have been suggested: Wolffian duct rests, embryonic rests of totipotent cells, misplaced fragments of the embryonic dorsal myotomes, unilateral differentiation in teratomas, and, in the case of the spermatic cord tumours, the cremaster muscle, gubernaculum, and metaplasia from the muscular coats of the vas deferens or epididymis. White (1955) has shown that these tumours are embryonic sarcomata, the tissue consisting of immature mesenchyme which undergoes variable degrees of differentiation to striated muscle, to connective tissue, and possibly to smooth muscle. Some parts of the tumour have a myxomatous structure which does not at first suggest malignancy. In the bladder the growth originates in the submucosal and superficial layers at the base of the bladder and extends down the urethra, right through the membranous portion in the male and the whole length of the female urethra. Ureteric extension is uncommon. Histologically, the tumour is the same whether it arises in the bladder or elsewhere in the urogenital tract. The clinical behaviour of the tumours and their prognosis are very different, the polypoid bladder tumours presenting more often with strangury and urinary retention and having a much better prognosis than the solid variety of bladder rhabdomyosarcoma. This is in complete contrast to the other types, in which, apart from 1 child with vaginal rhabdomyosarcoma and 2 with spermatic cord tumours, all the patients have died from metastases. The tumour recurs locally before there is widespread lymphatic and blood-stream spread, local recurrence being most likely the result of incomplete removal.

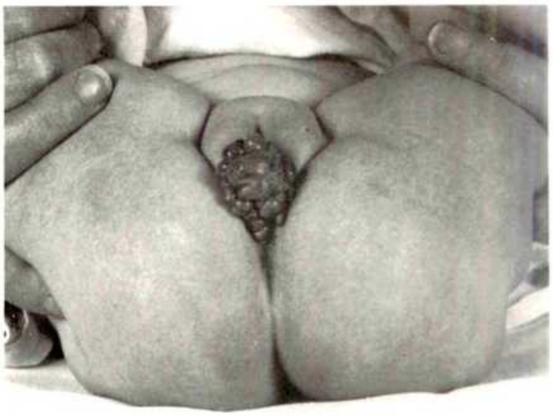

FIG. 7.—Classic sarcoma botryoides in which there are grape-like protuberances of the tumour projecting from the vaginal introitus.

Diagnosis is made on clinical grounds and can be confirmed by endoscopic biopsy. Suprapubic cystostomy should never be performed to obtain a biopsy specimen or for the purposes of temporary urinary diversion. Differential diagnosis is from: (*a*) ectopic ureterocele, especially if complicated by infection or oedema, but the upper-urinary-tract anomaly associated with ureterocele should establish the diagnosis; (*b*) hamartomatous conditions such as neurofibromatosis or haemolymphangioma of the bladder with which there may be associated café-au-lait spots or skin haemangiomas; (*c*) eosinophilic cystitis or cystitis cystica.

Radical lymph-node dissection has not been performed because, apart from spread to lumbar lymph-nodes, there is haematogenous spread to the lungs, kidneys, liver, and bone. Lymph-nodes have not usually been enlarged at the time of operation and microscopic involvement on histological examination has not been a predominant feature in our cases, except with vaginal rhabdomyosarcoma, where spread is early and surgical lymphadenectomy has not been helpful in controlling the disease. Irradiation and chemotherapy have not been helpful in widespread disease or in reducing the incidence of local recurrence. *Figs.* 8 and 9 show the survival periods of the 42 cases of embryonic rhabdomyosarcoma of the urogenital tract in the present series.

Children with prostatic rhabdomyosarcoma presented with signs and symptoms similar to those of adult prostatism. All the tumours were palpable on rectal examination and confirmation of the diagnosis was usually made at the time of operation. Differential diagnosis is from prostatic abscess, in which the child has pyrexia, systemic disturbances, and leucocytosis. Diagnosis can be confirmed by aspiration. The results of treatment of prostatic rhabdomyosarcoma have been disappointing. Of our 9 patients, 5 have died very early after surgery; local recurrence occurred in all 7 cases before distal spread and death ensued. It is less than a year since operation in the remaining 2 cases. These results suggest that surgical extirpation was incomplete and better results may be obtained by a more radical approach.

Arean and Kreager (1965) reviewed 44 patients aged 5–15 years with spermatic cord rhabdomyosarcoma reported in the literature up to 1965. Results were poor, but the 2 survivors in the present series are free of tumour 10 years after surgery. One patient had obvious tumour embolus in one of the veins of the cut end of the spermatic cord. Both were given actinomycin D postoperatively.

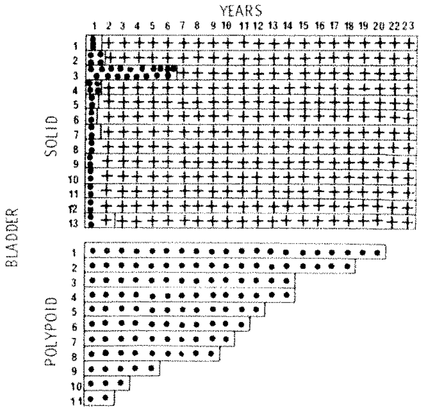

FIG. 8.—Survival times of children with embryonic rhabdomyosarcoma of the bladder. ●, Alive. +, Dead.

One of the characteristic features of rhabdomyosarcoma of the vagina appears to be spread of the tumour to the lymph-nodes, although lymphadenectomy has not improved results. The other feature is its presentation as grape-like masses protruding from the vaginal introitus (sarcoma botryoides). The 5-month-old child who had a simple restricted vaginectomy is alive 6 years after surgery, whereas the other 3 patients died following local recurrence and distant metastases. Earlier diagnosis and treatment may provide long-term survivors. Vaginal discharge in the very young should always be investigated.

Chemotherapy and radiotherapy have not been used prophylactically, except when there has been doubt about complete excision of the tumour. Neither treatment has substantially altered the prognosis although in cases with local recurrence there has been some temporary relief of symptoms. Sutow, Sullivan, Reid, Taylor, and Griffith (1970), reviewing survival data on 78 children with rhabdomyosarcoma (orbit 15, head and neck 31, extremities 8, sarcoma botryoides 5, genito-urinary other than vagina 7, others, 12), indicated that age, histology, primary site, extent of disease, and treatment each had a significant influence on the prognosis. The best survival occurred in patients with sarcoma botryoides and in children less than 7 years of age and the poorest with alveolar rhabdomyosarcoma.

CONCLUSIONS

Polypoidal bladder tumours have a better prognosis than any of the other varieties of rhabdomyosarcoma of the urogenital tract. The solid bladder and prostatic tumours may do better with wider excision to include possible extra-bladder and extra-prostatic extensions of the tumour. Our patients with spermatic cord tumours have survived for long periods after excision of the tumour together with the cord, testis, and epididymis. Vaginal tumours may do better if diagnosed and treated earlier. Reviewing our cases it is apparent that if local recurrence has not occurred in bladder rhabdomyosarcoma within the first 2 years after surgery the patient has probably been cured. This was so in all our cases, except 1 in whom recurrence was noted 6 years after surgery. Local recurrence usually occurs within the first postoperative year followed rapidly by distant lymphatic and haematogenous spread. Hence, it would seem logical that to improve our results we would have to diagnose these tumours earlier, before they are surgically inoperable, and then to perform radical surgery to extirpate the tumour and its possible sites of recurrence, especially as the tumour when it recurs is not responsive to chemotherapy and irradiation.

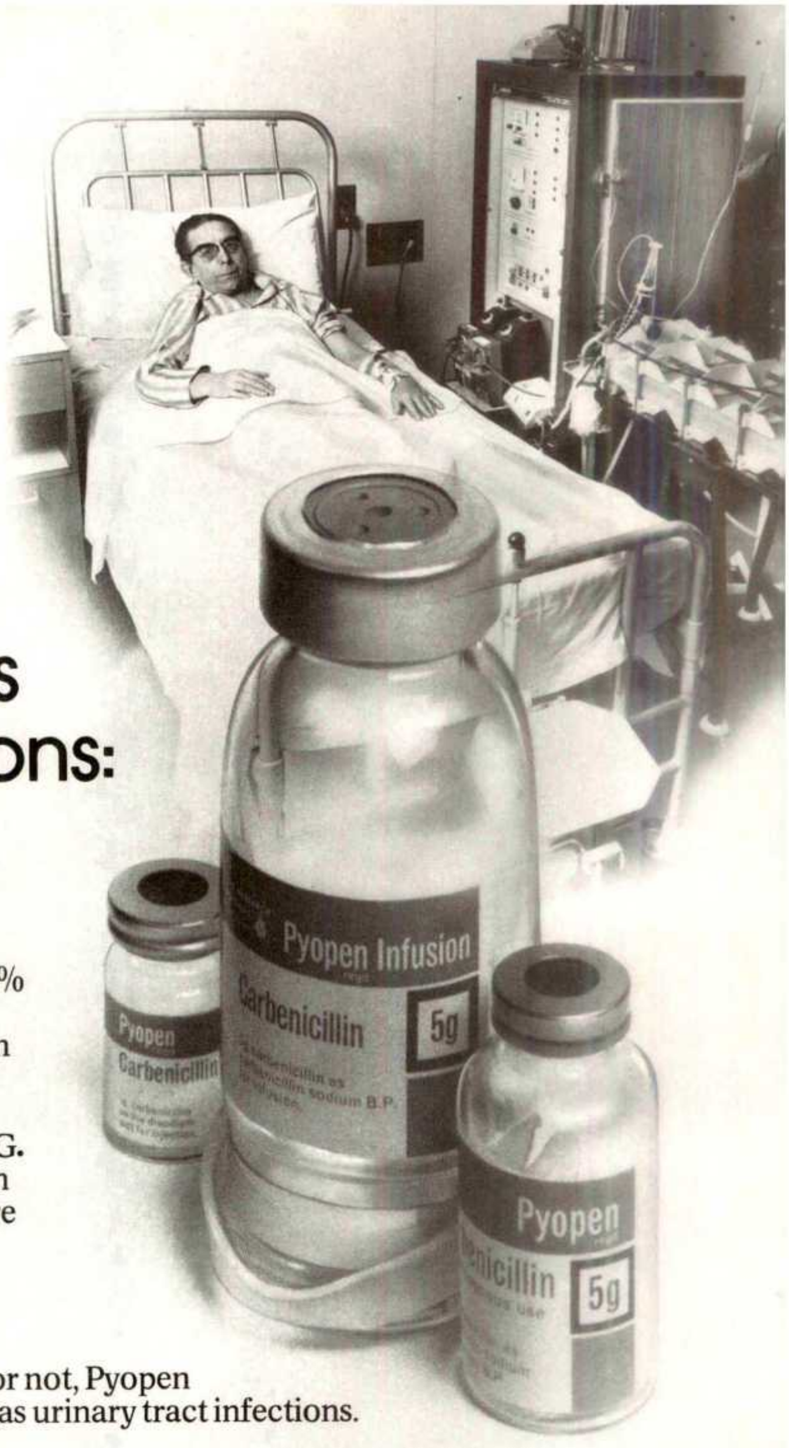
Now, to simplify treatment of pseudomonas urinary infections:



Pyopen

Penicillin safety and a published 76% success rate in 543 patients of varying renal status confirm Pyopen as a simple solution to a difficult problem.

For patients with normal kidneys 5G. 6 hourly is easily given using Pyopen infusion. For patients in renal failure or with impaired renal function a simple dosage of 2G. 8 hourly, by infusion or into the dialysate, is often sufficient.

Whether the kidneys are impaired or not, Pyopen provides the answer in pseudomonas urinary tract infections.

Adult dosage: Chronic urinary tract infection: 5G. 4–6 hourly
Acute uncomplicated infections: 2G. 6 hourly
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen–by infusion or injection

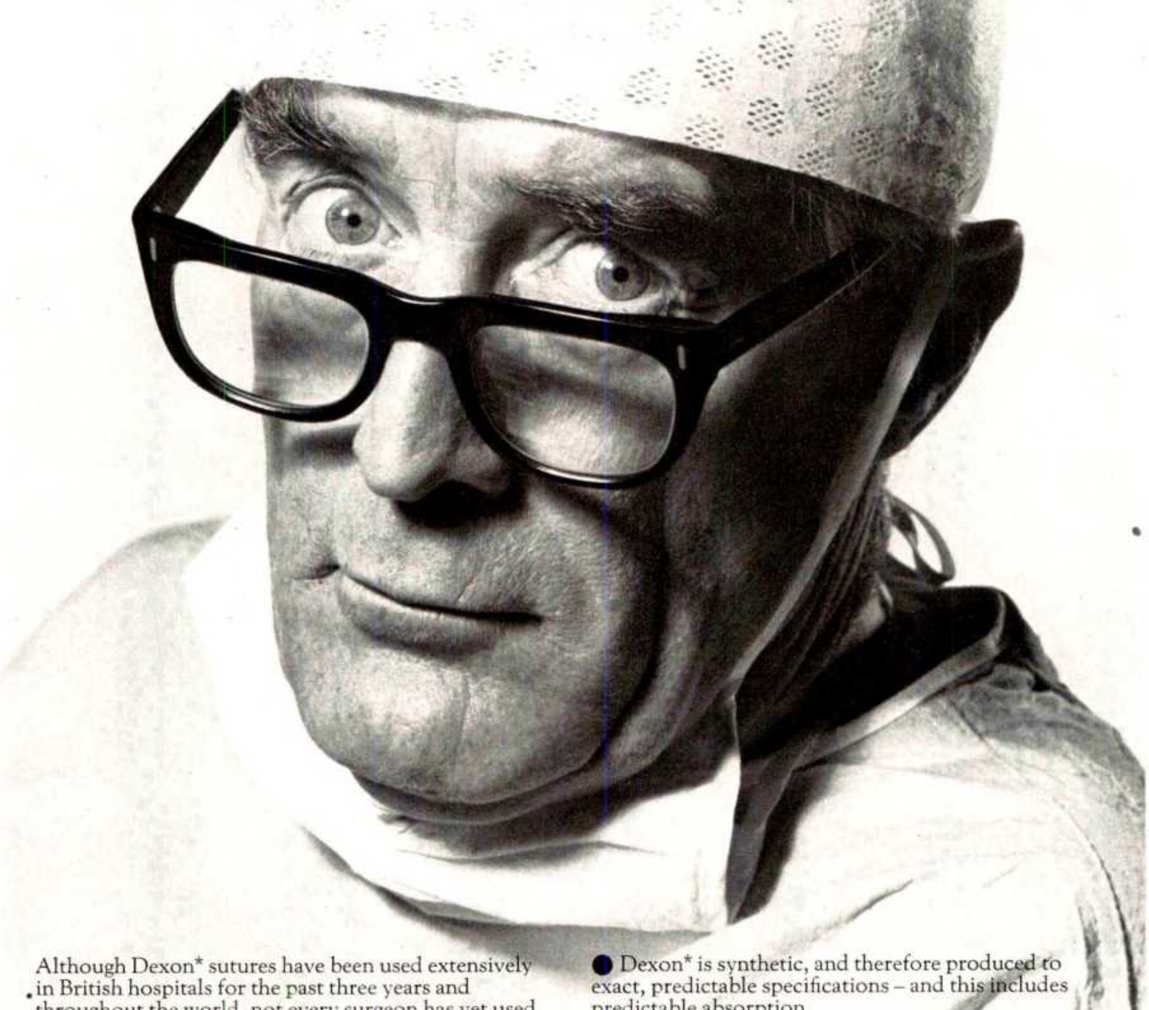
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.

Dexon* is the suture that superseded catgut – but

don't take our word for it!



Although Dexon* sutures have been used extensively in British hospitals for the past three years and throughout the world, not every surgeon has yet used them and so demonstrated their advantages for himself.

● Dexon* is a synthetic absorbable suture that causes minimum tissue reaction and inflammation.

● Although it is totally absorbable it is consistently stronger than catgut for the critical first 7–10 days of healing.

● The braided construction means that every knot holds securely.

● Dexon* is synthetic, and therefore produced to exact, predictable specifications – and this includes predictable absorption.

● Cost savings can be made when Dexon* is used in place of a variety of other suture materials.

We will be happy to tell you more about Dexon sutures but*

Why not prove Dexon* for yourself ?

THE DIAGNOSIS AND PROPHYLAXIS OF PULMONARY COMPLICATIONS OF SURGICAL OPERATION

BY G. LASZLO, G. G. ARCHER, J. H. DARRELL, J. M. DAWSON, AND C. M. FLETCHER

DEPARTMENTS OF MEDICINE, SURGERY, BACTERIOLOGY, AND RADIODIAGNOSIS, THE ROYAL POSTGRADUATE MEDICAL SCHOOL AND HAMMERSMITH HOSPITAL, LONDON

SUMMARY

Eighty-eight non-bronchitic and 52 bronchitic patients undergoing elective general and plastic surgical operations in two wards were studied for postoperative chest complications, which were diagnosed by increased purulence of sputum and radiological changes at 24 or 48 hours. Eighty per cent of the patients undergoing upper abdominal surgery and 30 per cent of the other patients had chest complications. Postoperative bronchitis or pneumonia severe enough to delay discharge was found in 14 patients (10 per cent). Twice-daily physiotherapy to the chest did not affect the outcome in 86 patients without chronic bronchopulmonary disease. Routine administration of ampicillin to 'cover' chronic bronchitics undergoing general anaesthesia was found to be of no value in a controlled trial of the 52 bronchitic patients. However, bacteriological and radiological studies lend some support to the suggestion that prophylaxis with a bactericidal antibiotic may reduce the incidence and morbidity of postoperative pulmonary infections in patients having upper abdominal operations.

THE importance of infection in causing bronchial and pulmonary complications of surgical operations is uncertain. Administration of prophylactic antibiotics has often been recommended, but early clinical trials showed penicillin to be valueless (Palmer and Sellick, 1952; Thulbourne and Young, 1962). Prophylactic broad-spectrum antibiotics are often prescribed for bronchitic patients with upper respiratory-tract infections, but when the present study was planned their value in the prophylaxis of postoperative chest complications had not been tested. In this paper we report the incidence of bronchial and pulmonary complications of surgical operations, bacteriological studies of sputum, and the results of a trial of prophylactic ampicillin in a group of patients with simple or obstructive chronic bronchitis.

At the same time we noted that the ward physiotherapist spent much time of undetermined usefulness in treating the chests of healthy patients having minor operations. We therefore carried out a survey of all elective admissions to a general surgical unit over a period of 6 months in an attempt to assess the value of standardized routine physiotherapy given to patients without chronic bronchitis or abnormal ventilatory function.

MATERIALS AND METHODS

One hundred and forty male and female patients who were admitted from their homes on two regular admitting days each week to undergo elective operation under the care of one surgical firm were included in the trial. The operations are listed in *Table I*. All the patients were seen by the medical registrar (G. L.) and judged 'bronchitic' (52 patients) or 'normal' (88 patients). He also performed daily clinical assessments but remained unaware how the patient had been treated until after discharge. The patients were allocated at random to 'treatment' and 'control' groups.

Pre- and Postoperative Assessment.—All the patients were assessed by means of a standard questionary, clinical examination, and, in most cases, spirometry.

The questionary was as follows:—

1. Do you ever bring up phlegm?
2. Do you bring up phlegm on most days in the winter for as much as 3 months in the year?
3. Do you ever get short of breath?
4. Do you ever wheeze?
5. Do you smoke? (details).

The 52 patients who gave a positive answer to question 2 were classed as 'bronchitic'. Those in whom 1-second forced expired volume (F.E.V.$_1$) was more than 2 standard deviations below normal for age and height (Ferris, Anderson, and Zickmantel, 1965) were considered to have 'airways obstruction'. At first all those answering 'No' to questions 1–4 who had normal values of forced expired time were not tested by spirometry. Later, F.E.V.$_1$ was measured in all subjects. Patients with reduced F.E.V.$_1$ were all bronchitic.

Sputum.—The patients were instructed to expectorate all sputum before and after operation into special cartons and this was graded daily for volume and purulence according to the criteria of Miller and Jones (1963):—

0	No sputum.
M1	Mucoid.
M2	Suspicion of pus.
P1	Up to $\frac{1}{3}$ pus.
P2	Up to $\frac{2}{3}$ pus.
P3	Pus.

A change of two grades was considered to be evidence of a postoperative chest complication (e.g., from 0 to M2 or from M1 to P1). Any sputum was cultured at least once postoperatively and thereafter if there was any deterioration in macroscopic grade. Duplicate samples of sputum were cultured on blood-agar and chocolate-agar incubated in air. *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae* were regarded as potential pathogens. Macroscopic grading was checked by means of films stained with Gram's stain.

Radiological Assessment.—Chest radiographs were taken preoperatively and on the first and second days after operation whenever possible in the X-ray Department rather than in the ward. Preoperative films were taken in the anteroposterior projection as well as in the postero-anterior projection to facilitate comparison with the postoperative films which were taken in the ward. The different focus-film distances used in the department and ward films did not produce any interpretive difficulties. Lateral films were not used.

The results were assessed by a single radiologist (J. M. D.) without access to clinical information. The preoperative radiographs were not used in the preoperative clinical assessment of patient groups but solely as a base-line for subsequent change.

Radiographic lesions were scored as follows:—

0 No lesion.
½ Minimal or 'subsegmental' (shadowing extending over less than one interspace in any dimension).
1 Major or 'segmental' (shadowing extending over one interspace or more in any dimension).

Each lung was divided into six zones and each was scored. Where more than one lesion was seen in the same zone the scores were added. A score of 1 or more on the 2 postoperative days was regarded as significant, i.e., minimal lesions in more than one zone or persisting in two or more films were counted as significant.

Postoperative Clinical State.—Each patient was examined daily; temperature and chest signs were noted.

Procedure for Non-bronchitic Patients.—Patients allocated to the treated group were visited by the physiotherapist once preoperatively for instruction, twice on the day of the operation, and twice daily for 5 days thereafter for breathing exercises, percussion, assisted coughing, and leg exercises. Patients in the control group were visited equally frequently but given leg exercises only. When a chest infection was diagnosed a message was left for the physiotherapist to start treatment whether it had been given previously or not.

Procedure for Bronchitic Patients.—Patients diagnosed as having chronic bronchitis were allocated at random to a group to be given prophylactic ampicillin or to a control group. The allocation of the patient was known to the surgical registrar (G. G. A.) who prescribed the treatment. All the treated patients received ampicillin, 500 mg. by intramuscular injection at the time of the premedication (1–2 hours preoperatively) and 8-hourly thereafter for 5 days. The antibiotic was given orally in the same dose as soon as possible. In the event of clinical deterioration treatment was decided by the house staff in consultation with the surgical registrar. This did not affect the trial since the result for that particular patient was now apparent. In general, wound infections requiring antibiotics became apparent after the immediate postoperative period and did not interfere with the trial. The 'single blind' arrangement resulted in virtually no interference with clinical management of the patients. All the bronchitic patients received physiotherapy, including percussion and postural drainage, three times daily. Those with airways obstruction also received inhalations of isoprenaline before physiotherapy.

Chest complications were classified as follows:—

Type 0 No chest complication.
Type 1 Deterioration of sputum by 2 or more purulence grades on one or more postoperative days—'Bronchitis'.*
Type 2 Deterioration of the radiograph by a score of 1 or more without a change in the postoperative sputum grading—'Collapse'.*
Type 3 Deterioration of both the sputum and the radiograph—'Pneumonia'.*

Infections which persisted after 10 days were classified as 'severe'.

Eighty-eight non-bronchitic patients and 52 patients with chronic bronchitis were included. The incidence of chronic bronchitis was similar to that found in a survey of working men in the neighbourhood (Fletcher, Peto, Speizer, and Tinker, 1970).

Statistical analysis was performed by calculating χ^2 and applying Yates's correction for all 2×2 tables. $P > 0\cdot05$ is rated as not significant (N.S.).

RESULTS

Non-bronchitic Subjects.—Physiotherapy did not reduce the total incidence of chest complications which was diagnosed radiologically (types 2 and 3); physiotherapy was, in fact, associated with rather more frequent sputum deterioration which may have been due to its assisting expectoration (*Table II*).

The site of operation, previous smoking habit, and age were the most important factors influencing the incidence of chest complications (*Table III*). Patients over the age of 40 were more liable to chest complications (55 per cent compared with 31 per cent). Upper abdominal operations carried an incidence of 81 per cent, while the risk from operations at other sites was 29 per cent. Fifty-three per cent of smokers but only 22 per cent of non-smokers developed chest complications. A previous history of occasional expectoration from the chest during respiratory infections was not significantly associated with an increase in complications. No bronchopulmonary complications appeared in a group of 14 patients without malignant disease with no history of sputum production and undergoing non-abdominal operations. When such patients had upper abdominal incisions they fared as badly as the rest. Exclusion of this 'low-risk' group made no difference to the conclusion that physiotherapy was ineffective in preventing chest complications of minor (non-abdominal) surgery. There was a slightly, but not significantly, lower incidence of radiological change in treated patients having abdominal operations than in the control patients (6 out of 12 treated patients; 9 out of 13 untreated patients).

Pathogenic organisms were isolated after operation from the sputum of 11 out of 12 patients with 'pneumonia'. Seven of these infections were classed as severe. In contrast, pathogens were recovered from only 6 out of 12 sputa from patients with postoperative 'bronchitis', and only 2 of these patients had severe infections. Commensal organisms were isolated from 6 patients with postoperative 'bronchitis' and 3 of these cases had persistent infections. Specimens from the remaining 6 patients in this group were lost. No multiresistant organisms were isolated.

* Two patients included in the survey are omitted from this trial because of departure from the prescribed therapy.

Bronchitic Subjects.—Administration of ampicillin did not affect the incidence of pulmonary complications. The bronchitic subjects, who were all smokers, had the same number of complications as the non-bronchitic smokers. There was no difference between the older and younger patients, nor between those with and without evidence of airways obstruction (*Table IV*).

Pathogens were isolated from only 2 preoperative sputum specimens out of 30 cultured. These persisted after operation but neither patient suffered complications. Unfortunately, a number of postoperative specimens were lost. However, there were more pathogens in the postoperative sputa from the untreated group (9 out of 22; 5 lost) than in the group treated with ampicillin (2 out of 18; 7 lost). In patients having abdominal operations there were 4 out of 6 specimens with pathogens in the untreated group and 2 out of 7 in the ampicillin group. The pathogens in the treated group were both sensitive to ampicillin.

Pathogenic organisms were isolated after operation from the sputum of 6 out of 8 patients who developed 'pneumonia' after abdominal operation. Only 1 patient undergoing a non-abdominal operation developed 'pneumonia' although pathogens were isolated from 6 out of 16 sputa. Thus, although infection with pathogens increased the likelihood of 'pneumonia' after abdominal surgery and ampicillin reduced the rate of isolation of pathogens the antibiotic did not confer any clinical benefit.

There was no association between deterioration in sputum grade and the presence of fungi and coliform organisms which followed antibiotic treatment. No multiresistant bacterial strains were isolated.

All Patients.—*Table V* shows that there was a significant association between the presence of pathogens in the postoperative sputum cultures and the incidence of radiological change.

Pulmonary embolism was diagnosed in only 1 (non-bronchitic) patient in this series; she was the only patient who died of pulmonary complications of surgery.

* Average age 53 yr.

† Average age 40 yr.

The groups are all comparable for age and number of major operations except where noted.

None of the differences in incidence is statistically significant.

Most bronchopulmonary complications occurred on the first or second postoperative day. All of 65 patients in whom radiological changes appeared in the first 48 hours had temperatures above 37·2° C. except 1 case receiving corticosteroid replacement after adrenalectomy. Pyrexia was associated with increased purulence of the sputum in 75 per cent of patients without radiological change. Eighty-four per cent of the patients with pyrexia in the first 48 hours postoperatively had objective signs of chest complications. The correlation of crepitations at the bases with fever and with radiological change was poor.

Severe Complications.—Pulmonary complications prolonged the stay in hospital of 15 patients (11 per cent). None of these patients had received ampicillin; 14 of them had not been graded bronchitic on admission, and the one who had chronic bronchitis was in the control group. Ten were smokers; all but 4 underwent major operations. Details of these patients are given in *Tables VI* and *VII.*

Table V.—THE RELATIONSHIP BETWEEN TYPE OF ORGANISM ISOLATED FROM POSTOPERATIVE SPECIMENS OF SPUTUM AND RADIOLOGICAL CHANGES IN NORMAL AND BRONCHITIC PATIENTS

DISCUSSION

The factors affecting the incidence of postoperative pulmonary complications have been studied and reviewed extensively by Anscombe (1957), Palmer (1962), Collins, Darke, and Knowelden (1968), and Wightman (1968). Our results in untreated patients undergoing abdominal surgery (other than inguinal herniotomy) agree well with those of Collins and others (1968), both as to the incidence of radiological change (55 per cent compared with 68 per cent) and in the number of patients without any evidence of chest complications (20 per cent compared with 14 per cent). We found, as Collins and others did, that smoking and age affected postoperative bronchial infection significantly. It seems that a history of any previous expectoration in a smoker is associated with the same increased risk of postoperative bronchitis as that of regular expectoration for at least 3 months in the winter, which is the accepted definition of simple chronic bronchtis (Medical Research Council, 1965).

Postoperative bronchopulmonary infection is common. Twenty-two per cent of all our patients expectorated sputum containing pus without any radiological change and a further 16 per cent had both purulent sputum and radiological change. Pathogenic organisms were isolated from just over one-third of such patients.

The part played by infection in producing postoperative pneumonia seems to depend on the type of operation. There was a significant association between pathogenic bacteria and radiological shadowing after abdominal surgery, but not after operations where the peritoneum was not opened, when pathogens were often isolated but radiographic lesions were rare. This suggests that postoperative pneumonia is most likely to develop when a pathogenic organism is present in the respiratory tract and there is interference with the breathing. Collins and others (1968) were able to halve the incidence of radiological change by giving adequate doses of prophylactic penicillin and streptomycin, a combination with bactericidal properties similar to those of ampicillin. All their patients had upper abdominal operations and the response to the prophylactic antibiotic was similar regardless of age or 'chest history'.

We were able to reduce the number of pathogenic bacteria isolated by giving ampicillin, although in 2 treated bronchitic patients with pneumonia, organisms showing *in vitro* sensitivity to the antibiotic were isolated during treatment. In our controlled comparison of the effects of ampicillin in bronchitic patients the drug reduced the incidence of postoperative isolation of pathogens but not the incidence of chest complications. Severe complications were, however, commoner in the non-bronchitic patients, none of whom had ampicillin. Combining both groups, severe complications occurred in none of the 25 patients receiving ampicillin, but in 15 out of 113 patients not receiving ampicillin (13 per cent). When upper abdominal operations alone are considered, as in the trial of Collins and others (1968), the differences are more striking, though the numbers are too small to permit statistical analysis (*Table VII*). This study, therefore, lends some support to the suggestion of Collins and others (1968) that broad-spectrum antibiotics may have a prophylactic effect after upper abdominal surgery, since we found pathogens in the sputum of all the severe cases of postoperative pneumonia.

Pseudomonas was isolated on only 2 occasions and no multiresistant staphylococci were found; had these organisms been prevalent at the time of the trial a different conclusion might have been reached. If the source of the pathogens were known other preventive measures, preferable to chemoprophylaxis, might be taken.

There is no general advantage to be gained from giving routine antibiotic 'cover' to bronchitic subjects receiving general anaesthesia for minor operations. It may, however, be advisable to treat the patient perioperatively when pathogens are already present in the sputum, as illustrated by 1 of our bronchitic patients in whom preoperative tetracycline had failed to clear a long-standing pneumococcal infection. Perioperative ampicillin produced a remission without further complications.

Collins and others (1968) stated: 'It is believed that an increase in temperature during the first 48 hours is almost always caused by chest infection.' Infection shown by radiographic changes or purulent sputum accounted for nearly all the pyrexia in the early postoperative period in the present study. Except in 1 patient receiving steroids, the chest radiographs were all normal when the oral temperature was below 37·2° C. in the immediate postoperative period.

Our findings confirm those of Nichols and Howell (1970) that regular twice-daily physiotherapy, including breathing exercises, percussion, and encouragement of coughing, is of no apparent value to non-bronchitic subjects regardless of age, operation, or smoking habits. There is room for investigation of the value of vigorous treatment in the early postoperative period, as suggested by Palmer and Sellick (1962). It is interesting that among the bronchitic subjects who had minor operations, only 1 patient showed collapse radiographically. The more intensive physiotherapy given to this group may therefore have been beneficial, but since the services of trained physiotherapists are always in demand their time should not be spent in useless visits to previously healthy subjects having minor operations.

Acknowledgements.—This study was possible because of the co-operation of Miss J. L. Morris and the qualified staff of the Physiotherapy Department, Hammersmith Hospital, who carried out the prescribed treatment and arranged their schedules to fit in with the protocol.

We are indebted to Professor R. B. Welbourn for critical reading of the manuscript and advice during the initiation of the study.

MALNUTRITION AND MALABSORPTION IN CROHN'S DISEASE WITH REFERENCE TO THE EFFECT OF SURGERY

BY N. H. DYER AND A. M. DAWSON

ST. BARTHOLOMEW'S HOSPITAL, LONDON

SUMMARY

Sixty-three patients with Crohn's disease showed a high incidence of nutritional deficiencies as judged by laboratory tests. Malabsorption of fat (33 per cent) and vitamin B_{12} (60 per cent) was not sufficiently severe to account for the malnutrition. Malnutrition was especially severe in unoperated patients with active disease, whereas malabsorption was prominent in patients with recurrent disease after resection although they had less active disease and less severe nutritional deficits. Surgery should not be withheld from a malnourished patient for fear of inducing further malnutrition; excision of toxic inflammatory disease will not only improve the immediate outlook but will also reduce the severity of further recurrences. Xylose-excretion tests give a spurious impression of malabsorption in Crohn's disease, possibly as a result of occult renal impairment, and should be abandoned.

NUTRITIONAL disturbance is a common complication of Crohn's disease (Cooke, 1955; Ensrud and Sauer, 1957; Kogan, Schapira, Janowitz, and Adlersberg, 1957; Pimparkar, Mourhan, and Bockus, 1960; Tytgat, Vantrappen, Rutgeerts, and Vandenbroucke, 1967; Dotevall and Kock, 1968; Hertzberg, Myren, and Semb, 1969; Krause, Bergman, and Norlen, 1971). Although the number of possible causes are legion (*Table I*), malnutrition is frequently attributed to malabsorption (Crohn and Yarnis, 1958; Bockus, 1964). However, the role of malabsorption may have been overemphasized because the disease attacks the submucosa rather than the mucosa and frequently spares the jejunum. Kiefer and Arnold (1950) pointed out that malabsorption which resulted from resection of bowel in Crohn's disease was rarely extensive enough to account for the associated malnutrition, and Hoffbrand, Stewart, Booth, and Mollin (1968) suggested that anorexia was a major factor causing folate deficiency in their patients. The importance of impaired dietary intake, fistulous losses, and sepsis in contributing to undernutrition has been stressed by Clark and Lauder (1969), particularly in the postoperative period.

Table I.—FACTORS PRODUCING MALNUTRITION IN CROHN'S DISEASE

- Decreased intake of food
- Presence of active inflammation
  - Increased nutritional requirements
  - Toxic depression of metabolism
- Malabsorption
  - Loss of bowel
    - Inflammation
    - Resection
    - By-pass
  - Stagnant-loop syndrome
    - Stricture
    - Fistula
    - Surgical blind loop
- Gastro-intestinal loss
  - Blood
  - Protein
  - Water and electrolytes
  - Bile-salts
- Minor factors
  - Rapid intestinal transit
  - Impaired bowel function above an obstruction

We have studied an unselected series of patients in order to establish the incidence and severity of malnutrition and malabsorption, as indicated by simple laboratory investigations, and comparisons have been made between patients with active recurrent disease following a bowel resection and those with primary disease.

MATERIALS AND METHODS

Sixty-three patients were studied over a 2-year period; all had symptoms which were sufficiently severe to warrant admission to hospital. The symptoms of those who had suffered a relapse after operation were of comparable severity to the symptoms of patients who had not undergone operation, and the majority of the patients with postoperative recurrences had not been followed up so that they had not been promptly readmitted to hospital. The diagnosis of Crohn's disease was confirmed histologically in 40 patients (63 per cent) and was based on typical clinical and radiological features in the remaining 23, 3 of whom had undergone laparotomy without biopsy. There were 39 females (62 per cent) and 24 males. Their ages ranged from 14 to 71 years with a mean age of 37 years. Only 5 patients were on systemic steroid treatment but 2 others had been given steroid enemata.

The patients were divided into six anatomical groups. Seven patients had diffuse disease which involved the jejunum together with variable amounts of the ileum and colon. Thirteen patients had ileocaecal disease, only 1 of whom had more than 30 cm. of terminal ileum involved. Eight patients had ileocolic disease which involved the terminal two or three loops of the ileum and the ascending colon; one patient had disease extending from the proximal ileum to the splenic flexure. Eight patients had colonic disease which was limited to the right colon in 4 and was total in the other 4 cases. Three patients had disease limited to the anorectal region. Twenty-four patients had been operated on previously; most had undergone ileo-colic resections and had developed recurrent disease in the remaining terminal ileum. Seven patients had been operated on for jejuno-ileitis but only 1 had undergone jejunal resection; 11 patients had undergone surgery for ileocaecal disease, of whom 9 had had resections but 2 had had 40-60 cm. of ileum by-passed and excluded; 6 patients had ileocolic disease and had received more extensive resections; 1 patient had had local excision of disease limited to the descending colon.

The activity of the disease was arbitrarily graded by a system which awarded points for certain clinical and laboratory characteristics. One point was scored for each of the following (Dyer, 1970): symptoms of disease (pain, diarrhoea in an unresected patient, weight-loss, systemic complications); temperature above 37·2° C. during 3 of the first 10 days; haemoglobin less than 11·0 g. per 100 ml.; white-cell count above 11,000 per c.mm.; erythrocyte-sedimentation rate (Westergren) above 20 mm. in 1 hour; serum albumin less than 3·5 g. per 100 ml. Thus patients could be separated into seven grades (0-6).

Haemoglobin and serum albumin were estimated by routine laboratory techniques. Serum folate was measured by the method of Waters and Mollin (1961). Serum vitamin B_{12} was measured by the method of Anderson (1964). Xylose absorption was estimated after an overnight fast followed by the oral administration of 25 g. of D-xylose and 600 ml. of water; urine was collected for the next 5 hours and a blood-sample was taken at $1\frac{1}{2}$ hours. Xylose was measured by the method of Roe and Rice (1948). Faecal fat was estimated by the method of Van der Kamer, Ten Bokkel Huinink, and Weyers (1949). Vitamin-B_{12} absorption was measured by the method of Schilling (1953); after an overnight fast 0·5 μg. of the labelled vitamin was administered with 150 mg. of hog intrinsic factor and a flushing inject of 1000 μg. of unlabelled vitamin was given subcutaneously 2 hours later. Not every patient had every investigation.

RESULTS

Evidence of Malnutrition (*Fig.* 1).—

Haemoglobin.—Seventy-five per cent of the males had a haemoglobin concentration of less than 12·5 g. per 100 ml. and 54 per cent of the females had a concentration below 11·5 g. per 100 ml. The incidence and degree of anaemia were similar in unoperated patients regardless of the main site of disease. In females the haemoglobin levels were significantly higher in those admitted with recurrent disease after operation ($t = 2·38$, $P < 0·025$); in males there was no such difference. There was a progressive fall in haemoglobin associated with increasing activity of the disease ($P < 0·001$).

Serum Albumin.—Forty-four per cent of 59 patients had values below 3·5 g. per 100 ml. Patients with unoperated disease involving the colon with or without associated ileal lesions had a mean level of 3·0 g. per 100 ml. which was significantly lower than the 3·6 g. per 100 ml. which was found in patients whose disease was confined to the small bowel ($t = 2·13$,

$P<0.05$). Although operated patients had a higher mean level than unoperated ones, this did not quite achieve significance ($t=1.84$, $P<0.1$). There was a progressive fall in serum albumin with increasing activity of disease ($P<0.005$). No direct correlation could be demonstrated with blood-urea levels, although subnormal urea concentrations (less than 20 mg. per 100 ml.) were only found in active disease. There was a significant correlation with serum-calcium levels ($r=+0.64$, $P<0.001$), the few patients with divergent results all having steatorrhoea.

Serum Folate.—Sixty-four per cent of the patients had levels below 4·0 ng. per ml. Significant differences could not be demonstrated between patients

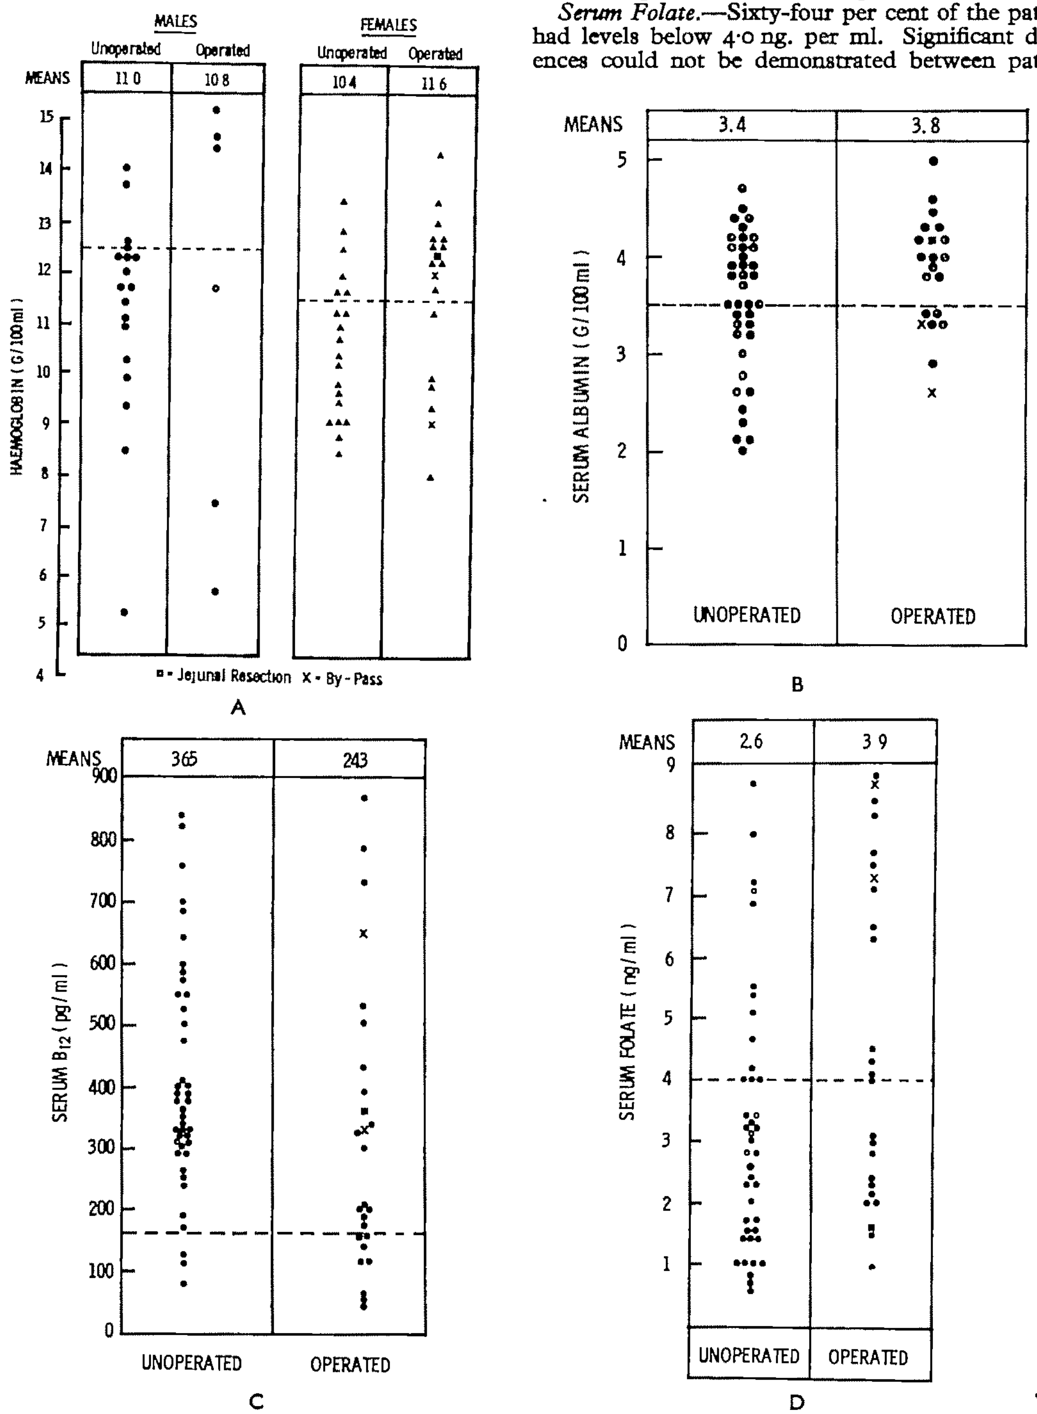

Fig. 1.—Scatter diagrams comparing the levels of (A) haemoglobin (in males and females), (B) serum albumin, (C) serum vitamin B_{12}, and (D) serum folate in patients with unoperated Crohn's disease against levels in patients with recurrent disease after operation. Dotted lines indicate normal limits. ×, Patients with an ileal by-pass. ■, Patients who had had a jejunal resection.

with disease at different sites except that unoperated patients had lower values than patients admitted with recurrent disease after surgery ($t = 2{\cdot}42$, $P < 0{\cdot}02$). There was a progressive fall in folate levels with increasing disease activity ($P < 0{\cdot}002$).

Serum Vitamin B_{12}.—Sixteen per cent of the patients had levels below 160 pg. per ml. Although the mean vitamin B_{12} values were significantly lower in patients who had undergone ileal resection ($t = 2{\cdot}63$, $P < 0{\cdot}02$), 3 unoperated patients had values below the normal range. These patients all had evidence of disease in the ileum and the lowest value occurred in a patient who had had symptoms for over 20 years. Four patients with resections of less than 30 cm. of ileum were not vitamin-B_{12} deficient, whereas 2 of the 3 with resections of more than 100 cm. developed very low levels within 3 years; the third patient appeared to be protected by preservation of the ileocaecal valve and a small cuff of the terminal ileum.

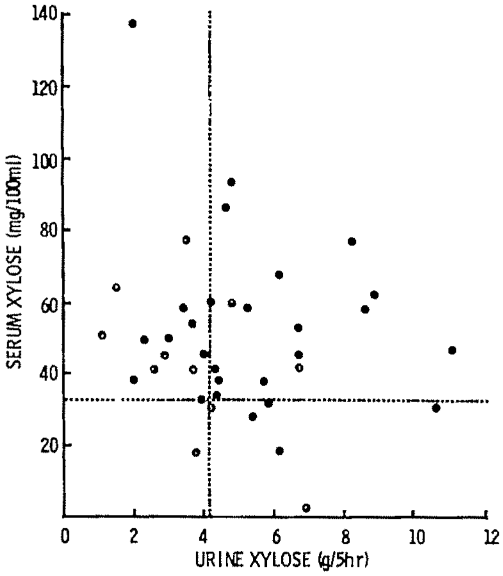

FIG 2.—Comparison of 5-hour urinary excretion of xylose with blood levels at 1½ hours in 38 patients with Crohn's disease. Dotted lines indicate lower limits of normal.

Xylose Tolerance.—This test is an indirect assessment of jejunal function which depends not only on the intestinal absorption of the sugar but also on the excretion of xylose in the urine. Although 43 per cent of 42 patients excreted less than 4·2 g. per 5 hours and 23 per cent of 39 patients had serum levels of less than 32·5 mg. per 100 ml., only 1 patient had both abnormalities (*Fig.* 2), which by these strict criteria indicates that malabsorption of xylose is rare even in the presence of jejunal disease.

Because impaired urinary excretion of xylose is the usually accepted criteria of jejunal dysfunction we have analysed our data further. The mean excretion of xylose for patients with ileocolic or colonic involvement was greater than that for patients with disease confined to the small bowel ($t = 2{\cdot}22$, $P < 0{\cdot}05$), but jejunal disease did not result in a greater impairment of excretion than ileocaecal disease and 3 patients with disease apparently confined to the colon had subnormal xylose excretion (*Fig.* 3). There was no difference in xylose excretion when unoperated and operated patients were compared. Regression analysis showed a significant correlation between increasing blood-xylose levels and increasing activity of the disease ($P < 0{\cdot}025$), and a progressive fall in urinary excretion with increasing activity only just failed to achieve significance ($P < 0{\cdot}1$). Only 2 patients had raised blood-urea levels and only 2 were aged over 65 years, so that neither uraemia nor old age was influencing the results. There was no correlation with faecal fat excretion or with the level of serum folate, a vitamin which is absorbed in the jejunum.

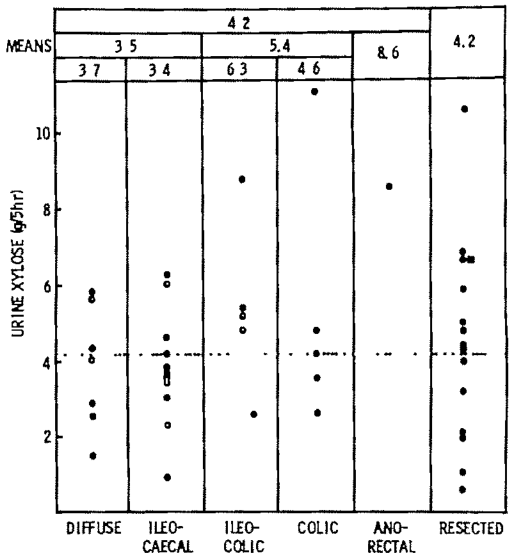

FIG. 3.—Urinary xylose excretion in 42 patients with Crohn's disease after oral administration of 25 g. of xylose related to the site of disease Dotted line indicates 4 2 g. per 5 hours. ■, Patients who had had a jejunal resection.

Faecal Fat.—Thirty-three per cent of 48 patients excreted more than 6·0 g. of fat per 24 hours. Although severe steatorrhoea was commoner after resection (*Fig.* 4), faecal fat excretion was not significantly greater in unoperated patients in this study ($t = 1{\cdot}97$, $P < 0{\cdot}1$). There were no differences in mean faecal fat excretion in unoperated patients with disease at different sites although no patient with disease apparently confined to the colon or rectum had steatorrhoea. The 2 patients with an ileal by-pass did not have steatorrhoea. There was no direct correlation between faecal fat excretion and disease activity or with the serum levels of calcium, magnesium, and cholesterol, nor did urinary excretion of xylose or vitamin B_{12} correlate with fat excretion. The degree of fat excretion did not correlate with the amount of ileum resected, but 1 patient whose ileocaecal valve had been left in situ after a large resection appeared to be protected from steatorrhoea (*Fig.* 5).

Vitamin-B_{12} Absorption.—Sixty per cent of 42 patients had subnormal absorption and operated patients absorbed significantly less vitamin B_{12} than unoperated ones ($t = 4{\cdot}08$, $P < 0{\cdot}001$). However, the incidence and degree of malabsorption did not differ amongst unoperated patients with different primary sites of disease, 48 per cent of whom had subnormal results including 2 of the 4 patients with disease apparently confined to the colon (*Fig.* 6). Only 3 of the 18 operated patients excreted more than 15 per cent of the vitamin; 2 had resections of less than 30 cm. and the third had an intact ileocaecal valve (*Fig.* 7). There is a tendency for vitamin B_{12} absorption to decrease with increasing amounts of ileal resection provided that the ileocaecal valve is removed, although an intact valve does not guarantee normal absorption. Severe malabsorption may also occur with minor resections or even in the absence of operation, but there was no correlation of vitamin B_{12} malabsorption and disease activity.

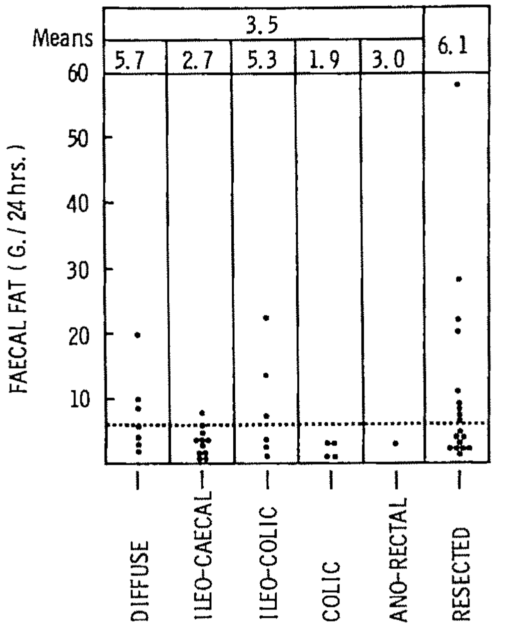

FIG. 4.—Faecal fat excretion in 48 patients with Crohn's disease related to the site of disease. Dotted line indicates 6·0 g. per 24 hours.

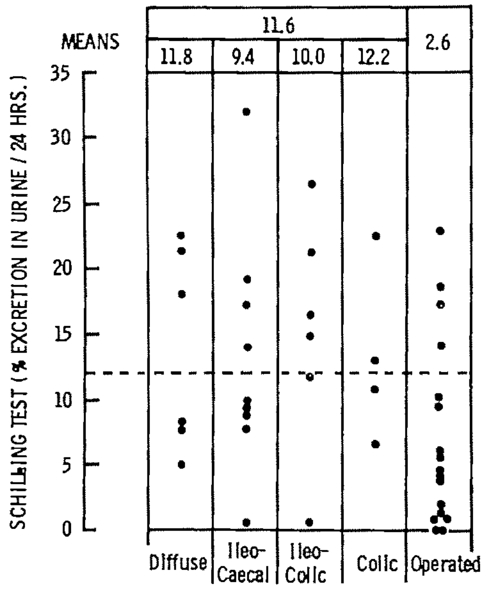

FIG. 6.—Correlation of vitamin-B_{12} absorption (Schilling test) with the site of disease in 42 patients with Crohn's disease. Dotted line indicates 12 per cent absorption.

DISCUSSION

This study not only confirms that there is a high incidence of nutritional abnormalities in Crohn's disease but relates the degree of disturbance to a measurement of disease activity. Although previous workers have noted an association of malnutrition with active disease, the degree of activity has not been defined (Tytgat and others, 1967; Hoffbrand and

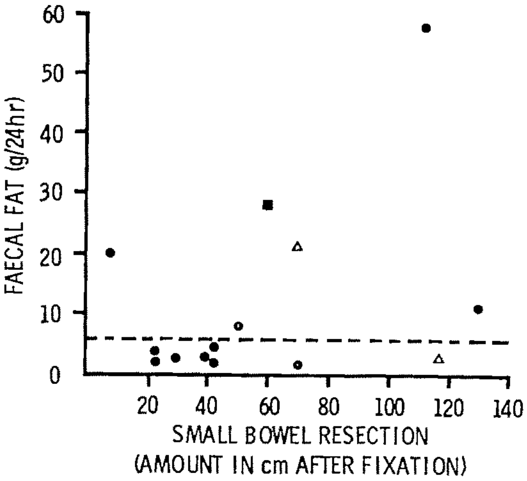

FIG. 5.—Correlation of faecal fat excretion with the amount of bowel resection in 14 patients with recurrent Crohn's disease. ■, Patients who had had a jejunal resection △, Patients whose ileocaecal valve remained in situ.

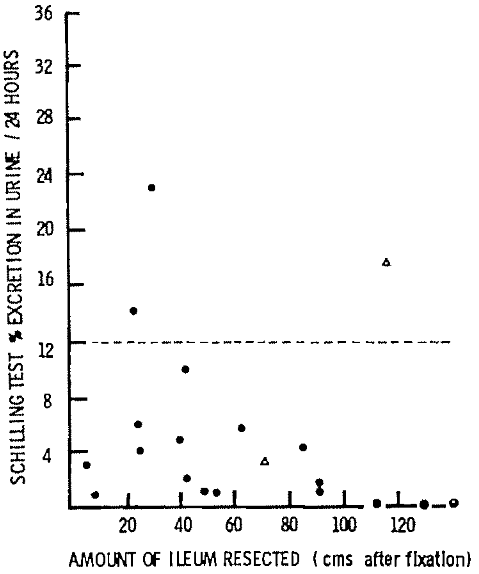

FIG. 7.—Correlation of vitamin-B_{12} absorption (Schilling test) with the amount of bowel resected in 20 patients with recurrent Crohn's disease △, Patients whose ileocaecal valve remained in situ.

others, 1968). Our measurements have shown that active or severe disease is not confined to patients with diffuse jejuno-ileitis (Bockus, 1964), since activity and malnutrition are especially liable to complicate colonic disease; the finding of severe hypoalbuminaemia and the less marked tendency to folate deficiency and anaemia in colonic disease also suggests that malabsorption is not a major cause. Patients with active disease frequently also have profound anorexia and so malnutrition may be the result of starvation. There may also be increased demands for essential nutrients owing to excessive production and loss of inflammatory and other cells so that decreased blood levels may merely represent rapid clearance. Hypoproteinaemia may result from decreased protein synthesis, hypercatabolism of serum proteins, or loss of protein into the bowel (Waldmann, 1970). Our results support the theory of enteric protein loss; the lack of correlation between serum-albumin and blood-urea levels suggests that neither starvation nor decreased protein synthesis is of major importance and that the presence of hypoalbuminaemia is not a reliable index of total protein deficiency. Moreover, some nutritional parameters are interdependent and results should be interpreted with care; hypocalcaemia is usually associated with hypoalbuminaemia because of the loss of the binding protein and rarely indicates malabsorption of calcium with its attendant risk of osteomalacia. Osteomalacia may erroneously be suspected if there is a coincidental increase in serum alkaline phosphatase; this disturbance, however, is usually due to abnormal liver function rather than to disturbed bone metabolism in such patients (Dyer and Dawson, 1972).

The less severe degree of malnutrition in patients who have developed recurrent disease after resection should not be dismissed as the result of selection of patients, because similar indications for admission obtained in all the cases. Moreover, the majority of the patients were often living at a distance from the hospital so that they were not seen at an earlier stage of their illness. Kalser, Roth, Tumen, and Johnson (1960) found that incomplete resection in patients with jejuno-ileitis led to a great improvement in health in spite of the effects of the disease left behind and the malabsorption resulting from surgery. When our patients are graded for disease activity, significantly more unoperated patients have active disease compared with operated ones (*Fig.* 8). Thus, it appears that the total amount of inflamed tissue determines the degree of malnutrition and that reduction of this 'toxic mass' is of prime importance. However, these results should not encourage indiscriminate surgery since adrenocorticotrophic hormone and azathioprine therapy can also dramatically reduce the activity of Crohn's disease within a few days.

The results of the xylose test give very little evidence that jejunal malfunction is important in the genesis of the nutritional disturbance. Thus, although the sugar is predominantly absorbed in the jejunum (Fordtran, Soergel, and Ingelfinger, 1962) changes in renal function and urinary xylose excretion may be of equal importance in giving an abnormal result. This factor has been disregarded by previous workers who have reported variable degrees of 'malabsorption' in Crohn's disease (Benson, Culver, Ragland, Jones, Drummey, and Bougas, 1957; Christiansen, Kirsner, and Ablaza, 1959; Fowler and Cooke, 1960; Shiner, Vakil, and Wilcox, 1962; Dotevall and Kock, 1968; Hertzberg and others, 1969). The recent studies by Kendall (1971), who has shown that intravenously administered xylose is poorly excreted in Crohn's disease, confirm our suspicions of occult renal dysfunction; only 1 of 39 patients had low levels of xylose in both blood and urine whereas active disease was associated with falling urine and rising blood levels. The indiscriminate application of this urinary excretion test is to be deprecated and the presence of a normal blood-urea level is no safeguard against a spurious result.

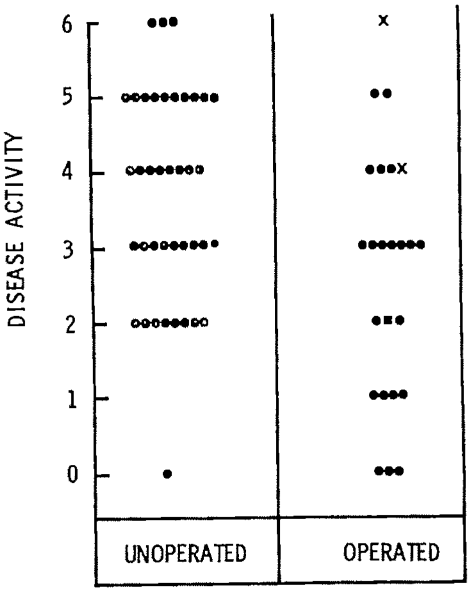

FIG. 8.—Disease activity in 63 patients with Crohn's disease. Twenty-one of the 39 unoperated patients had very active disease (grades 4–6) compared with 7 of the 24 operated patients with recurrent disease ($\chi^2 = 4\cdot54$, $P < 0\cdot05$). ×, Patients with an ileal by-pass. ■, Patients who had had a jejunal resection.

Malabsorption of fat and vitamin B_{12} was attributed to the presence of extensive disease or massive resection (Cooke, 1955; Bockus, 1964). However, our results confirm that malabsorption may also follow relatively small ileal resections and is sometimes a feature of unoperated localized disease of the ileum (Ensrud and Sauer, 1957); this has recently been explained by the discovery that the terminal ileum is the main site of absorption of vitamin B_{12} and conjugated bile-salts (Booth and Mollin, 1959; Lack and Wiener, 1967). The role of bacteria in the production of malabsorption of fat and vitamin B_{12}, as in the stagnant loop syndrome, has been overemphasized, since bacterial overgrowth is variable in Crohn's disease and cannot be directly correlated with malabsorption (Vince, Dyer, O'Grady, and Dawson, 1972). We did not find the severe degrees of steatorrhoea that have been reported by some American workers (Kalser and others, 1960; Pimparkar and others, 1960), possibly because our surgeons have tended to conserve as much bowel as feasible at operation. However, the incidence of malabsorption in our patients was similar to that reported by Hertzberg and others (1969), but their patients were all investigated after operation and there was often no evidence of active recurrent disease. The clinical importance of mild steatorrhoea associated with unresected ileal disease has yet to be established, although the development of megaloblastic anaemia due to malabsorption of vitamin B_{12} is well documented. However, the present study has confirmed that vitamin-B_{12} malabsorption is common in a large series of unoperated patients, the incidence being similar to the 58 per cent noted by Dotevall and Kock (1968). Our findings appear to contradict the work of Schofield (1967), who found that vitamin B_{12} deficiency occurred only after ileal resections of more than 100 cm. and was not a feature of small resections or unoperated disease, but his conclusions were based on serum vitamin-B_{12} levels which usually only become abnormal after massive resection. The results of the Schilling test are unlikely to be abnormal owing to subtle dysfunction such as obtains for the xylose test, because similar results have been found in Crohn's disease using a whole-body counter (Dyer, 1972). Not only may this vitamin-B_{12} malabsorption lead to megaloblastic anaemia in unoperated patients (Dyer, Child, Mollin, and Dawson, 1972), but an abnormal absorption test may also be a valuable sign of early Crohn's disease at a stage when radiography of the ileum is normal.

The relatively minor degrees of malabsorption noted in our patients were insufficient to account for the nutritional disturbances observed and the lack of correlation of malabsorption with disease activity also suggests that malabsorption and malnutrition are unrelated. Our studies suggest that malabsorption is of little clinical significance except in the genesis of vitamin-B_{12} deficiency. On the other hand, it may account for the symptom of diarrhoea which is sometimes due to either steatorrhoea or the cathartic action of unabsorbed bile-salts on the colon (Hofmann, 1967).

Acknowledgement.—This work was supported by a grant from the Board of Governors of St. Bartholomew's Hospital.

PARTIAL HEPATECTOMY USING A CARBON-DIOXIDE LASER

BY R. R. HALL,

SUMMARY

Partial hepatectomy by means of a carbon-dioxide laser has been performed in 13 dogs. The operative technique is described, and its advantages and the absence of morbidity and mortality during the 10 weeks after operation are discussed.

IN a previous report it was shown that incisions of the liver made with a carbon-dioxide laser are accompanied by much less haemorrhage than similar incisions made by surgical diathermy or scalpel. For this reason it was suggested that the laser might be useful in routine hepatic surgery (Hall, 1971). This report describes the successful performance of partial hepatectomy by means of a carbon-dioxide laser.

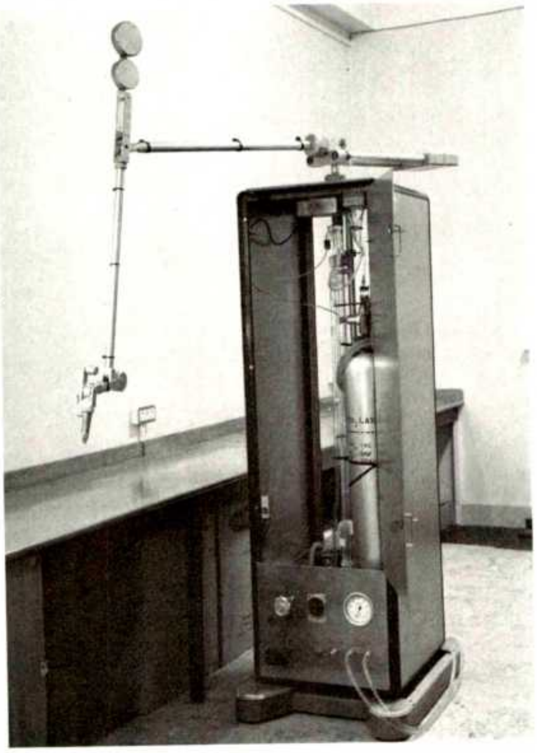

FIG. 1.—Surgical laser. The infra-red beam emerges from the vertical laser (central glass tube) and is reflected along the counter-balanced arm to the focusing handpiece.

THE LASER

The surgical laser (*Fig.* 1) is the first British prototype designed specifically for use in the operating theatre. It provides 35 W. of infra-red radiation (wavelength 10·6 μm.) focused by a gallium-arsenide lens to a spot 0·25 mm. in diameter at the working end of the light, mobile, hand-held instrument (*Fig.* 2). This is held so that the focus of the laser beam is always at the surface of the tissue to be incised. The intense heat at the focus vaporizes the tissue to a depth of several millimetres, the exact depth of the incision depending upon the laser-power density used and the speed at which the beam is moved over the tissue.

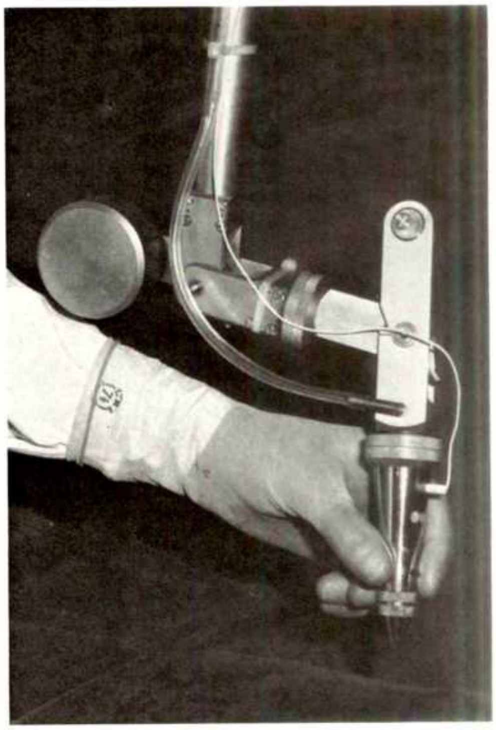

FIG. 2.—Handpiece of the surgical laser.

The laser's action is uniform and gentle (Stellar, Polanyi, and Bredermeir, 1971; Hall, Beach, Baker, and Morison, 1971) compared with the irregular explosive arcing of cutting diathermy. There is no direct contact between the instrument and the tissue so that adhesion of the probe cannot occur. Alternatively, the laser can be held out of focus so that the power is spread over a larger area and heats the tissue slowly rather than vaporizing it, in a manner similar to that of coagulation diathermy.

MATERIALS AND METHODS

Thirteen operations were performed on mongrel dogs weighing 14–18 kg. Full sterile surgical technique was employed under i.v. Nembutal anaesthesia with spontaneous respiration.

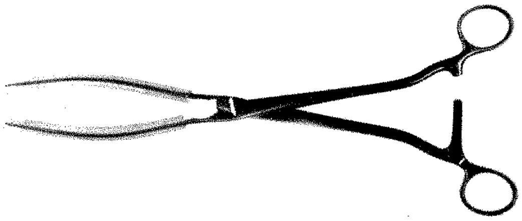

FIG. 3.—Modified Moynihan clamp for atraumatic compression of the liver.

At the commencement of the operation the left femoral artery was catheterized by the Seldinger method to provide continuous monitoring of the systolic blood-pressure.

Upper midline laparotomy was performed using the laser to incise all the layers of the abdominal wall in 10 dogs, bleeding vessels being coagulated with the laser. In 3 dogs scalpel incision was performed, bleeding vessels being ligated in the usual manner. Laser radiation at 10·6 μm. is completely absorbed by water, and therefore several gauze swabs soaked in physiological saline solution were placed behind the liver to protect the posterior abdominal viscera from unintentional exposure.

Blood-flow through the liver must be arrested while resection is performed (Mullins, Jennings, and McClusky, 1968; Hall, 1971). In the first 2 dogs this was achieved by occluding the portal vein and hepatic artery at the porta hepatis with a small Satinsky clamp. However, it was found that such occlusion of the total hepatic circulation could cause severe hyperkalaemia (Hall, 1972) and the method was discontinued. Instead, only the circulation to the portion of liver to be excised was occluded by applying a clamp across the liver lobe. A Moynihan stomach clamp was modified for this purpose (*Fig.* 3) by creating a greater curvature of the blades to fit the contour of the liver and covering them with soft polyvinyl. By this means adequate compression of the lobar vessels was obtained without trauma to the capsule or parenchyma.

Having applied the clamp across the posterior third of the left lobe the anterior half was resected with the laser. The laser beam was moved slowly backwards and forwards across the liver, gentle traction separating the incision so that the laser focus was always at the depth of the incision to vaporize fresh liver parenchyma. This was a simple process that left a dry liver surface, at the centre of which the transected major vessels were clearly visible. These were dealt with in one of two ways.

First, the vessels were sealed by heat coagulation using the laser out of focus. It was possible to coagulate veins up to 5 mm. in diameter by this method and when the clamp was removed no bleeding occurred. This method of laser coagulation was used without any other form of haemostasis in 4 dogs; the swabs were removed from behind the liver and the abdomen was closed without any further precaution or drainage of the operation site.

However, it was considered that this method would not be adequate for the largest vessels that would be encountered in the human liver; the laser would not obviate ligation of these. Thus, in the remaining 9 dogs when resection was complete the open ends of the left hepatic artery and vein and portal vein were oversewn with 0000 Ethiflex sutures. The clamp was then removed and if some of the intermediate-sized vessels bled they were readily coagulated with the laser. No bile leakage was ever observed and the abdomen could be closed without drainage.

Wound closure was completed in 7 dogs using chromic catgut for the peritoneum and linea alba, with silk for the skin. This method was abandoned because of poor healing, and the remaining wounds were closed with interrupted 000 monofilament nylon to the linea alba and skin as two separate layers.

The femoral artery catheter was left in situ at the end of the operation to allow continuous measurement of the blood-pressure during the first 20 hours of recovery. All the dogs were fully recovered and active within 5–15 hours and were returned to normal accommodation after 24 hours. Each dog received Penidural, 1 ml. i.m. immediately, and streptomycin, 0·5 g. i.m. daily for 5 days. The dogs were sacrificed between 5 days and 10 weeks following operation: 1 on the fifth day, 6 on the seventh day, and 2 each at 7, 8, and 10 weeks. Post-mortem examination and liver biopsy were performed in each case.

AUTOPSY FINDINGS

Wound Healing.—All the incisions which had been closed with nylon (2 scalpel, 4 laser) healed well. Those which had been closed with catgut and silk (1 scalpel, 6 laser) were complicated by oedema, serosanguineous discharge, poor skin healing, and breakdown of the deeper layers of the wound. From this small group it appeared on clinical assessment that the healing of laser wounds compared with scalpel incisions was not impaired; the complications were due to the use of catgut.

Liver.—Examination on the fifth and seventh postoperative days revealed no free fluid in the abdomen, no haematoma, and no bile staining of the peritoneum or viscera adjacent to the liver. The liver surface which had been cut by the laser was covered by a layer of pale necrotic tissue up to 2 mm. deep that still had a slightly charred superficial appearance. This layer was soft and easily removed from the underlying liver which was separated from it by a tough fibrous capsule. Histological examination (*Fig.* 4) showed it to be comprised of necrotic liver parenchyma separated from normal liver tissue by a layer of fibrous tissue, polymorphonuclear leucocytes, and macrophages. Sections of blood-vessels which had been sealed by laser coagulation (*Fig.* 5) showed occlusion by a plug of fibrin, the luminal surface of which was covered with intact endothelium.

At 7–10 weeks after operation the peritonal cavity of all the dogs was normal. There were no signs of secondary haemorrhage, bile leakage, or sepsis. Adhesions of the cut liver surface to the stomach and omentum had developed in 2 dogs. In all cases the laser surface of the liver was covered by a capsule that was normal on macroscopic and microscopic examination (*Fig*. 6). The necrotic surface layer was no longer

present, blood-vessels were closed by fibrous tissue, and the liver parenchyma appeared entirely normal.

DISCUSSION

Since the first recorded partial hepatectomy was performed (Langenbush, 1888) a variety of surgical techniques have been employed (Beck, 1902; Wangensteen, 1951; Nakayama, 1957; Balasegaram, 1968; Smith, 1969).

The particular asset of the laser for hepatic surgery is the primary sealing of the smaller arteries and veins which are present throughout the liver substance that are not large enough to warrant ligation but require haemostasis by other means. The laser overcomes this problem by thermal coagulation during the process of the incision and in doing so it is superior to conventional diathermy. The same process also closes the bile-ducts.

The use of the laser thus enables translobar resections to be performed with comparative ease, avoiding the necessity of formal hemihepatectomy and permitting bilateral or multiple liver resections at one operation. The practical application of this in clinical surgery has been discussed previously (Hall, 1971).

This present study, which includes long-term survival, shows that partial hepatectomy using a carbon-dioxide laser is a simple, safe operation accompanied by a minimum of haemorrhage, no bile leakage, sound healing, and no late complications.

Acknowledgements.—We are very grateful to Lord Brock, Director of the Department of Surgical Sciences, Royal College of Surgeons of England, for providing the facilities for this study; to Miss M. Jacques, Mrs. C. Hill, and Mr. J. Manders of the same department, and Mr. J. Watson of the Buckston Brown Farm, Downe, Kent, for their technical assistance; to the Department of Health and Social Security for a grant for the laser construction and animal expenses.

We also wish to thank Dr. A. Levine and the staff of the Histopathology Department of the Royal Marsden Hospital for preparing the histological material, and Mr. K. Morman of the Institute of Cancer Research for the photomicrographs.

THE EFFECT OF INCREASED OXYGEN IN ACUTE LIMB ISCHAEMIA

By C. G. STALKER, A. J. McEWAN and I. McA. LEDINGHAM
DEPARTMENT OF SURGERY, UNIVERSITY OF GLASGOW, WESTERN INFIRMARY, GLASGOW

SUMMARY

Acute hind-limb ischaemia was produced in anaesthetized, ventilated dogs. During ischaemia the femoral venous oxygen tension fell markedly and both oxygen extraction and consumption appeared to increase. Oxygen at 2 ATA produced a relatively small increase in oxygen availability to the ischaemic tissues; femoral venous oxygen tension rose by 20 mm. Hg but oxygen extraction and consumption remained elevated.

THE clinical use of hyperbaric oxygen in the treatment of peripheral ischaemia is largely empirical. There is a need for more critical examination of the relationship between high arterial oxygen tension and ischaemia, particularly since the former is associated with vasoconstriction under normal circumstances (Bird and Telfer, 1966). The present study examines the effect of hyperoxia in acute ischaemia of the canine limb with particular reference to blood-flow and oxygen exchange.

MATERIALS AND METHODS

Studies on 10 large dogs were performed within one of the large compressed-air chambers at the Western Infirmary, Glasgow. Anaesthesia was induced with sodium thiopentone (2·5 mg. per kg.) and maintained with trichlorethylene. Intermittent suxamethonium chloride was given as required to prevent reflex movement. The dogs were intubated and intermittent positive-pressure ventilation was established using a Palmer pump, the stroke volume of which was adjusted to maintain the arterial carbon-dioxide tension (Pa_{CO_2}) between 35 and 45 mm. Hg. The inspired oxygen concentration was measured with a paramagnetic oxygen analyser (Servomex OA 101 Mk II). A catheter inserted in the brachial artery.

was advanced to lie in the mid-aorta proximal to the site of arterial ligation. Arterial blood samples were withdrawn from this site and pressure recordings were made using an ink-jet recorder (Elema Schönander Mingograph 81). Limb and mid-oesophageal temperatures were recorded on an Ellab TE3 Universal Thermocouple and the latter temperature was maintained constant within ± 1° C.

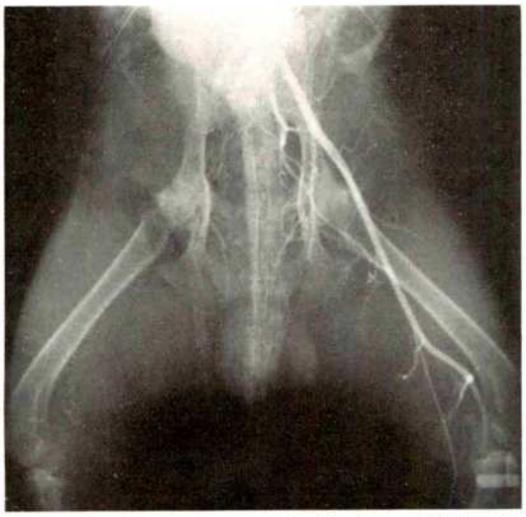

FIG. 1.—Arteriogram demonstrating the degree of ischaemia produced by tightening of the arterial snares on the right side.

The canine hind-limb is well supplied with collateral arterial channels. The lower limb vessels were exposed, therefore, at the root of the aorta, and the circumflex, iliac, and median sacral vessels were ligated (there was no resultant significant change in limb blood-flow). Snares placed around the external and internal iliac arteries permitted the establishment of periods of limb ischaemia which could be terminated at will. The degree of ischaemia produced by the occlusion of the snares is illustrated in the arteriogram (*Fig.* 1). A T-tube was inserted, at the level of the groin, into the femoral vein of the limb under study and the animal was heparinized (100 mg. per kg. i.v.). Blood-flow was measured by first clamping the proximal limb of the T-tube and then collecting the effluent venous blood over a period of 30 or 60 seconds. Blood removed in this fashion was retransfused. The bulk of the blood passing out of the limb traversed the T-tube (*Fig.* 2). Venous pressure was recorded before and after each flow measurement. After the initial surgery the animal was allowed to settle for a minimum period of 1 hour.

Mid-aortic and femoral venous blood samples were withdrawn for measurement of oxygen and carbon-dioxide tension and pH using a triple electrode system (Radiometer Micro Electrode Unit with *p*H Meter 27 and Gas Monitor) calibrated with gases of known concentrations. Correction for the difference in oxygen-tension measurement between gas and blood was made using tonometered blood (McDowall, Ledingham, and Tindal, 1968). Further correction of the blood gases and *p*H was made for any temperature difference between the electrode recirculation system and the animals' mid-oesophageal temperature (Radiometer Blood Gas Calculator—984300). The latter also permitted calculation of the blood-oxygen saturation from *p*H and P_{O_2}, taking into account base excess and the animals' temperature. Haemoglobin (Hb) and packed-cell volume (P.C.V.) were measured at intervals throughout each experiment. The following derived data were calculated:—

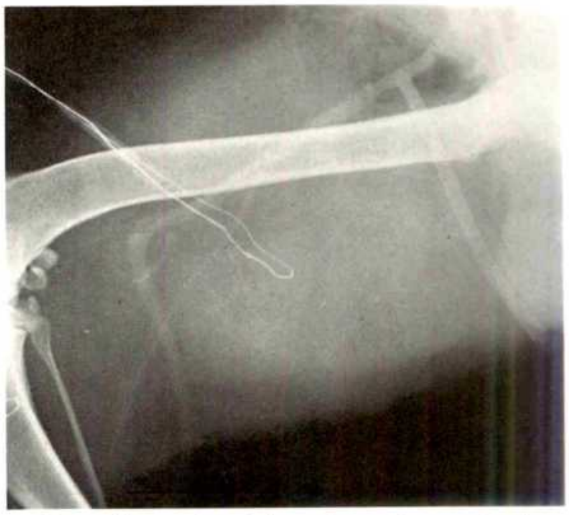

FIG. 2.—Venous phase of the arteriogram demonstrating that the bulk of the radio-opaque medium traversed the femoral venous T-tube.

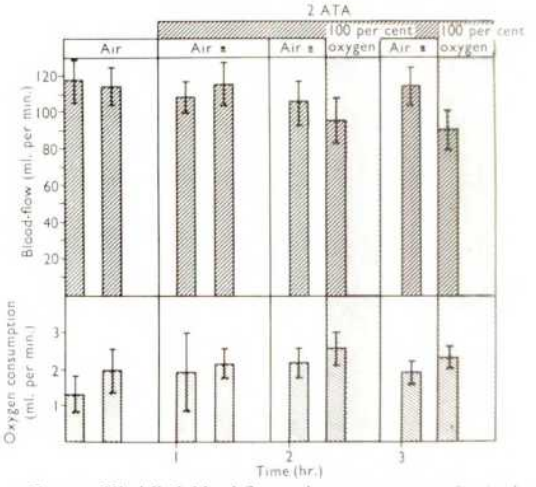

FIG. 3.—Hind-limb blood-flow and oxygen consumption in the contralateral non-ischaemic limb before and during the ischaemia. No significant changes occurred in flow or consumption in the contralateral limb. Oxygen at 2 ATA produced a small but, on the second occasion, significant decrease in limb blood-flow.

1. Blood oxygen content (ml. per 100 ml.) =

$$\text{Hb (g.)} \times 1{\cdot}34 \times \frac{\text{O}_2\ \text{saturation}}{100} + P_{O_2}\ \text{(mm. Hg)} \times 0{\cdot}0031\ \text{(Bunsen coefficient).}$$

Within the range of 7–24 ml. per 100 ml. blood there was a close relationship between this indirect method of measurement of the oxygen content and the direct method of Van Slyke ($y = 0{\cdot}37 + 1{\cdot}06x$; $r = 0{\cdot}983$; Ledingham, McBride, Parratt, and Vance, 1970). Furthermore, in the present study a periodic check was made of the oxygen saturation with the standard haemoreflector (Kipp) and the oxygen content with the Van Slyke apparatus. Comparison of the two methods of measurement of saturation (70 readings) revealed a regression (r) of 0·910 and for the oxygen content (20 readings) of 0·980.

2. Limb oxygen consumption (ml. per min.) =

$$\frac{\text{Femoral vein flow (ml. per min.)} \times \text{femoral arterio-venous oxygen content difference (ml. per 100 ml.)}}{100}$$

3. Limb oxygen availability (ml. per min.) =

$$\frac{\text{Femoral vein flow (ml. per min.)} \times \text{arterial oxygen content (ml. per 100 ml.)}}{100}$$

4. Limb oxygen extraction (per cent) =

$$\frac{\text{Femoral arteriovenous oxygen content difference (ml. per 100 ml.)} \times 100}{\text{Arterial oxygen content (ml. per 100 ml.)}}$$

After the period of stabilization brief periods of ischaemia (15 minutes) were produced, preliminary experiments having shown that the bulk of the changes in flow and oxygen exchange occurred during this time with subsequent complete recovery of the limb. The initial period of ischaemia was established at normal atmospheric pressure, with the inspired gas mixture adjusted to maintain arterial oxygen tension (Pao$_2$) between 95 and 105 mm. Hg. The subsequent stages of each experiment were conducted at 2 atmospheres absolute (ATA), the inspired gas being either 'air-equivalent' (i.e., *circa* 10 per cent O$_2$/90 per cent N$_2$) or 100 per cent O$_2$.

In 5 of the animals of the study, measurements of blood-flow and oxygen exchange were made in the contralateral non-ischaemic limb (the limb vessels were exposed in an identical fashion but were not ligated). The measurements were completed immediately after the comparable measurements in the ischaemic limb.

RESULTS

The experimental protocol and the mean values of limb blood-flow and limb oxygen consumption of all 10 dogs are indicated in *Table I*. After ligation blood-flow fell from 105 ± 7 ml. per minute (mean ± S.E. of the mean) to 39 ± 4 ml. per minute and oxygen consumption rose from 1·06 ± 0·30 ml. per minute to 3·31 ± 0·64 ml. per minute. Release of the arterial snares was associated with a return to normal of both values. Increased atmospheric pressure (with Pao$_2$ unchanged) had no significant effect on blood-flow or on oxygen consumption either during control runs or consequent upon ischaemia. Exposure to 100 per cent oxygen at 2 ATA also failed to produce a significant change in the response of flow or oxygen consumption to ischaemia.

Pao$_2$, femoral venous oxygen tension (Pvo$_2$) and carbon-dioxide tension (Pvco$_2$), femoral arteriovenous oxygen content difference (Δavo$_2$), and oxygen extraction are indicated during the various stages of the experiment in *Table II*. Pvo$_2$ and Pvco$_2$ were 71 and 39 mm. Hg during control runs and 33 and 53 mm. Hg respectively during ischaemia; femoral arteriovenous oxygen content difference rose from 1·1 to 9·5 ml. per minute, and extraction of oxygen correspondingly increased from 5 to 42 per cent. When the arterial oxygen tension was increased to 1226 mm. Hg during ischaemia, Pvo$_2$ fell from 76 to 54 mm. Hg and Pvco$_2$ rose from 42 to 62 mm. Hg. The femoral arteriovenous oxygen content difference rose from 1·1 to 8·0 ml. per minute and the oxygen extraction from 5 to 31 per cent.

Throughout the various stages of the experiment the blood-pressure remained stable. The fall of temperature in the hind-limb during each 15-minute period of ischaemia was minimal.

Table I.—COMPARISON OF LIMB BLOOD-FLOW AND OXYGEN CONSUMPTION IN THE ISCHAEMIC AND THE CONTRALATERAL NON-ISCHAEMIC LIMB

		ISCHAEMIC LIMB (10 dogs; mean ± S.E. of the mean)		CONTRALATERAL NON-ISCHAEMIC LIMB (5 dogs; mean ± S.E. of the mean)	
		Flow (ml. per min.)	O$_2$ Consumption (ml. per min.)	Flow (ml. per min.)	O$_2$ Consumption (ml. per min.)
Air		105 ± 7	1·06 ± 0·30	117 ± 12	1·30 ± 0·46
		$P < 0{\cdot}0005$	$P < 0{\cdot}0025$		
Air + ischaemia		39 ± 4	3·31 ± 0·64	114 ± 10	1·96 ± 0·60
2 ATA	Air equivalent	107 ± 6	0·89 ± 0·18	108 ± 8	1·92 ± 1·06
		$P < 0{\cdot}0005$	$P < 0{\cdot}0025$		
	Air equivalent + ischaemia	40 ± 4	3·36 ± 0·66	115 ± 12	2·14 ± 0·43
	Air equivalent	108 ± 7	0·92 ± 0·27	105 ± 12	2·17 ± 0·42
		$P < 0{\cdot}0005$	$P > 0{\cdot}0005$		
	100 per cent O$_2$ + ischaemia	42 ± 5	3·01 ± 0·34	95 ± 12	2·57 ± 0·45
	Air equivalent	107 ± 7	0·82 ± 0·12	114 ± 11	1·91 ± 0·31

	100 per cent O$_2$ + ischaemia	37 ± 3	2·65 ± 0·28	90 ± 11	2·33 ± 0·29

In the contralateral non-ischaemic limb of 5 of the animals (*Fig.* 3, *Table III*) blood-flow and oxygen consumption remained essentially stable throughout, although evidence of the vasoconstrictive effect of hyperoxia on the intact circulation (Bird and Telfer, 1966) was noted during both hyperoxic runs, the fall in flow being of statistical significance on the second occasion (114 to 90 ml. per minute, $P < 0\cdot005$).

	Air equivalent + ischaemia	8·2 ± 0·7	3·36 ± 0·66	24·3 ± 1·8	2·14 ± 0·43
	Air equivalent	22·6 ± 1·5	0·92 ± 0·27	22·1 ± 2·1	2·17 ± 0·42
	100 per cent O_2 + ischaemia	10·1 ± 1·2	3·01 ± 0·34	23·3 ± 2·9	2·57 ± 0·45
	Air equivalent	21·9 ± 1·2	0·82 ± 0·12	23·6 ± 2·4	1·91 ± 0·31
	100 per cent O_2 + ischaemia	8·8 ± 0·6	2·65 ± 0·28	21·9 ± 3·1	2·33 ± 0·29

The effect of oxygen administration at 2 ATA on oxygen availability and oxygen consumption is indicated in *Table IV* in both the ischaemic and the contralateral non-ischaemic limbs. During ischaemia at 2 ATA, oxygen availability was 8·2 ± 0·7 ml. per minute with air as the inspired gas and 10·1 ± 1·2 ml. per minute during the first exposure to 100 per cent oxygen ($P < 0\cdot05$) with no significant changes in the corresponding value for oxygen consumption. In the contralateral non-ischaemic limb the increase in arterial oxygen tension with 100 per cent oxygen was counterbalanced by a fall in blood-flow. Thus, no significant change in oxygen availability occurred; oxygen consumption also remained unchanged. Excluding the first control run, oxygen consumption in the non-ischaemic limb was consistently higher than in the contralateral ischaemic limb during control runs.

DISCUSSION

Relatively little information is available about the effect of ischaemia on oxygen exchange in peripheral tissues. It has been shown that muscle oxygen tension falls after femoral arterial ligation in the rabbit (Ackerman and Brinkley, 1966), and desaturation of femoral venous blood during ischaemia has been reported (Wang, Reich, Lesko, and Jacobson, 1966). The present experiments have confirmed that a substantial increase in oxygen extraction occurs in the acutely ischaemic limb. A surprising observation, perhaps, was that oxygen extraction was greater than that which could be related solely to the reduction in limb blood-flow with the result that total hind-limb oxygen consumption rose significantly. If this represents a true increase in oxygen consumption per unit of tissue, no conclusion can be drawn as to whether the increase was spread uniformly throughout the limb or affected only a part of the limb. The alternative explanation for the increase in total limb oxygen consumption, namely the diversion through the T-tube of effluent blood from a larger drainage area, seems unlikely during ischaemia and, in any case, could not have accounted for more than a fraction of the calculated increase. Two points are worthy of mention in relation to the observed changes in oxygen consumption. First, the pre-ischaemic femoral venous oxygen tension was higher and the oxygen extraction lower than has been previously reported (Wang and others, 1966). Thus, changes in the femoral venous oxygen tension after ischaemia would inevitably be greater than in experiments in which the initial femoral venous oxygen tension was lower. Secondly, although limb blood-flow was considerably reduced by arterial ligation, the mean flow was 40 ml. per minute during ischaemia which might not have been low enough to produce a reduction in oxygen consumption in the hind-limb tissues, at least for the short duration of ischaemia obtaining in the present study. Pappenheimer (1941) found, in the isolated perfused dog limb, that clamping of the femoral artery was not associated with a fall in the oxygen consumption until the blood-flow had fallen to around 40 ml. per minute, thus confirming earlier work by Freund and Janssen (1923), who reported that there was a critical level of blood-flow below which diminished oxygen consumption occurred in the canine limb (the value was 0·05 ml. per g. per minute). Of interest in relation to the raised oxygen consumption noted in the present study was the observation (von Euler, 1931; Pappenheimer, 1941) that adrenaline injected into the isolated perfused limb produced a fall in the blood-flow of 30 per cent with a concomitant increase in the oxygen consumption, as calculated by the product of blood-flow and arterial venous oxygen content difference. A similar mechanism in the present experiments could have been mediated only at a local level since clamping of the femoral artery produced no significant change in the heart-rate, or the blood-pressure or blood-flow in the contralateral non-ischaemic limb.

The administration of 100 per cent oxygen at 2 ATA was associated with an increase in oxygen availability during ischaemia since the arterial oxygen content rose with no significant further fall in the blood-flow. The mean femoral venous oxygen tension rose by 20 mm. Hg, which could imply improved tissue oxygenation; the absence of any significant alteration in the elevated oxygen consumption, however, complicates the interpretation of the findings in the venous blood. Clearly further studies are necessary to examine in more detail individual variation in response to ischaemia and increased oxygen tension, particularly during periods of more prolonged ischaemia.

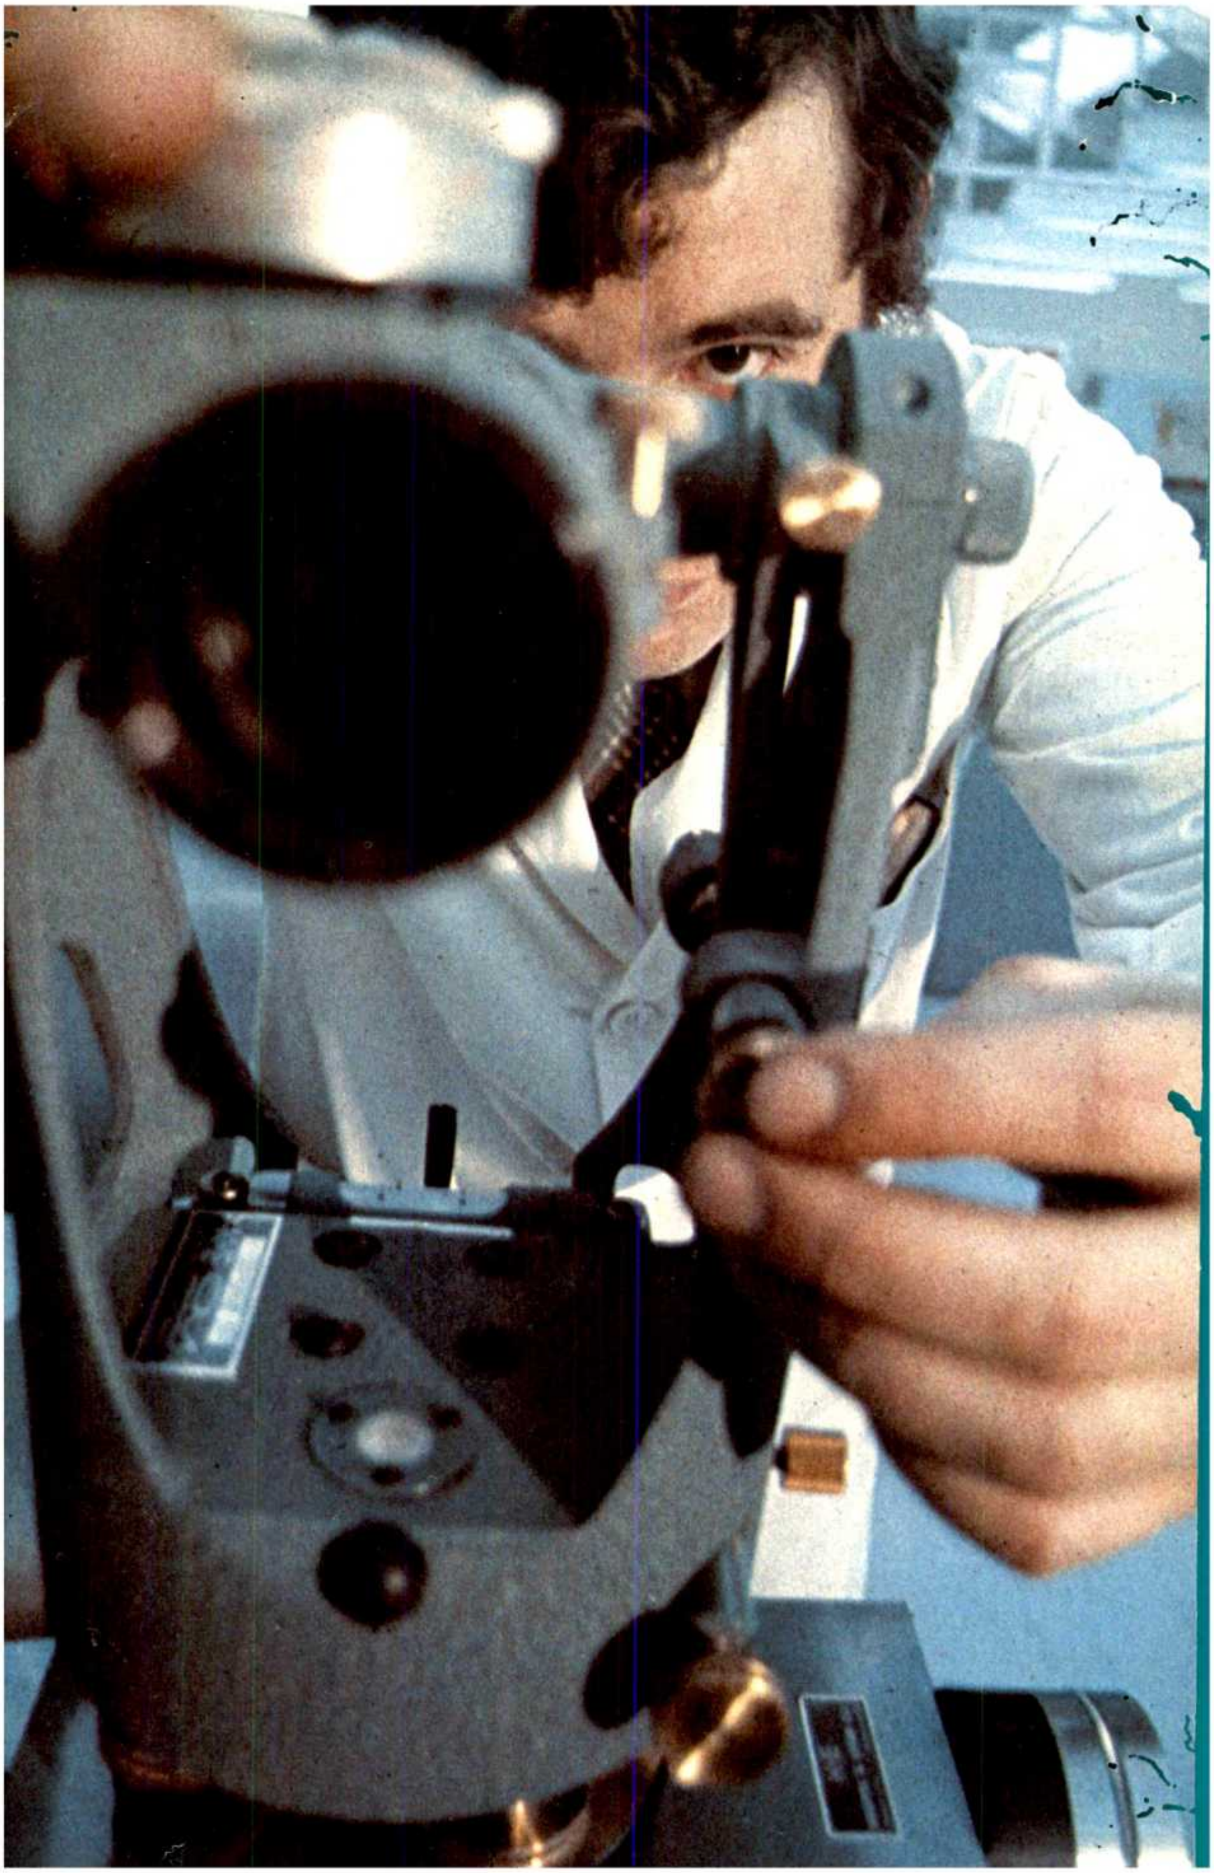
ETHICON*

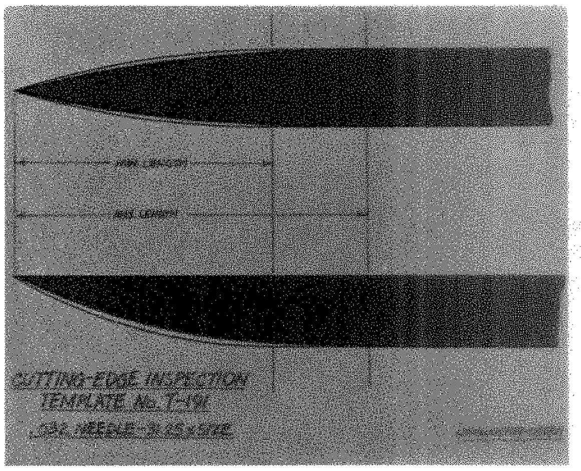
...leadership in wound repair



Donald Bremner sets his sights on surgical accuracy

In the early stages of making an ETHICON needle, a short length of steel wire is subjected to some thirteen different processes on a 20-foot journey past various cutting, forming, grinding and sharpening stations. Donald Bremner is using a special, very accurate, theodolite to align these processes with each other and with the needle.

Accurate setting means an accurate product – a needle tested by shadowgraph magnification to within 0·04 mm (and that's the tolerance on a large, abdominal needle).



This is only the beginning. Throughout the Sighthill plant of ETHICON perfectionists like Donald Bremner are dedicated to giving the surgeon *precisely* what he wants.

ETHICON

ETHICON LIMITED, SCOTLAND

Tissue approximation needs ETHICON precision

Tolerances for ETHICON sutures range from 0·0002″ (for gauge conformity in natural catgut) to 0·0001″ (for 6 mm micro-surgical needles). For every ETHICON suture is shaped by the needs of the surgeon. It is our concern to meet these needs with precision.

ETHICON
Surgical Gut

Dependable strength and absorption properties. Chromic and plain gut presented for every field of surgery.

ETHICON

THE AETIOLOGY AND PREVENTION OF PANCREATITIS FOLLOWING BILIARY-TRACT OPERATIONS

By M. R. B. KEIGHLEY* and N. G. GRAHAM
HUDDERSFIELD ROYAL INFIRMARY

SUMMARY

The incidence of pancreatitis complicating biliary-tract operations is reported from a prospective survey of 75 patients. This study confirms that pancreatitis is much more frequent after choledochotomy than after cholecystectomy alone. Biochemical pancreatitis was demonstrated in over a third of the patients in whom the duct was explored.

The validity of elevated serum amylase in the diagnosis of this complication is established provided that clinical evidence of pancreatitis is also present. The significance of amylasaemia in the immediate postoperative period in the absence of clinical signs is questioned.

Reflux of duodenal contents into the pancreatic duct may be provoked by operative damage to the sphincter of Oddi. In these patients clinical pancreatitis invariably occurred. The avoidance of sphincterotomy in the prevention of this potentially serious postoperative complication is advised. Since pancreatitis was more common after negative exploration of the common bile-duct the value of operative cholangiography in the avoidance of this complication is discussed.

Postoperative pancreatitis is a well-known complication of biliary-tract operations, particularly following supraduodenal exploration of the common bile-duct and transduodenal sphincterotomy (Thomson, Howard, and Vowles, 1957; Partington, 1966). This complication carries a high mortality of the order of 80 per cent (Thomson and others, 1957; Trapnell, 1966) and, although this occurs in a relatively small number of patients following these procedures, it is an event that should be avoided whenever possible.

It is well recognized that the diagnosis of postoperative pancreatitis which frequently occurs in the immediate postoperative period may be difficult (Burton, Eckman, and Haxa, 1957). The importance and validity of serum-amylase estimations in the early detection and diagnosis of this condition have been stressed (Perryman and Hoer, 1954; Mahaffey and Howard, 1955; Keighley, Johnson, and Stevens, 1969).

Until recently postoperative pancreatitis has been thought to be caused by trauma to the gland at operation (Warren, 1951; Blatherwick and Pattison, 1954; Burton and others, 1957). The other factors which have been incriminated include local ischaemia (Burton and others, 1957), ductal obstruction from instrumental oedema or the long-arm T-tube (Diffenbaugh and Strohl, 1956), biliary reflux into the pancreatic duct (Herman and Knowles, 1963), and the reflux of infected bile (Bryne and Joison, 1964). More recently the aetiological importance of duodenal contents entering the pancreatic duct through a damaged or incompetent sphincter has received considerable support (Pfeffer, Stasior, and Hinton, 1957; McCutcheon and Race, 1962; McCutcheon, 1968). It is suggested that this mechanism explains the incidence of pancreatitis following traumatic exploration of the common bile-duct and sphincterotomy (Warren, 1961), and its association with prolonged postoperative ileus and a distended duodenal loop following Polya gastrectomy (Perman, 1935; Wallensten, 1958).

Trapnell (1966) states that postoperative pancreatitis is more common where previous pancreatic inflammation has occurred.

CLINICAL MATERIAL AND METHODS

This communication reports the incidence of pancreatitis following biliary-tract operations. A prospective study of 75 consecutive cases was undertaken during the course of 1 year, from a single surgical unit of one hospital.

The incidence of pancreatitis was assessed by either clinical features or raised serum-amylase results. In the immediate postoperative period when clinical signs were liable to be masked by the effect of recent abdominal surgery, routine serum-amylase estimations were performed. Features of an acute onset of upper abdominal pain, radiating to the back, associated with repeated vomiting and signs of upper abdominal rigidity with absent bowel-sounds were regarded as evidence of pancreatitis. The diagnosis was confirmed by raised enzyme levels, using serum amylase and urinary diastase for this purpose. A control sample was taken on the day prior to operation and a further specimen on the morning following surgery at least 3 hours after the last postoperative sedation had been given. When elevated results were recorded further daily estimations were undertaken until the levels fell to less than 200 units.

Serum-amylase levels greater than 500 units (Somogyi, 1938) were considered to be abnormal. Provided that other conditions associated with elevated amylase had been excluded, figures of over 1000 units were regarded as diagnostic of pancreatitis; this was also supported by a urinary diastase greater than 200 units.

The incidence of pancreatitis following choledochotomy was studied. Supraduodenal exploration of the common bile-duct was performed in 26 (36 per cent) of the patients in this series. In 4 of these, transduodenal sphincterotomy was also undertaken on account of difficulty in the extraction of impacted stones at the lower end of the duct, in cases with chronic pancreatitis, or where exploration from above had been technically inadequate.

---

* Present address: University (St. James's) Hospital, Leeds.

The indications for choledochotomy in this survey included a previous history of jaundice, pancreatitis, or cholangitis; where the duct at operation appeared dilated or contained palpable stones; where small calculi occurred within the gall-bladder. Operative cholangiography had not been undertaken during the course of this survey.

Table I.—POSTOPERATIVE PANCREATITIS IN RELATION TO TIME OF ONSET, SERUM AMYLASE, AND THE PRESENCE OF SYMPTOMS

CASE	OPERATION IN ADDITION TO CHOLECYSTECTOMY	MAXIMUM POSTOPERATIVE AMYLASE	TIME OF ONSET OF PANCREATITIS	SYMPTOMS
	Immediate postoperative pancreatitis

Table II.—POSTOPERATIVE PANCREATITIS FOLLOWING BILIARY-TRACT OPERATIONS

OPERATION	NO. OF CASES	PANCREATITIS		SYMPTOMS PRESENT IN PATIENTS WITH PANCREATITIS	
		No.	Per cent	No.	Per cent
Cholecystectomy alone	49	1	2	1	100
Supraduodenal choledochotomy	26	10	39	6	60
Choledochotomy alone	22	6	27	2	33
With sphincterotomy	4	4	100	4	100

Supraduodenal exploration of the duct was performed using Desjardin's forceps and the patency of the sphincter was confirmed with Bake's dilators. T-tube drainage (of the short-arm variety) was routinely used after choledochotomy.

Specimens of bile collected from the gall-bladder at operation and from the T-tube in the postoperative period were submitted for aerobic and anaerobic culture. The relationship of pancreatitis to the presence of organisms within the biliary tract was analysed, and evidence of previous pancreatitis was noted.

FINDINGS

Postoperative pancreatitis occurred in 11 of the 75 patients undergoing biliary-tract operations, an overall incidence of 15 per cent. In all these patients the serum-amylase level was greater than 500 units (*Table I*).

Five cases developed pancreatitis within 24 hours of operation. Most of these patients had no clinical signs suggestive of pancreatitis and the diagnosis was made on the elevated enzyme levels alone. In the remainder the diagnosis was established betwee the second and tenth postoperative days on the basi of the clinical signs. This was confirmed by a raise urinary diastase and a serum amylase consistentl above 1000 units. Where the diagnosis was mad within 24 hours of operation and no clinical sign occurred, levels between 500 and 1000 units only wer demonstrated. In all these patients the preoperativ amylase level had been less than 200 units.

A high incidence of postoperative pancreatitis (1 cases—39 per cent) occurred in patients undergoin exploration of the common bile-duct, compared wit 1 case (2 per cent) following cholecystectomy alon (*Table II*). Where transduodenal exploration throug the sphincter was also performed in addition t supraduodenal choledochotomy, postoperative pan creatitis invariably occurred. In two-thirds of th patients developing pancreatitis following sup duodenal choledochotomy the diagnosis was m on the raised enzyme levels alone, whereas whe sphincterotomy was also performed signs invariabl accompanied grossly elevated enzyme results.

Prophylactic Trasylol, in a dose of 100,000 unit administered 6-hourly parenterally, was given to 2 of the 26 patients undergoing choledochotomy fo 36 hours immediately after operation. Raised serur amylase occurred in 8 of these cases (36 per cent despite this measure.

The patient developing pancreatitis followin cholecystectomy alone was of interest. A vagotom and pyloroplasty had also been undertaken for concomitant duodenal ulcer and the postoperativ course was complicated by prolonged ileus lastin for 5 days. This patient was readmitted on the tent postoperative day with signs of upper abdomin guarding and rebound tenderness associated wit profuse vomiting, and the serum amylase was raise to a level of 1277 units.

Postoperative pancreatitis was also assessed i relation to the presence of stones in the commo bile-duct. These were found in only 46 per cent c the patients undergoing choledochotomy. Evidenc that stones had not been overlooked was confirme by normal postoperative T-tube cholangiography Postoperative pancreatitis occurred more frequentl in patients in whom no stones were found (70 pe cent; *Table III*). As a result of these findings the value of clinical criteria for exploring the duct was analysed. The only reliable indication for choledochotomy was the finding of palpable stones at operation, although in a third of patients with choledocholithiasis these were impalpable. A previous history of jaundice, cholangitis, and pancreatitis was unreliable evidence of stones within the duct (*Table IV*).

Table III.—POSTOPERATIVE PANCREATITIS FOLLOWING CHOLEDOCHOTOMY IN RELATION TO CHOLEDOCHOLITHIASIS AND PREVIOUS PANCREATITIS

	No. of Cases	Percentage of Cases	Postoperative Pancreatitis	
			No.	Per cent
Choledochotomy	26		10	39
Choledocholithiasis	12	46	3	30
No stones	14	54	7	70
Previous pancreatitis	12	46	4	40
No previous pancreatitis	14	54	6	60

Table IV.—THE VALUE OF CLINICAL INDICATIONS FOR CHOLEDOCHOTOMY IN 26 CASES

Indications	Stones present (12 Cases)		No Stones (14 Cases)	
	No.	Per cent	No.	Per cent
Jaundice	10	84	11	78
Pancreatitis				
Preoperative	5	42	4	28
At operation	6	50	6	43
Cholangitis	4	33	5	35
Dilated common bile-duct	9	75	7	50
Palpable stones	8	67	0	—
Dilated cystic duct and small calculi in gall-bladder	5	42	7	50
Sludge in common bile-duct	6	50	5	35
Biliary colic	9	75	14	100

Table V.—POSTOPERATIVE PANCREATITIS AND ITS RELATIONSHIP TO ORGANISMS WITHIN THE BILIARY TRACT

	No. of Cases	Per cent
Overall incidence of infected gall-bladder bile	27 out of 75	36
Infected gall-bladder bile with pancreatitis	4 out of 11	36
Overall incidence of infected T-tube bile	19 out of 26	73
Infected T-tube bile with pancreatitis	6 out of 10	60

The incidence of postoperative pancreatitis was not related to the occurrence of organisms either in the gall-bladder at operation or in the T-tube in the postoperative period (*Table V*). Postoperative pancreatitis was independent of previous inflammatory episodes within the gland (*Table III*).

In patients developing clinical pancreatitis in the postoperative period the morbidity was increased in terms of prolonged hospital stay, but the overall mortality in this survey was nil. In those patients where a raised serum amylase was the only indication of pancreatitis the length of hospital stay was not extended.

DISCUSSION

The results have demonstrated a high incidence of pancreatitis following choledochotomy. This occurred in over a third of the patients in whom the common bile-duct was explored. Where transduodenal choledochotomy through the sphincter was performed postoperative pancreatitis ensued in every case. There was a high incidence of negative findings when the duct was explored and pancreatitis was more common when the stones were not found.

The validity of serum-amylase levels as a sole criterion for a diagnosis of pancreatitis in the postoperative period was reviewed. As there were no preoperative control figures above the normal range, this would suggest that abnormal results in the postoperative period were probably significant. Where clinical features of pancreatitis were absent within the first 24 hours after operation, serum amylase levels, although elevated, were rarely above 1000 Somogyi units. In these patients the serum-enzyme results returned to normal within 24 hours and the presence of amylasaemia did not appear to influence the overall recovery. It is suggested, therefore, that a raised serum amylase in the immediate postoperative period following supraduodenal choledochotomy does not necessarily signify overt pancreatitis.

This study has investigated some of the factors concerned in the aetiology of pancreatitis following biliary-tract surgery. No importance is attached to the presence of organisms in the biliary tract from the results of this survey. There was no evidence of pancreatic duct filling on postoperative T-tube cholangiography in patients developing pancreatitis in the postoperative period. It is suggested, therefore, that biliary reflux up the pancreatic duct is not an important factor in the pathogenesis of this condition. Direct trauma to the gland has been investigated elsewhere, and it is considered that this is not responsible for pancreatitis following operative procedures, although local trauma to the sphincter alone appears to play an important part in the occurrence of this condition (Keighley and others, 1969).

There has been adequate experimental evidence to suggest that an important cause of pancreatitis in cases with an isolated duodenal loop is duodenal reflux, which can be prevented by tying the pancreatic duct (McCutcheon and Race, 1962; Williams and Bryne, 1967). This would explain the development of this complication in the patient with a prolonged period of ileus following cholecystectomy, thus allowing stagnant duodenal contents to accumulate and to fill the pancreatic duct. Sphincterotomy and extensive exploration of the common bile-duct which rendered the sphincter of Oddi incompetent were invariably followed by clinical pancreatitis. It is suggested from this study that duodenal reflux into the pancreatic duct is an important cause of clinical pancreatitis following these procedures.

In discussing the avoidance of postoperative pancreatitis, these findings have shown that whenever transduodenal sphincterotomy was performed in addition to supraduodenal choledochotomy, clinical pancreatitis with biochemical evidence of pancreatic autodigestion occurred in every case. It would appear that the prophylactic administration of Trasylol in the immediate postoperative period does not protect against this complication. It is argued, therefore, that sphincterotomy should be avoided whenever possible. The value of choledochoduodenostomy in patients with pre-existing pancreatic disease and choledocholithiasis with a dilated common bile-duct has previously been documented (Burgess and Kidd, 1967). Therefore where choledochotomy is indicated the avoidance of trauma to the sphincter might be an important factor in the prevention of this potentially dangerous postoperative complication (Blatherwick and Pattison, 1954).

Since negative exploration of the common bile-duct was associated with a high incidence of postoperative pancreatitis it is argued that this would not have occurred if choledochotomy had been avoided.

The importance of satisfactory operative cholangiography in the definition of stones and the avoidance of unnecessary exploration has been clearly shown (Swedburg, 1952; McEvedy, 1970; Wheeler, Sonpong, and Williams, 1970). Other workers have experienced a similar incidence of negative findings when the common bile-duct is explored on clinical indications alone (Glenn, 1952; Thomson, 1956). It is therefore concluded that pancreatitis could have been avoided in 70 per cent of cases undergoing choledochotomy if operative cholangiography had defined when this was unnecessary. It is suggested that the value of routine operative cholangiography lies not only in the definition of stones but also in the avoidance of unnecessary choledochotomy complicated by a high incidence of postoperative pancreatitis.

Acknowledgements.—We wish to thank Dr. A. M. Barlow, Dr. H. J. Black, and the technicians in the Department of Pathology at Huddersfield Royal Infirmary for their co-operation and help in the biochemical and bacteriological analyses of the present series.

COMPUTER-ASSISTED STATISTICAL ANALYSIS OF SKELETAL SCINTIGRAMS*

By C. S. B. GALASKO†

BREAST UNIT AND DEPARTMENT OF SURGERY, ROYAL POSTGRADUATE MEDICAL SCHOOL, LONDON

Summary

Forty-two consecutive skeletal scintigrams of the dorsal and lumbar spine have been statistically analysed using an Elliott 4120 Computer. Each patient had, in addition, anteroposterior and lateral radiographs of the dorsal and lumbar spine taken. All the patients have been followed up for a minimum of 18 months. In each patient the radiological, scintigraphic, and statistically analysed data have been compared and the accuracy of the results determined by the subsequent progress made by the patient. The results indicate that the computer analysis introduced both false positives and false negatives, and it i suggested that, at the moment, the computer assisted statistical analysis of the skeletal scintigran is not sufficiently reliable for clinical use.

During the past few years much work has bee carried out on the analysis of scintigrams obtaine from either a rectilinear scanner or a gamma camera in an attempt to improve the sensitivity of th technique (Tauxe, 1968, 1969; Laughlin, Kenny Weber, Dwyer, Mayer, Greenberg, Dimich, an Hasan, 1969; Winkler, Akhtar, and Knopp, 1969 Hutchinson, St. Clair Neill, and Rimmer, 1971) Unfortunately, these studies have been carried ou on either known phantoms or patients whose follow up has been inadequate.

---

* Based on a paper given to the Surgical Research Society in January, 1971.

† Present address: Nuffield Orthopaedic Centre, Headington, Oxford.

The division of the scintigram into areas must be arbitrary, since any lesion will be an unknown factor as regards its presence, size, depth in the tissues, and uptake of isotope until the scintigram has been obtained and examined. It is possible, therefore, that the analysis of the data may introduce inaccuracies.

C

FIG. 1.—Scintigram of the dorsal spine. A, A lesion (arrowed) can be seen in the centre of the spine. A second area of increased uptake due to the 'edge effect' of the camera (E) can also be seen. B, The computer-assisted statistical analysis of the data. Areas represented by 'A' contain the highest count rate. In the areas 'B' the number of counts is 3 standard deviations less than 'A', and 'C' represents count rates 3 standard deviations less than 'B'. C, Areas 'A', 'B', and 'C' have been marked in. The pattern is similar to the original scintigram.

The present study was carried out to assess the clinical usefulness of computer-assisted statistical analysis of skeletal scintigrams.

MATERIALS AND METHODS

Forty-two consecutive scintigrams of the dorsal and lumbar spine were analysed. Each scintigram was obtained with the gamma camera $1\frac{1}{2}$ hours after the intravenous injection of 1·5 m.c. ^{18}F. The data were fed into a Laben 512-channel multichannel analyser via a specially constructed circuit. The multichannel analyser was used in a bidimensional mode with a 16 × 32-channel matrix so that each scintigram was divided into 512 areas arranged in 16 rows of 32 areas. Each area represented approximately 2 × 2 cm. at the crystal face. The total number of counts accumulated in each square was then printed out and the data were processed in an Elliott 4120 computer.

The computer program was designed so that the area with the highest count rate would be designated by the letter 'A'. Each area containing a total of counts 3 standard deviations less than 'A' would be represented by 'B', each square which was less than 'B' by 3 standard deviations would be represented by 'C', etc.

Standard anteroposterior and lateral radiographs were taken of each region and the radiological, scintigraphic, and statistically analysed findings were compared.

All the patients have been carefully followed up for a minimum of 18 months to assess the accuracy of the findings.

RESULTS

The results are shown in *Tables I–IV*. In 5 of the 42 regions examined skeletal metastases were evident on the radiograph. Three of these lesions were present on both the scintigram and the computer print-out, but in 2 instances the lesions were seen on the scintigram but were not detected by the statistical analysis of the data. These must be considered as 2 false negatives for the computer analysis.

In 9 instances the radiographs were normal, but lesions were seen both on the scintigram and on the analysed print-out (*Fig.* 1). These 9 scintigrams are further analysed in *Table II*. In 7 cases the lesions have subsequently been confirmed either on serial radiographs or at autopsy, and although the remaining 2 lesions have not yet been confirmed, these patients have developed skeletal metastases at other sites. In 2 patients several lesions were seen on the scintigram, although only 1 lesion was apparent on the computer print-out. In both cases all the lesions were subsequently confirmed.

The statistical analysis indicated regions with a significantly increased uptake in 7 instances, although both the scintigrams and the radiographs had been considered normal (*Table III*). As yet none of these 'lesions' has been confirmed, but 1 patient has developed skeletal metastases at other sites. One of the 'lesions' was found in 1 of the control patients in whom there is no sign of malignant disease or of any skeletal abnormality to account for this increased uptake, and this must be regarded as a false positive.

There were 6 instances where the scintigram was abnormal although both the radiographs and the statistical analysis were normal (*Fig. 2*, *Table IV*). In 5 patients the lesions have already been confirmed, indicating that in these 5 instances the statistical analysis was incorrect. The remaining patient in this group has developed metastases at other sites.

The two areas of 'edge-effect' can be seen but the lesion in L.V.₃ is not apparent.

DISCUSSION

Since this study was commenced there have been many improvements in the computer analysis of scintigrams, particularly in the development of more sophisticated equipment. Unfortunately, the authors of the vast majority of papers have not followed up the patients whom they have examined. If their analysis showed an additional abnormality it was assumed that this was due to a lesion present in the patient. With the lack of adequate follow-up the incidence of false positives or false negatives introduced by the analysis was not known. Much of this work has been carried out by non-clinicians who may not have appreciated the difference that an abnormal scintigram may make to a particular patient's treatment.

In this series each patient has been followed up for a minimum of 18 months. The results obtained

Table I.—COMPARISON OF THE FINDINGS ON THE RADIOGRAPHS, SCINTIGRAPHIC PRINT-OUT, AND COMPUTER-ASSISTED STATISTICAL ANALYSIS OF THE SCINTIGRAPHIC DATA IN 42 CONSECUTIVE SCINTIGRAMS OF THE DORSAL AND LUMBAR SPINE

	RADIOGRAPH POSITIVE		RADIOGRAPH NEGATIVE	
	Computer Positive	Computer Negative	Computer Positive	Computer Negative
Scintigram positive	3	2	9	6
Scintigram negative	0	0	7	15

Table II.—FOLLOW-UP OF THE PATIENTS WITH LESIONS PRESENT ON THE STATISTICAL ANALYSIS AND THE SCINTIGRAPHIC PRINT-OUT BUT WITH NORMAL RADIOGRAPHS

2	Advanced cancer	Metastases at other sites
4	Advanced cancer	Radiograph positive
2	Advanced cancer	Autopsy positive
1	'Early' cancer	Radiograph positive

indicate that, at the present time, the computer-assisted analysis of the skeletal scintigram is not sufficiently reliable for clinical use. Overall there were at least 1 false positive and 5 false negatives in the statistical analysis of the 42 scintigrams, whereas none of the lesions demonstrated on the pictorial scintigram has been shown to be incorrect.

It has been widely accepted that a change in the count rate at the detector head is significant if the change is greater than 3 standard deviations (Vernon, 1968). It is possible that if one accepted only 2 standard deviations as being significant, less false negatives would have occurred with the computer analysis.

Table III.—FOLLOW-UP OF THE PATIENTS WITH NORMAL RADIOGRAPHS AND SCINTIGRAMS BUT WITH 'LESIONS' PRESENT ON THE STATISTICAL ANALYSIS

No. of Patients	*Group of Patients*	*Follow-up*
1	Advanced cancer	Metastases at other sites
5	'Early' cancer	Well
1	Control	Well

Table IV.—FOLLOW-UP OF PATIENTS WITH LESIONS PRESENT ON THEIR SCINTIGRAM BUT WITH RADIOGRAPHS AND STATISTICAL ANALYSIS APPARENTLY NORMAL

No. of Patients	*Group of Patients*	*Follow-up*
2	Advanced cancer	Positive radiograph
3	'Early' cancer	Positive radiograph
1	'Early' cancer	Metastases at other sites

Wherever an area of increased uptake occurs it will be appreciated visually. The areas for the multichannel analysis are defined irrespective of any localized increased uptake of isotope. If a lesion occurs in the middle of one of these defined areas it will probably be seen on the statistical analysis. If the lesion overlaps into three or four areas its increased uptake may be dampened to such a degree by the remaining normal tissue in each area that when the data are analysed the increase may not be statistically significant.

If, as in most instances, the system being examined is an experimental one the preselection of areas to avoid the 'lesion' spilling into several squares may be acceptable, but in the clinical situation it is possible that these manœuvres may introduce false positives and false negatives.

A significant difference between areas is only an indication that a significantly different count rate has been detected at the counting head, and although it is frequently assumed that the eye perceives changes in this manner (Rose, 1948; Dewey and Sinclair, 1961; Matthews, 1964) this may not be the case and the eye may build up images, not by comparing areas but by integrating a series of boundaries to complete a shape (Brownell, 1964). Although it is relatively easy to program a computer to analyse numerical data and to determine the significance of any changes, it is virtually impossible, at the moment, to program for pattern recognition, and it is probable that pattern recognition plays an extremely important role in reading scintigrams. This may also explain why the results obtained from the statistical analysis of the data were inferior to those obtained from the visual interpretation of the scintigrams.

It is hoped that with the introduction of more sophisticated apparatus the computer-assisted analysis of the skeletal scintigram will become more reliable, but it must be stressed that adequate follow-up is essential to determine the incidence of false negatives and false positives. Only if the latter, particularly false positives, can be eliminated will computer-assisted statistical analysis become sufficiently reliable for clinical use.

Acknowledgements.—I am indebted to Mr. P. Vernon, Department of Medical Physics, Royal Postgraduate Medical School, for developing the computer program and for his constant advice, and to Professor J. F. Fowler, Department of Medical Physics, for the facilities provided. I also wish to thank Professor R. B. Welbourn and Mr. J. I. Burn, Department of Surgery, Royal Postgraduate Medical School, for allowing me to investigate their patients and for their constant encouragement.

SHORT NOTES OF RARE OR OBSCURE CASES

PNEUMOMEDIASTINUM AND SUBCUTANEOUS EMPHYSEMA AFTER PERFORATION OF THE DUODENUM DURING GASTROSCOPY

BY R. N. ALLAN AND C. J. SMALLWOOD
THE GENERAL HOSPITAL, STEELHOUSE LANE, BIRMINGHAM

SUMMARY

The first case of duodenal perforation during gastroscopy is reported. The patient's symptoms were mild in contrast to the dramatic picture of perforated peptic ulcer. He developed a pneumoperitoneum, pneumomediastinum, and, in addition, subcutaneous emphysema of the neck—signs more commonly associated with oesophageal rupture than perforation of the duodenum.

The aetiology of these signs and the prevention of this complication are discussed.

PERFORATION of the upper oesophagus and stomach during gastroscopy is a rare though well-recognized complication using the rigid gastroscope. It is usually caused by direct trauma (Schindler, 1940; Jones, Doll, Fletcher, and Rodgers 1951). The present case is unusual because the duodenum was perforated by insufflation of air during the procedure, and it is interesting that while this patient presented many of the physical signs associated with oesophageal perforation, investigation prior to operation accurately located the site of the leak to the duodenum.

CASE REPORT

In 1962 this man presented with a 5-month history of epigastric discomfort, anorexia, vomiting, weight-loss, and a recent haematemesis. At laparotomy there was a benign gastric ulcer on the lesser curve. A Billroth-I partial gastrectomy was performed and he made an uninterrupted recovery.

In January, 1971, at the age of 73 years, the patient was readmitted with a 2-week history of epigastric pain, anorexia, profuse bile-stained vomiting, weight-loss, and general malaise. There were no abnormal signs on examination and therefore he was treated initially with intravenous fluids and nasogastric suction. A barium-meal examination 5 days after admission showed satisfactory emptying of the stomach with no evidence of recurrent ulceration.

In view of the negative barium-meal examination gastroscopy was performed under local anaesthesia. The gastroscope was passed easily into the stomach. More air than usual was blown in because the gastric remnant proved difficult to dilate. The gastric mucosa and gastroduodenal junction were normal.

Immediately after the examination there were no abnormal signs or symptoms. Within 2 hours, however, the patient complained of slight epigastric pain and the abdomen became distended and firm but there was no rigidity or rebound tenderness. He had a tachycardia (110 per minute) but his blood-pressure remained normal. A few minutes later he developed marked subcutaneous emphysema of the neck and upper chest wall. Straight radiographs of the chest and abdomen showed evidence of a pneumoperitoneum, pneumomediastinum, and extensive subcutaneous emphysema of the chest wall (*Fig.* 1).

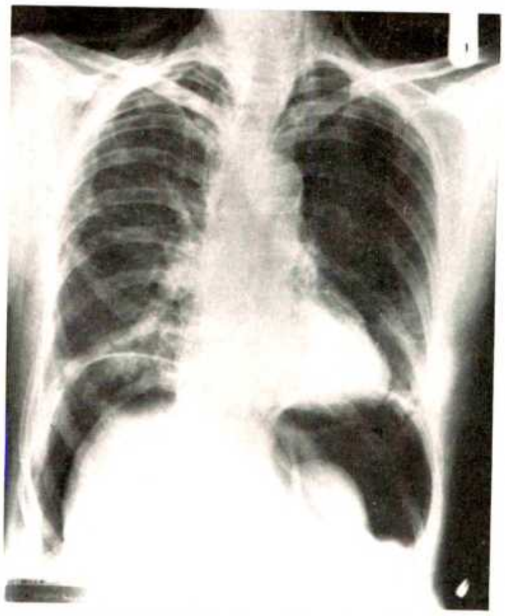

FIG. 1.—Chest radiograph, showing pneumoperitoneum, pneumomediastinum, and subcutaneous emphysema of neck.

A Gastrografin swallow showed the oesophagus to be intact, but there was a perforation in the first part of the duodenum with leakage into the peritoneal cavity (*Fig.* 2).

A laparotomy was performed under general anaesthesia through the old right upper paramedian incision. There was a large volume of free air in the peritoneal cavity, air in the falciform ligament, and numerous adhesions in the upper abdomen. A small quantity of bile-stained fluid flowed from Rutherford-Morrison's pouch. After unpicking the adhesions which bound the duodenum to the undersurface of the liver, a perforation was found in the anterior wall of the duodenum, 1·5 cm. in length. The mucosa appeared normal and the duodenal wall, though thin, had none of the appearances associated with chronic ulceration. The perforation was closed vertically with continuous plain catgut in two layers. Toilet to the peritoneal cavity completed the operation. The patient made an uneventful recovery, the surgical emphysema rapidly regressed, and he was discharged on the tenth postoperative day.

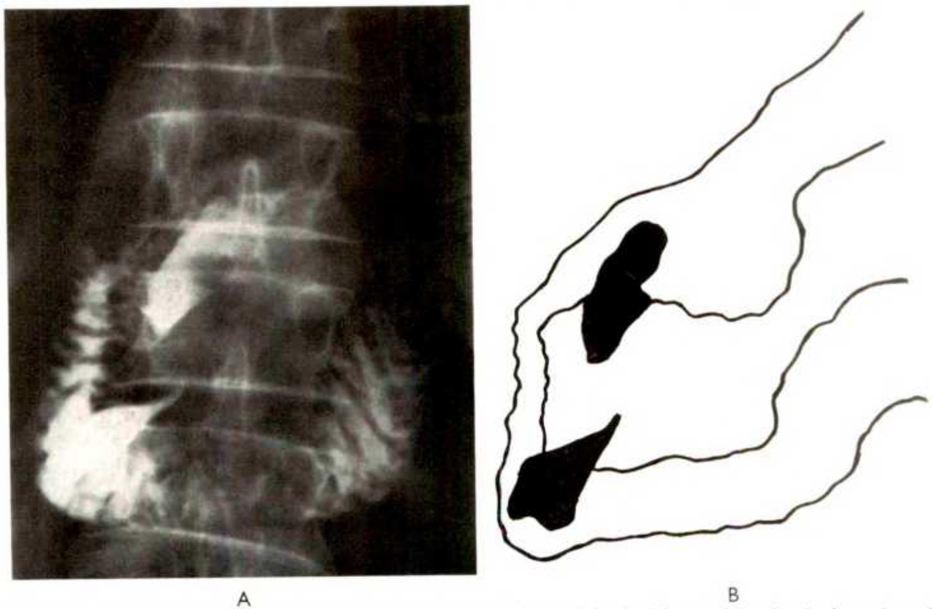

FIG. 2.—A, Barium-meal film, showing Gastrografin leaking from the duodenum (*above*) with some lying free in the peritoneal cavity (*below*). B, Diagrammatic representation of A.

DISCUSSION

Perforation of a viscus during gastroscopy is a rarity. In an extensive survey by English gastroscopists covering 49,000 examinations only 50 perforations of the oesophagus were recorded, an overall rate of 1·2 per 1000 examinations using the rigid gastroscope (Jones and others, 1951). This complication is now less common with the introduction of improved and flexible instruments (Calem, 1962). Perforation of the oesophagus and stomach result from direct trauma; even the jejunum may be perforated if the patient has had a gastro-enterostomy (Rumball, 1939). Duodenal perforation has not been reported before as a complication of either gastroscopy or duodenoscopy (Classen, 1971). There is a single example in the literature of air leaking during gastroscopy from the base of a bleeding gastric ulcer, which at operation appeared to have perforated some time prior to the examination and subsequently had sealed off (Hirschowitz, Balint, and Fulton, 1962).

During the examination of the patient presented here the gastroscope was not passed beyond the gastroduodenal junction, the perforation thus resulting from over-inflation of the duodenum rather than from direct trauma. Air insufflation of the stomach is essential in order to see the gastric mucosa adequately when using a side-viewing instrument. In patients who have had previous gastric resection more air is often used because there is no longer a competent pylorus to retain the air in the gastric remnant. This complication could be prevented by fitting the gastroscope with a pressure-release valve, thus avoiding an excessive rise in intragastric pressure.

The symptoms in this patient, like those described in the literature, are not typical of a spontaneously perforating peptic ulcer because the patient has been heavily sedated, the stomach is empty, and the diaphragms are splinted by the resulting pneumoperitoneum (Boon, 1951).

In this patient a diagnosis of oesophageal perforation was considered initially but the Gastrografin swallow showed the oesophagus to be intact and a perforation to be clearly evident in the first part of the duodenum. This accurate localization of the site of perforation is essential to subsequent surgical management.

The pneumomediastinum probably resulted from old adhesions sealing off the duodenum from the general peritoneal cavity, thus permitting air to track extraperitoneally into the mediastinum and up into the neck. The pneumoperitoneum followed the breakdown of adhesions which had sealed the duodenum and gastroduodenal suture line from the general peritoneal cavity. Though the mucosa of the duodenum appeared normal, both radiologically and at operation, the perforation may have occurred through either the base of an acute ulcer or at the site of a suture-line leak following the original operation which had subsequently sealed off; the latter seems the more likely.

Acknowledgements.—We should like to thank Dr. P. W. Dykes and Mr. G. T. Watts for permission to publish details of this case. Dr. D. K. M. Toye has given us considerable help in preparing this publication.

ADENOCARCINOMA DEVELOPING IN AN ILEOCYSTOPLASTY

By P. W. LEEDHAM and H. R. ENGLAND

DEPARTMENTS OF MORBID ANATOMY AND UROLOGY, THE LONDON HOSPITAL

SUMMARY

Multifocal adenocarcinoma and carcinoma-in-situ arising in the suture line of an ileocystoplasty are reported in a 52-year-old woman who presented with haematuria 15 years after bladder reconstruction for tuberculosis. An origin in the ileal mucosa was established by microscopy. There are similarities with a transitional-cell carcinoma in an ileocystoplasty which has recently been recorded. Both cases are related to tumours associated with ureterosigmoidostomy where the site, tumour types, and latent period are similar. Aetiological factors seem to include a long latent period (15 years or more) and possibly the direct action of urine, recurrent infection, and mucosal ulceration. It is concluded that all patients with gastro-intestinal urothelial anastomoses must be followed up indefinitely.

NEOPLASTIC complications of bladder reconstruction performed for benign inflammatory conditions were unrecorded until recently when a transitional-cell carcinoma arising in an ileocystoplasty was documented (Smith and Hardy, 1971). A second case is now reported in which an adenocarcinoma developed in an ileocystoplasty performed 15 years previously for tuberculosis.

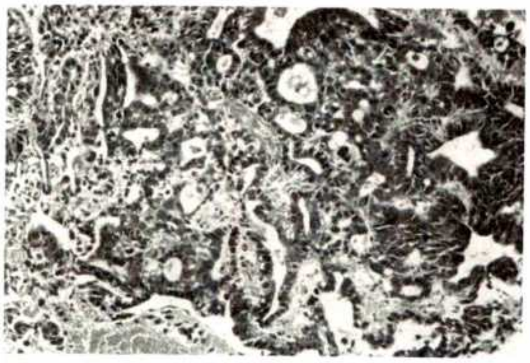

FIG. 1.—Section of the biopsy material, showing a moderately differentiated adenocarcinoma. Normal ileal mucosa is not present. H. and E. (× 96.)

CASE REPORT

A. W., a 34-year-old housewife, was first seen in 1953, when tuberculosis of the renal tract was diagnosed. She was treated with anti-tuberculous drugs but 2 years later a right nephro-ureterectomy was performed, and in early 1956 she had an ileocystoplasty for a contracted bladder. In this operation part of the antimesenteric border of an isolated segment of ileum was anastomosed to the fundus of the bladder.

During the next 5 years the patient developed frequent urinary infections despite adequate antibiotic therapy and complained of an ever-increasing frequency of micturition. *Mycobacterium tuberculosis* was not isolated again. At cystoscopy in 1960 she was shown to have an inflamed bladder with a capacity of only 150 ml. and it was apparent that the ileovesical stoma had contracted to approximately 1 cm. in diameter. One year later a pregnancy was terminated by hysterotomy and she was sterilized by tubal ligation. At the same time the ileovesical stoma of the ileocystoplasty was refashioned and a biopsy of the ileal mucosa near the suture line showed severe acute and chronic inflammation. The number of urinary infections were considerably reduced following this procedure but in 1964 the patient failed to attend for follow-up.

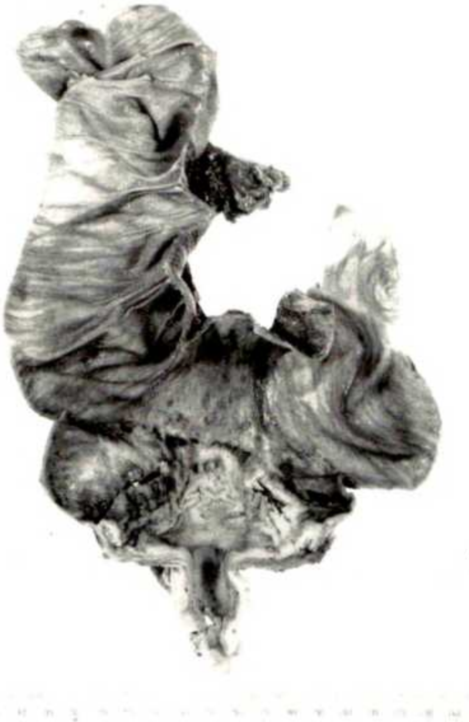

FIG. 2.—Ileocystoplasty specimen opened from behind showing the dilated ileal loop (*above*) anastomosed to the contracted bladder.

She was referred back in March, 1971, complaining of episodes of painless haematuria for a few months. No abnormality was found on clinical examination but microscopic haematuria was detected. Midstream specimens of urine were sterile on culture and the blood-urea and electrolytes were normal. An intravenous pyelogram showed a normal upper urinary tract on the left side and no filling defects were seen in the ileocystoplasty on a cystogram. However, at cystoscopy two red, friable polypoid tumours up to 1 cm. in diameter were seen at the ileovesical junction. No infiltration was felt by bimanual examination but biopsies showed fragments of adenocarcinoma (*Fig.* 1). At the end of April, 1971, the ileal loop, bladder, urethra, ovaries, Fallopian tubes, and uterus were removed and the left ureter was anastomosed to an isolated segment of sigmoid colon by the Leadbetter technique (Leadbetter, 1951). Her postoperative course was uneventful and she has remained asymptomatic.

PATHOLOGY.—The biopsy of the ileal mucosa which was taken in 1961 showed patchy acute mucosal ulceration with epithelial regeneration. There were also areas of severe submucosal chronic inflammation with dense lymphocytic aggregates and fibrosis. There was no evidence of malignant change or tuberculosis.

The uterus, Fallopian tubes, ovaries, and the ileocystoplasty were removed in 1971. The latter consisted of an isolated loop of dilated ileum, 25 cm. long, closed at both ends, and attached along part of its antimesenteric border to the bladder and urethra (*Fig.* 2). The distal 2 cm. of the right ureter was found opening into the vesical part 1·5 cm. above the bladder neck. The orifice of the left ureter was found in a similar position on the other side but the ureter had been cut off flush with the bladder wall. When the ileal loop and bladder were opened, three superficial papillary nodules up to 1 cm. in diameter were found in the region of the ileovesical anastomosis (*Fig.* 3). The vesical mucosa close to the suture line was wrinkled and greyish white (*Fig.* 3) but lower down became smooth and pink. There was slight irregular thickening of the ileum at the ileovesical junction but elsewhere it was thin-walled with a smooth mucosal lining.

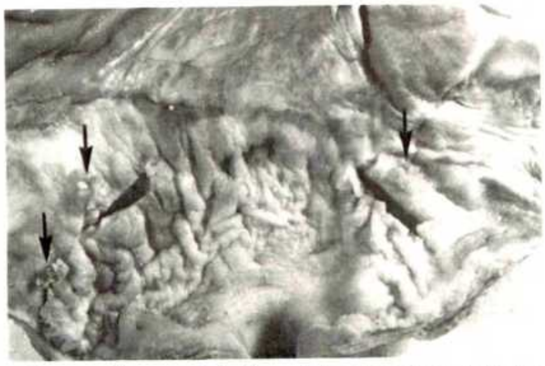

FIG. 3.—Close-up of the ileovesical anastomosis to show the three small adenocarcinomatous polyps (arrows). Below these the mucosa is pale and wrinkled but it is smoother near the bladder neck. (Urgent diagnostic blocks were taken before photography.)

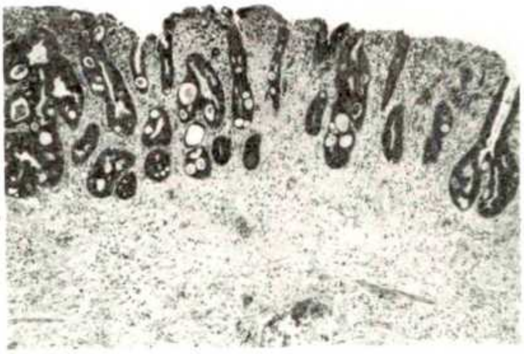

FIG. 5.—Section of the ileal mucosa close to the suture line. There is atypical epithelial proliferation with multilayering of cells within acini and an irregular back-to-back arrangement of the glands. Strands of muscularis mucosae are present in the lower part of the picture. H. and E. (× 39.)

Microscopy of the nodules showed moderately differentiated partly papillary and partly solid adenocarcinoma similar to that seen in the biopsy taken at cystoscopy (*Fig.* 1). The tumours were mainly confined to the mucosal layer with extensive infiltration of the lamina propria (*Fig.* 4) but early invasion through the muscularis mucosa was seen in a few areas. These neoplastic areas were completely separate from one another. However, the ileal epithelium adjacent to the nodules and elsewhere close to the suture line showed atypical epithelial proliferation with irregular multilayering of epithelial cells in glandular acini, numerous mitoses, and an early back-to-back arrangement of glands (*Fig.* 5). These changes were interpreted as a carcinoma-in-situ change of the ileal mucosa. There were also areas of adenomatous hyperplasia (*Fig.* 6). Away from the anastomosis the ileum had a flattened normal epithelium with only occasional villi still present and the muscle coat was atrophic with some increase in fibrous tissue. There was non-keratinizing squamous metaplasia of the mucosa for 1–2 cm. on the vesical side of the suture line, causing the wrinkled greyish appearance described above, but this gradually merged into normal transitional epithelium in the lower part of the bladder. There was no evidence of malignant change in the bladder mucosa.

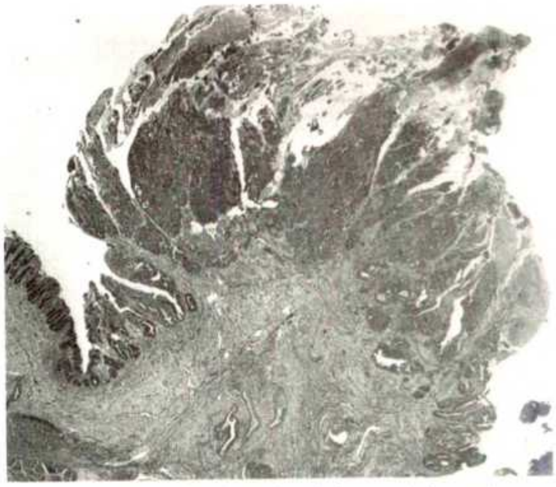

FIG. 4.—Section of a polyp to show dark areas of adenocarcinoma extending towards its base. There is superficial ulceration and more normal glandular epithelium is present on each side. H. and E. (× 12.)

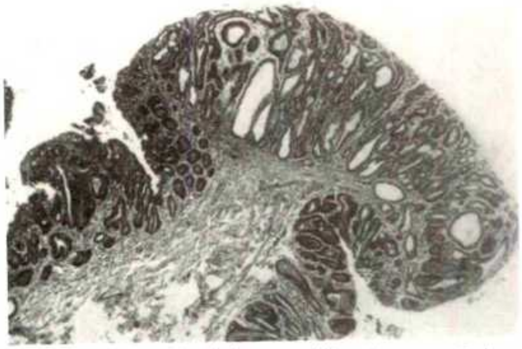

FIG. 6.—Section of the ileal mucosa. There is an area of adenomatous hyperplasia with regular glands each of which is surrounded by stroma and lined by a single layer of cells. There is no evidence of malignant change. H. and E. (× 24.)

Numerous blocks taken perpendicular to the suture line established that both the frank carcinoma and the in situ changes were in the ileal mucosa. Transitional or squamous epithelium was not present proximal to these changes and there were occasional islands of more normal ileal mucosa between these areas and the ileovesical junction. The location of this junction was further established by the presence of muscularis mucosa (*Fig.* 5) and the different arrangement of muscle layers in the ileal wall.

There was chronic inflammation and fibrosis in the subepithelial connective tissue on each side of the anastomosis, but no evidence of tuberculosis was found in any of the tissues. The uterus, ovaries, and Fallopian tubes were normal.

DISCUSSION

The presence of multifocal adenocarcinoma and carcinoma-in-situ close to the suture line in the ileal mucosa of an ileocystoplasty has been established by the microscopic findings in this case. Friable adenocarcinomatous polyps were the source of bleeding with which the patient presented, but because of their superficial nature it is possible that a cure has been effected by radical surgery. It is very unlikely that the neoplastic changes in the ileum are fortuitous and unrelated to its use in reconstruction of the bladder. Primary adenocarcinoma of the ileum is rare (Darling and Welch, 1959; Wood, 1967). There also seems little possibility that this could be a primary adenocarcinoma of the bladder since no connexion was established with the bladder mucosa. Indeed, the latter showed squamous metaplasia and no evidence of glandular metaplasia.

Neoplasia is not recorded in reviews of the complications of ileo- or colocystoplasty (Houtappel and Grundeman, 1960; Maged, 1968; Kuss, Bitker, Camey, Chatelain, and Lassau, 1970). Smith and Hardy (1971) have recorded the only other case which has a strikingly similar clinical history. The ileocystoplasty in their case was also performed for tuberculous contraction of the bladder and there was a long history of recurrent urinary infection following this operation. After a long latent period (17 years) the patient presented with haematuria. However, in their case there was a transitional-cell carcinoma in the ileal loop. Although it is not established how close the tumour was to the ileovesical junction it is possible that it arose in transitional epithelium which had spread across the suture line.

Tumours associated with ureterosigmoidostomy are also rare but have been reported more frequently (Dixon and Weismann, 1948; Urdaneta, Duffell, Creevy, and Aust, 1966), and Whitaker, Pugh, and Dow (1971) have recently reviewed 28 such tumours with some significant observations. In all the cases the tumour was close to the line of the anastomosis, and in 20 cases where there had been a previous benign lesion the mean latent period between ureterosigmoidostomy and the development of the tumour was 19 years. Both adenocarcinomas and transitional-cell carcinomas were recorded as well as adenomatous polyps and undifferentiated carcinomas. The close similarity with the two tumours now recorded in ileocystoplasties cannot be a coincidence and it is likely that the same aetiological factors are responsible.

The carcinogenic agent remains obscure, but the direct action of urine on the gastro-intestinal-urothelial junction over a long period would seem the most likely factor. Deconjugation of ortho-aminophenols, derived from the tryptophan metabolism, to yield active carcinogens in urine has been implicated in the development of carcinoma of the bladder (Boyland, 1959) and the same may apply in this situation. It may also be significant that in both ileal tumours there were long periods of recurrent urinary infection and there is direct histological evidence in the present case of mucosal ulceration and epithelial regeneration before the tumour developed. Recurrent regeneration over a long period of time could lead to neoplastic change as it does in other conditions such as ulcerative colitis. The occurrence of tumours exclusively on either side of the suture line might also be explained by relative ischaemia at this site which would make either the urothelial or the gastro-intestinal mucosa more susceptible to recurrent infection and ulceration.

Whatever the aetiology, the implications of the cases reported to date are obvious. It is apparent that neoplastic changes at the suture line in gastro-intestinal urothelial anastomoses are a rare but real hazard, even when performed for a benign condition. Patients at risk appear to be those who have survived 15 years or more and possibly those who have had a long history of recurrent urinary infections. More cases are likely to occur since these reconstructive procedures have increased in popularity over the past 20 years, particularly following the introduction of ileal loop diversion (Bricker, 1950). The type of tumour recorded here has not yet been reported in this situation, but persistent infection of the urine is a known complication (Kafetsioulis and Swinney, 1968).

It is concluded, therefore, that all patients with gastro-intestinal urothelial anastomoses should be followed up indefinitely so that there may be some chance of detecting neoplastic change as early as possible.

Acknowledgements.—We are grateful to Mr. G. C. Tressider for his encouragement and for allowing us to study one of his cases. Mr. S. Stevens, Mr. R. Hammond, and Miss L. Testa are thanked for technical, photographic, and secretarial assistance respectively.

A 'CORRUGATED' EXTRAHEPATIC BILE-DUCT: A NEW CHOLANGIOGRAPHIC PICTURE

By G. H. DICKSON*

SENIOR SURGICAL REGISTRAR, ASHFORD HOSPITAL AND ST. MARY'S HOSPITAL, PADDINGTON

SUMMARY

A patient with an operative cholangiogram showing appearances suggestive of multiple diverticula is recorded; these appearances are apparently unique.

In recent years the use of operative cholangiography has become routine in many centres. The cholangiographic picture of the biliary tract in health and disease is now well documented (Le Quesne, 1964). The present paper describes an unexpected operative cholangiogram picture obtained during a routine cholecystectomy.

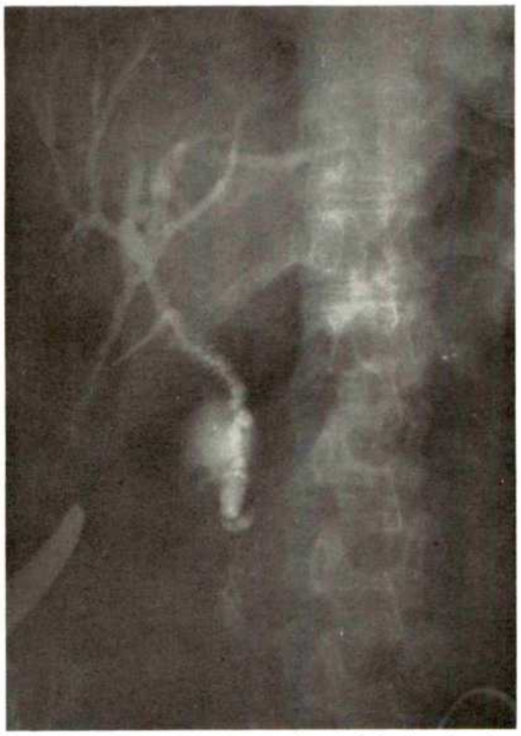

FIG. 1.—Operative cholangiogram after the injection of 6 ml. of contrast material into the cystic duct.

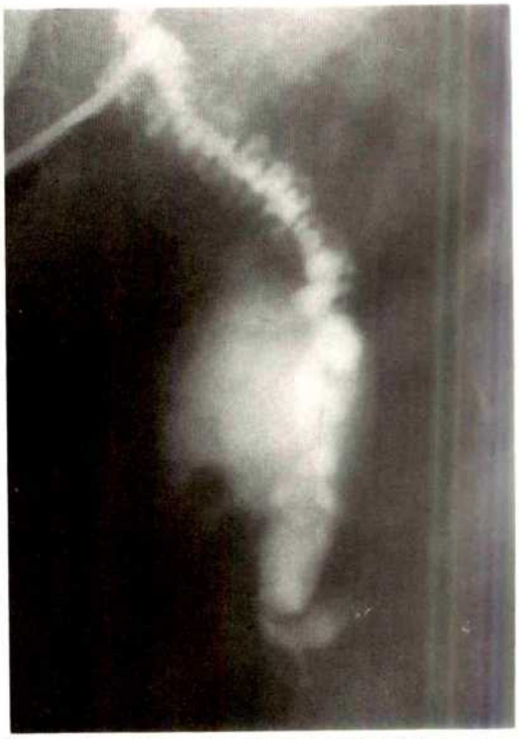

FIG. 2.—Part of *Fig.* 1 (magnified approximately three times), showing the corrugations of the bile-duct.

CASE REPORT

Mrs. L. C., a 59-year-old housewife with 3 children, presented with a 10-year history of dyspepsia which consisted of episodes of pain in the right hypochondrium spreading through to the back and interscapular region. She also complained of upper abdominal distension, flatulence, and fat intolerance. The discomfort did not seem to be related to meals and was not helped by alkalis. At no time had she been jaundiced and she gave no symptoms suggestive of latent jaundice such as a change in colour of her urine or stools. She had experienced no itching and her general health was good. There were no abnormal physical signs.

Single- and double-dose oral cholecystograms showed non-filling of the gall-bladder. An intravenous cholangiogram faintly outlined the common bile-duct which appeared to be normal; the gall-bladder again did not fill. A barium-meal examination and routine liver-function tests were normal.

At laparotomy on 14 Sept., 1970, the only abnormality found involved the biliary tract. The gall-bladder appeared distended and the wall was thickened. The common bile-duct was slightly opaque but was not dilated. During the cholecystectomy the lumen of the cystic duct was found to be obliterated as it entered the gall-bladder. The cystic duct was therefore dissected more centrally and an open lumen was found through which cholangiography was performed. Radiographs were taken after injecting 3, 6, and 9 ml. of contrast medium into the cystic duct. *Figs.* 1 and 2 are photographs of one of these radiographs; the other two radiographs were essentially the same. The walls of the common bile-duct

---

* Present address: Consultant General Surgeon, Worthing Hospital, Sussex.

(excluding the supra-ampullary portion) and the common hepatic duct were corrugated but not dilated. The intrahepatic ducts seemed to be normal. The terminal portion of the common bile-duct was symmetrically rounded and contrast medium entered both the duodenum and the pancreatic duct. As there appeared to be no dilatation of the common bile-duct and as the dye entered the duodenum with ease it was decided not to open the common bile-duct. The gall-bladder was removed in the usual way and was found to contain clear mucus but no stones or biliary gravel.

The histology of the gall-bladder showed changes consistent with chronic cholecystitis with the occasional Rokitansky-Aschoff's sinus. It is now over 2 years since the operation and the patient has had no further symptoms; liver-function tests which have been repeated recently are normal.

DISCUSSION

The films of this patient have been shown to a large number of surgeons, none of whom could recall having seen anything similar. Examination of the literature also failed to reveal any similar picture. This case would therefore appear to be unique.

If one remembers that the outside of the duct appeared normal at operation the corrugation seen on cholangiography can be interpreted in two ways: first, there may be protrusions of the mucosa outwards into the wall of the duct forming intramural diverticula or saccules; secondly, the mucosa may be being pushed into the lumen of the duct by 'tumours' or 'pseudotumours'. With these suggestions in mind the following scheme for the differential diagnosis has been made.

Intramural Diverticula or Saccules.—Solitary diverticula of the biliary ducts are a well-known entity; intrahepatic and periampullary diverticula have been described (Sterling, 1949; Jackson and Maxwell, 1964; Kune, 1965; Maxwell, Jackson, Davis, Eisen, and Poller, 1967) but the most common variety is the choledochal cyst (Alonso-Lej, Rever, and Pessagno, 1959). A few cases of multiple choledochal cysts have been described (Engle and Salmon, 1964; Esguerra-Gomez and Riveros-Gamboa, 1965). These diverticula involve *all* the layers of the duct wall, thus being unlike the case recorded here.

A true *intramural* sacculation of the gall-bladder exists in adenomyomatosis, a disease for which there are many synonyms including cholecystitis glandularis proliferans and multiple Rokitansky-Aschoff's sinuses. According to Jutras, Longtin, and Lekesque (1960) this disease is an acquired condition of multiple intramural pulsion diverticula probably caused by excessive intraluminal pressure in association with mural inflammation. Adenomyomatosis has not been described outside the gall-bladder and this is thought to be due to the fact that the gall-bladder, unlike the other biliary passages, has a thick muscular wall. It should, however, be noted that the wall of the common bile-duct does contain some muscle-fibres (Burden, 1925; Bloom and Fawcett, 1968).

Recently the author was shown a photograph of a post-mortem specimen demonstrating a dilated and sacculated common bile-duct which was obstructed by a carcinoma of the pancreas. That dilatation occurs in this situation is well known but it is usually uniform and the walls of the duct are smooth. In the present case no obvious obstruction or dilatation was present.

Intraluminal 'Tumours' and 'Pseudotumours'.—Hodes (1965) lists the causes of multiple mural filling defects of the gall-bladder under the above title. Although most of these conditions have not been described as occurring in the common bile-duct their existence is theoretically possible. The tumorous conditions include papillomatosis, adenomatosis, and carcinomatosis. The pseudotumorous conditions include cholesterolosis, adenomyomatosis, neuromatosis, elastosis, lipomatosis, fibromatosis, and hyalinocalcinosis. Biliary gravel and multiple parasites may also produce intraluminal filling defects.

A further condition that has been mentioned in the differential diagnosis is primary sclerosing cholangitis. This condition causes a diffuse irregular narrowing of all the extrahepatic biliary tree and sometimes the intrahepatic ducts are likewise affected (Warren, Athanassiades, and Monge, 1966). This disease does not seem to occur without evidence of obstructive jaundice.

The possible causes of the cholangiogram picture obtained in our patient have been outlined but none of them completely fits the clinical picture. The histology of the gall-bladder was unhelpful; it did, however, show chronic inflammatory changes and it seems possible that the common bile-duct was similarly affected.

Acknowledgements.—I would like to thank Mr. O. D. Morris for allowing me to publish this case. I am grateful to Mr. N. M. Matheson who supplied me with the photograph of the post-mortem specimen described in the text.

I am also grateful to the following who were kind enough to comment on this case: Professor A. J. Harding Rains, Professor W. Hess, Professor L. P. Le Quesne, and Professor S. Sherlock.

AN UNUSUAL CASE OF SWALLOWED DENTAL PLATE AND PERFORATION OF THE SIGMOID COLON

BY I. G. M. CLEATOR
LEITH HOSPITAL, EDINBURGH

AND J. CHRISTIE
WESTERN GENERAL HOSPITAL, EDINBURGH

SUMMARY

A case of swallowed dental plate is described in which impaction and perforation occurred in the sigmoid colon. This was treated by resection and end-to-end anastomosis combined with transverse colostomy.

CASE REPORT

A 62-YEAR-OLD woman was admitted to the surgical ward at Leith Hospital on Wednesday, 12 Sept., 1968, having swallowed a portion of her upper dental plate while eating fish and chips. This had occurred on the preceding Saturday and later she had dosed herself liberally with castor oil. At first she had had colicky abdominal pain which had become generalized on the day prior to admission. On examination she was found to have a rigid abdomen with peritonism and was maximally tender in the lower abdomen. An erect radiograph of the abdomen revealed a radio-opaque object in the hypogastrium midway between the umbilicus and the pubic symphysis (*Fig.* 1).

Through a low right paramedian incision exploration of the bowel revealed an indurated inflamed area of sigmoid colon approximately 15 cm. long and perforated in its antimesenteric border by a tooth. There was an abscess cavity in relation to the mesentery of the bowel containing a large quantity of foul-smelling pus. Resection of the affected area with end-to-end anastomosis using interrupted silk sutures was carried out and this was supplemented by transverse colostomy. The abdomen was closed in layers leaving a suprapubic drain down to the anastomotic site.

Early postoperative progress was uncomplicated and 3 months later when barium, instilled into the distal colostomy opening, was seen to pass unimpeded to the anus, closure of the colostomy was planned and undertaken. The patient has since returned to normal bowel habit.

PATHOLOGY SPECIMEN.—Macroscopic examination showed the specimen to consist of 10 cm. of pelvic colon which was indurated and thickened by inflammation. A dental plate was impacted at its lumen and a tooth was seen to have perforated the antimesenteric border (*Fig.* 2). The dental plate had also perforated the bowel adjacent to the attachment of the mesocolon and there was an abscess measuring 2×3 cm. in the mesentery (*Fig.* 3). The dental plate was $2{\cdot}5 \times 3$ cm. in size and bore 3 teeth. There was no evidence of diverticular disease or neoplastic process in the specimen.

Microscopic examination revealed a non-specific inflammatory process of the bowel wall and mesentery and confirmed the presence of an abscess wall.

DISCUSSION

The alimentary canal is remarkably resistant to perforation by foreign bodies and, as Turner (1946) pointed out, even dangerous-looking objects usually make an easy passage once they have safely negotiated the gullet. No part of the gastro-intestinal tract is immune to perforation and Macmanus (1941), in a review of 93 cases, found that it occurred most commonly in the ileocaecal region. Foreign-body perforation of the sigmoid colon is not common and only 10 cases are reported in this region in Macmanus's review. Gaur (1967) has described perforation of the sigmoid colon by a cloth, and Goodhead (1965) has reported obstruction and perforation of the sigmoid colon by a garden cane which were treated by Mikulicz exteriorization.

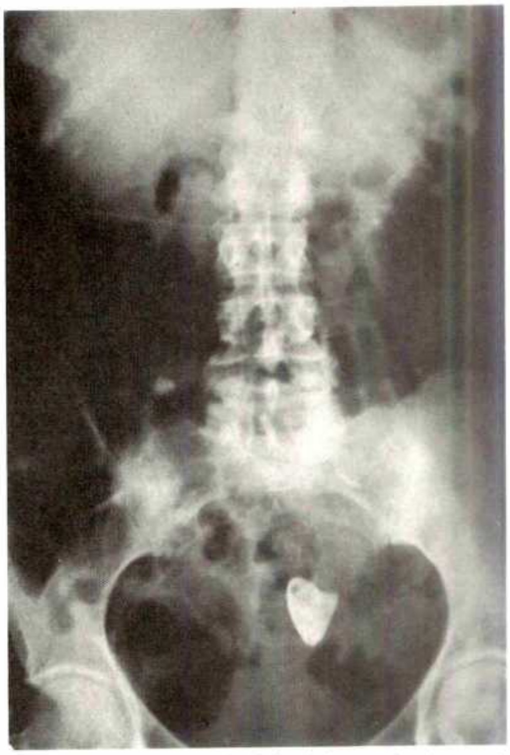

FIG. 1.—An erect radiograph of the abdomen, showing a radio-opaque object in the hypogastrium.

Some cases are recorded in which dental prosthetics have been accidentally swallowed. In the majority of these, impaction occurred in the region of the pharynx or oesophagus. Broken dental plates and partial dentures are more frequently responsible and it is not uncommon for this accident to occur during sleep (Kerr, 1966). Saunsbury (1964) has emphasized that there is a need for modified dental acrylic with greater radio-opacity than is provided by the one such material on the market at present. Barium sulphate is added in the manufacture of acrylic but this has the disadvantage that the acrylic becomes more brittle and less translucent. Metal wires often give precise radiological localization of dental apparatus, and porcelain incorporated in the manufactured teeth can be helpful as this substance shows up well on a radiograph. It was fortunate that in the case which we have described the dental plate was easily identifiable on a straight radiograph owing to its high content of barium sulphate.

It is strange that in the present case the plate passed uneventfully through the oesophagus, the duodenum, and the ileocaecal valve only to become

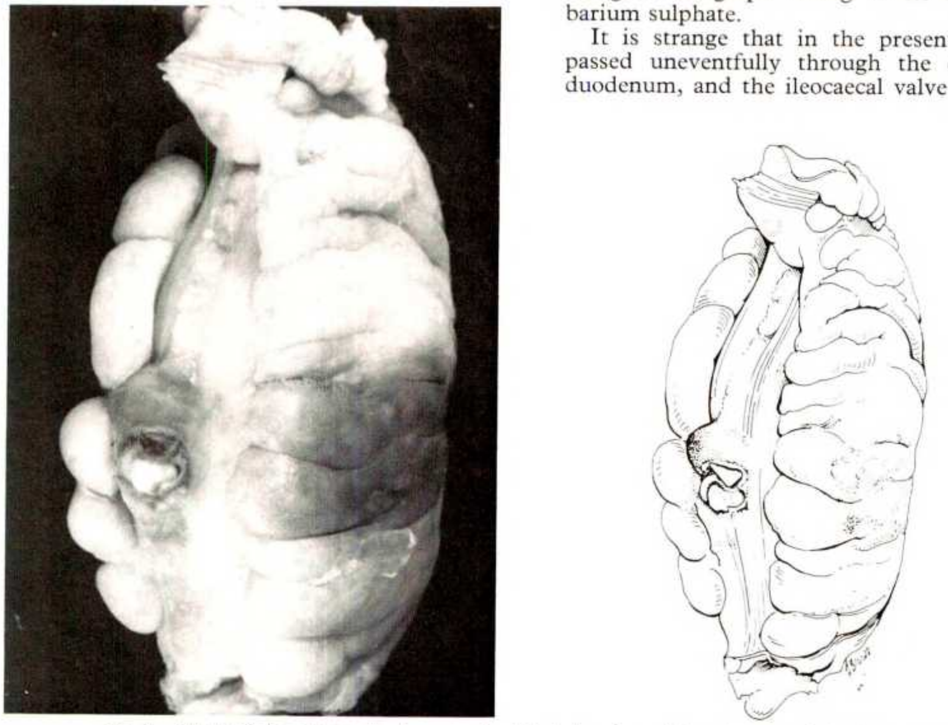

FIG. 2.—Pathological specimen, showing a tooth which had perforated the antimesenteric border of the colon.

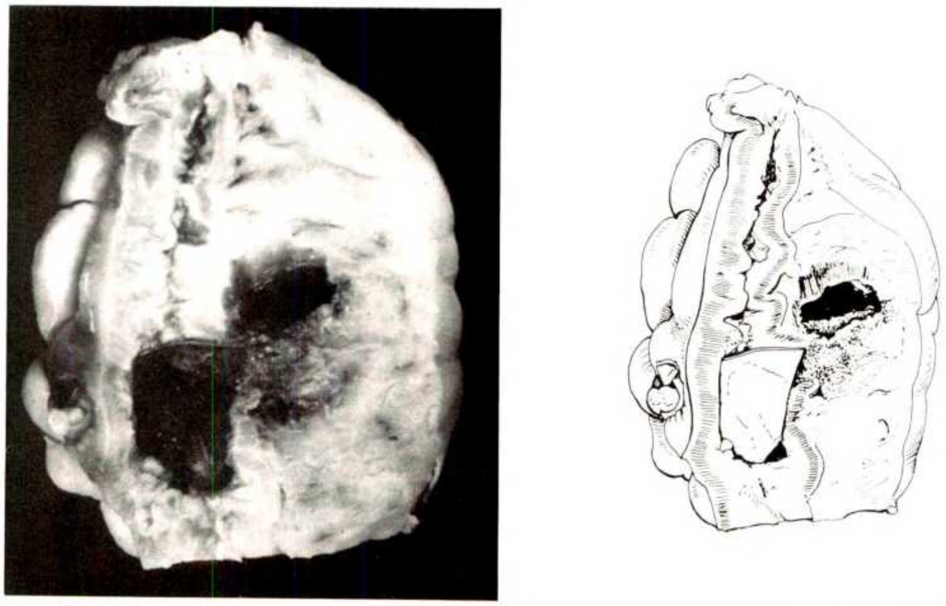

FIG. 3.—Pathological specimen, showing the dental plate which had perforated the bowel adjacent to the attachment of the mesocolon, and also an abscess in the mesentery.

impacted in the sigmoid colon. The resected portion of bowel was carefully examined for evidence of pre-existing disease that might have caused the hold-up, but apart from the extensive damage already noted it appeared to be normal. It may be that the liberal doses of castor oil that the patient had used to assist the passage of the foreign body had caused irritability and spasm of the sigmoid colon and this might account for the situation of impaction.

The particular form of operation used has recently been discussed by Painter (1968) in his paper on perforation of the large bowel due to diverticulitis and this seemed particularly well suited to a situation in which the colon had been extensively damaged by a foreign body. A transverse colostomy was effected to protect the anastomotic site from the passage of faeces, although Painter suggests in his article that such a procedure may be unnecessary in similar cases of resection for perforation of diverticulitis.

Acknowledgement.—We would like to thank the late Mr. A. F. M. Barron for his permission to publish the case.

REVIEWS AND NOTICES OF BOOKS

The Alcoholic Patient in Surgery. By ALBERT B. LOWENFELS, M.D., New York. 9 × 6 in. Pp. 268 + xii. Illustrated. 1971. Edinburgh: Churchill Livingstone. £6.

IN this well-produced volume the author has tried to review alcoholism in all its aspects—sociological, pharmacological, and pathological. There is an excellent chapter on the pathophysiology of alcohol-induced pancreatitis but in general if the book is really intended as a practical aid to the surgeon too much has been attempted. As a book of reference there is much useful and interesting background reading, but detailed guidance is lacking where it is needed most.

The cautionary instructions in the management of the drunkard with a head injury are welcome and this section should be compulsory reading for all casualty surgeons. The role of solitary or sequential blood-alcohol estimates in this context is not discussed.

Considering the price this book will be a more useful addition to a hospital library than to a personal collection.

Preoperative and Postoperative Care in Neurological Surgery. By BURTON L. WISE, B.A., M.D., F.A.C.S., San Francisco. 9¼ × 6 in. Pp. 128 + xi. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $8.75.

THIS book sets out to provide in an easily readable form sound and practical advice concerning pre- and post-operative management of the neurosurgical patient. It succeeds in this and will be of value to the young doctor entering this speciality.

General topics common to most branches of surgery are discussed, while clear explanations and recommendations are made regarding problems peculiar to neurosurgery, e.g., raised intracranial pressure and internal cerebral herniation.

Professor Wise's particular interest in the metabolic, endocrine, and fluid-balance disturbances encountered in neurosurgery is very evident throughout the three sections into which the book is divided. Section III, comprising about half the text, is exclusively devoted to these aspects.

Some parts of the first two sections on pre- and post-operative management (subdivided into general and neurosurgical) are perhaps a little tenuous in their detail. Bearing in mind the wide variations in established clinical practice this is excusable and is fully compensated for by an extremely comprehensive and useful bibliography appended to each section.

A short but salutary paragraph entitled 'Informed Consent' (to operation in the U.S.A.) in Section I gives one cause to ponder. It emphasizes the need for careful explanation to the patient (and/or his relatives) of the objectives and possible outcome and complications of neurosurgical procedures which may appear to be so straightforward to the uninitiated.

Der Notfall: Gastrointestinalblutung. Edited by HANS-JOACHIM STREICHER and JOACHIM ROLLE, Wuppertal-Elberfeld. 9 × 6 in. Pp. 170 + viii. Illustrated. 1972. Stuttgart: Georg Thieme Verlag. DM.34.

THIS book gives an account of a symposium held at Wuppertal-Elberfeld in March, 1970, at which German surgeons discussed the problems of gastro-intestinal bleeding. The topics covered first aid, resuscitation and transport, diagnostic methods, the causes and pathology of bleeding, and specialized problems such as bleeding in children.

Much of the discussion reflects interesting differences in attitudes in different parts of Germany, and British readers will note differences between German and British experience. There is a lack of controlled clinical trials but the new operation of proximal gastric vagotomy has been routinely performed in Munich for bleeding duodenal ulcer since 1964. The operation is accompanied by pyloroplasty and carries a mortality rate of only 5 per cent.

The Germans have had much more experience of bleeding oesophageal varices than most British surgeons, since every second case of bleeding is reported to be due to oesophageal varices by one author. The favoured operation is an emergency portacaval shunt and there is much discussion about the most effective management.

Human Embryology. Prenatal Development of Form and Function. Fourth edition. By W. J. Hamilton, M.D., D.Sc., F.R.C.S., F.R.C.O.G., F.R.S.E., London, and H. W. Mossman, M.S., Ph.D., Wisconsin. Pp. 646+xii. 1972. Baltimore: Williams & Wilkins Co. £10·50.

Since the termination of the Second World War Hamilton, Boyd, and Mossman's *Human Embryology* has been the standard work throughout the world.

This important work was first published in 1945 and was reprinted seven times in the following 20 years; now the fourth edition makes its appearance under the editorship of Professor Hamilton and Professor Mossman, Professor Boyd having died in 1968. There can be no doubt whatever that the new fourth edition is by far the best that has so far been published. The authors have made this book invaluable, not only to embryologists and anatomists but also to a vast number of surgeons practising plastic surgery, neonatal surgery, urological surgery, ophthalmic surgery, or ear, nose, and throat surgery as their specialty.

The authors have succeeded in dealing with the functional aspects of different organs during development.

An excellent additional chapter has been incorporated in this edition on the development, structure, and functional activities of the placenta. We are full of praise for this extensive work which deals with implantation, determination, differentiation, the organizer mechanism, abnormal development, and twinning.

Quite a feature of this large volume is the excellence of the numerous illustrations. The coloured drawings by A. K. Maxwell are superb. The illustrations of the development of the skeletal system will delight orthopaedic surgeons both at home and abroad.

An excellent production and a great credit to British and American scientific achievement.

Bioceramics—Engineering in Medicine. Edited by C. W. Hall, S. F. Hulbert, S. N. Levine, and F. A. Young, Texas. 9×6 in. Pp. 484+xi. Illustrated. 1972. London: John Wiley & Sons Ltd. £7 10.

This book records the proceedings of a symposium held in New Hampshire in 1970. It contains a wealth of information on implantable devices, and the physiological and pathological problems of prostheses are discussed in some detail. Dental, maxillofacial, and orthopaedic applications gain most consideration, but dissertations on tracheal prostheses and the maintenance of chronic percutaneous electronic leads as well as a discussion of reabsorbable implants are examples of the wide range of topics which are dealt with. The cost is prohibitive except for reference libraries and the specialist reader, for whom some record of the discussion would have been valuable.

Gastrin: Inaktivierung und Abbau. By Hans Peter Seelig, Heidelberg. 9¼×6¼ in. Pp. 110+viii, with 57 illustrations. 1972. Stuttgart: Georg Thieme Verlag. DM.39.

In this monograph the author deals with many aspects of the current knowledge of the antral hormone, gastrin. His personal research provides a large part of the data and attempts to elucidate the fate of gastrin in the body. *In vitro* experiments include work with liver, kidney, gastric antral mucosa, and skeletal muscle homogenates from rats. Human blood-serum has also been studied and all the preparations of this were shown to inactivate gastrin II which the author had purified from hog antra. In high-speed supernatants of kidney and liver homogenates two enzyme systems were found: a specific one (*p*H optimum 6·4) and an apparently non-specific one (*p*H optimum 8·2). Both these enzyme systems inactivated gastrin by deamidation of the C-terminus; sequential hydrolysis of the peptide then occurred.

The author then elaborates his reasons for believing that the liver is a major site of activation of gastrin *in vivo*, which is an interesting view and is not generally held in this country.

Lessons in Surgical Terminology for the Medical Transcriber. By Anne Hadley. 11×8½ in. Pp. 74+ix. 1972. Oxford: Blackwell Scientific Publications. £3·40.

There are far too few medical transcribers both in this country and in America and therefore this book has been published at an opportune time. The various medical vocabularies which are in everyday use are set out in 45 lessons for the 'would-be' medical transcriber.

The use of this book, together with one of the modern medical dictionaries, will greatly aid transcribers of medical lectures, discussions, and debates.

Conference on Shock. Edited by I. McA. Ledingham, M.B., Ch.B. (Glas.), and T. A. McAllister, M.B., Ch.B. (Glas.), Glasgow. 9¼×7 in. Pp. 193+ix. Illustrated. 1972. London: Henry Kimpton. £7.

As our capacity to record and quantify bodily responses becomes greater so it becomes more and more difficult to define the concept of 'shock', and one is tempted to wonder whether, in fact, the term has outlived its usefulness and should quietly disappear. It remains true, however, that patients with very severe acute illness, whatever the cause, have certain patterns of organ failure and system failure in common which demand similar responses on the part of their doctors. With this in mind, the Royal College of Physicians and Surgeons of Glasgow arranged a 2-day symposium on shock in October, 1970, to which experts contributed articles on subjects as diverse as cerebral blood-flow, the sequential assay of whole-blood histamine, crushed-chest syndrome, domiciliary management of myocardial infarction, and bacteriaemia. It is just possible that this is the last such symposium that will ever appear and it can certainly stand comparison with its predecessors. The individual articles are by and large excellent though the book as a whole suffers from a certain vagueness of aim as it is a combination of didactic reviews, personal accounts of research in progress, and speculative hypotheses. Dr. Sykes's article on the factors bringing about tissue hypoxia is an excellent example of the first type and unravels this complicated subject with masterful clarity. The chapters dealing with autoregulation in the renal circulation by Dr. Bell and the sequential assay of plasma catecholamines in early septic shock by John Griffiths are interesting accounts of experimental research, which perhaps should have (and indeed probably already have) been published in specialized journals. By contrast, A. M. Harper's account of the changes occurring in cerebral blood-flow during acute illness appears rather speculative, although it refers to personal work published elsewhere.

There is much more in the book which is individually excellent, and the conference was clearly a success and was enjoyed by its participants. Whether, in fact, this type of reportage is the best means of keeping the clinician abreast of applied physiology nowadays is more doubtful. Owing to the high price this symposium may sell less well than it deserves.

The History of Urology. By LEONARD J. T. MURPHY, M.S., F.R.A.C.S., F.A.C.S., Melbourne. 10 × 7 in. Pp. 531 + xiii. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $32.50.

UROLOGY, oldest of the surgical specialities, badly lacked a good history. There was Desnos's introductory chapter for the *Encyclopédie française d'Urologie* of 1914, and Bransford Lewis's 'History' written for the American Urological Association in 1933, but the one necessitated a long, dusty search and a struggle with the French, and the other, though amusing, nearly always gave the wrong references. Now Mr. Murphy, a practising urologist, has given us a sensible translation of Desnos with the dull bits left out and has added his own lucid contributions to bring the history up to date. The result is elegant and entertaining, full of illustrations, and backed with complete references. It unfolds the story of urology from the earliest days when surgery was urology and little besides, to the last century when the cystoscope and the Roentgen ray made urology the most precise and most accurate of surgical specialities.

Murphy recalls the brilliant heritage of Sylvius, Vesalius, Fallopius, and Eustachius and traces the story through Frère Jacques, Ambroise Paré, Cheselden, Guthrie, Hunter, Lister, and Bigelow. The roll is long and honourable, and even the great William Harvey did not shrink from operating on the testicle. We read again the sorry story of the squabble for recognition of priority in open prostatectomy—Murphy rightly gives credit to Moynihan's ex-house surgeon, McGill of Leeds; we learn of the rise and fall of that non-disease, the floating kidney, which now, alas, has passed the way of tongue-tie and chlorosis. We are told how glow-worms were used to illuminate the bladder and how bougies were generally passed on the upright patient (at St. Peter's they backed them up against a wall). Even that marvellous spoof, the biography of Coudé, is not forgotten.

This book will entertain and fascinate any surgeon, for it is not the story of a minor branch of surgery but of the main trunk, and still the most vigorous shoot, of a grand old tree.

Zahnerhaltungskunde. By ERNST SAUERWEIN, Bonn. 7½ × 4½ in. Pp. 278 + xi, with 76 illustrations. 1972. Stuttgart: Georg Thieme Verlag. DM.12.80.

THIS pocket book on conservative dentistry is mainly aimed at students and practising dentists. The many aspects of conservative dentistry, whether by medical or surgical treatment, are described. The book is well illustrated by line diagrams but the abbreviated text is difficult to read. A good knowledge of German is essential to follow this book but it may be of value to selected dental students.

Renal Transplantation. Theory and Practice. By JEAN HAMBURGER, M.D., JEAN CROSNIER, M.D., JEAN DORMONT, M.D., and JEAN-FRANÇOIS BACH, M.D., Paris. 9 × 6 in. Pp. 326 + xx. Illustrated. 1972. Edinburgh: Churchill Livingstone. £7.

THIS book on renal transplantation by one of the most experienced groups in the world is to be welcomed by all who are interested in the subject. Its presentation is scholarly with an excellent background of the biology of rejection of grafted tissues and a discussion of experimental and theoretical aspects of immunosuppression. Professor Hamburger and his colleagues have worked on both experimental and clinical aspects of transplantation since the early 1950's and one of the first successful non-identical twin transplants was performed by them in 1959. This patient received a kidney from his dizygotic twin, was treated with total body irradiation, and is still alive and well.

As the authors point out, most of the other experience with this method of immunosuppression has been disappointing, and the suggestion by Schwartz and Dameshek in 1959 that the anti-leukaemia drug, 6-mercaptopurine, appeared to make rabbits specifically tolerant to foreign protein and incapable of producing antibodies against that protein led to the use of this and related drugs in animals with kidney grafts. This work was perfomed initially in the United Kingdom and not in Dr. Merrill's laboratory in Boston as stated in the Preface.

The chapters on clinical kidney transplantation, assessment of patients, complications, and results are excellent. The moral and legal aspects are summarized very clearly. I have only one criticism of this book and that is that the main authors do not include a surgeon and since organ transplantation is primarily a surgical subject it is a little unkind to banish the surgeons and the surgery of transplantation to an appendix. The book can, nevertheless, be thoroughly recommended as an up-to-date text on all aspects of renal transplantation. The English translation by Mr. Anthony Walsh is excellent.

Nouveau Traité de Technique Chirurgicale, Volume 4. Edited by JEAN PATEL and LUCIEN LÉGER, Paris. 10 × 7¼ in. Pp. 508, with 476 illustrations. 1972. Paris: Masson & Cie Éditeurs. 390F.

VOLUME 4 of this massive 15-volume treatise on surgical technique deals with cardiac and breast surgery.

The section on cardiac surgery is based essentially on the experience of the cardiovascular surgical centre of the Broussais Hospital in Paris directed successively by F. d'Allaines and C. Dubost. This experience includes over 11,000 cardiac operations of which over 5000 were done by the open-heart technique. The first part of this section deals with general principles of cardiac surgery with special attention to pre- and postoperative management and includes an excellent account of the different approaches to the heart and the great vessels. All the congenital and acquired cardiac lesions are then dealt with, very full technical details and alternative techniques being given. The text is well illustrated by very clear and helpful drawings and each chapter includes many references from the world literature. There follow equally good sections on the coronary arteries, the pericardium, and the great vessels of the chest, with special emphasis on the aorta. A well-balanced chapter on cardiac transplantation and its technique is included in this section. The only criticism which could be levelled at this beautifully produced work is that the volume could have been made smaller by less discussion of the results in what sets out to be an account of surgical techniques.

Unfortunately the second section dealing with surgery of the breast is not of the same quality as the first section and one gets the impression that it was only added as an afterthought and that the authors were given strict instructions about limitation of space available. On the whole the text in this section is very sketchy and several of the illustrations are either unclear or unhelpful. Nevertheless, there is a good description of the cosmetic yet effective approaches for drainage of breast abscesses and excision of benign lesions of the breast, including exploration of the main ducts. The pages dealing with radical mastectomy based on the Halsted operation are badly set out with respect to the relevant illustrations and the authors describe an incision encircling the breast with a transverse extension across the axilla which looks difficult to close and probably results in swelling of the arm postoperatively. Simple mastectomy is dealt with very sketchily and the accompanying photographs are useless. A short account is given of 'conservative' radical mastectomy and there are brief accounts of extended radical mastectomies including, rather surprisingly, interscapulothoracic amputation which must be very rarely carried out nowadays. The Editors' deliberate policy is to include paediatric surgery and plastic surgery under the relevant systems, and this results in a chapter on several operations for plastic reconstruction of the breast which are well illustrated but not critically analysed. This whole section on breast surgery contains no references at all.

The essential and best part of this volume is that dealing with surgery of the heart and great vessels. This in itself makes it an excellent reference work which includes a wealth of information justifying its price of £32.

Gastroenterology: An Integrated Course. Edited by IAIN E. GILLESPIE, M.D., F.R.C.S., Manchester, and T. J. THOMSON, M.B., Ch.B., F.R.C.P., Glasgow. $8\frac{1}{2} \times 5\frac{1}{2}$ in. Pp. 270+ix. Illustrated. 1972. Edinburgh: Churchill Livingstone. £1·50.

THIS book comes as a very welcome companion in a rapidly expanding field of medicine and surgery. It provides the postgraduate with a rapid synopsis of current advances, and the interested undergraduate with an entrée into a specialized field.

One outstanding advantage of this book is that it deals with the medical and surgical aspects of gastro-enterology concurrently, evaluates the different forms of treatment, and helps both the surgeon and the physician to see the other's point of view.

It is written in an interesting and attractive form, and at its current price will enjoy considerable popularity.

Nouveau Traité de Technique Chirurgicale, Volume 6. Edited by JEAN PATEL and LUCIEN LEGER, Paris. $9\frac{3}{4} \times 7\frac{1}{4}$ in. Pp. 1223. Illustrated. 1972. Paris: Masson et Cie Editeurs. 390F.

THIS volume is one of a multi-volume textbook of operative surgery of which five volumes have previously been published.

This excellent work on head and neck surgery is up to the high standard of the others with beautifully clear line drawings illustrating the minutiae of surgical technique and a clear concise text which is easily followed without any deep knowledge of French explaining the indications for operation, the possible complications, and the post-operative care. Each chapter is preceded by a short description of the surgical anatomy involved.

For a textbook on head and neck surgery this volume covers many surgical disciplines. For example, there are aspects of surgery which would normally be considered the province of the ear, nose, and throat surgeon. There is a chapter on the vascular lesions affecting the major vessels of the neck. The surgery of the vocal cords and of the thyroid is covered as well as the surgery of the tongue and larynx. There is also a section which is devoted to plastic surgery as it affects the head and neck with reference to such general problems as scalp injuries and the excision of rodent ulcers, and also rhinoplasty and face-lifting, together with plastic surgery of the eyelids.

Such diversity makes this volume essentially a book of reference. It is not likely that any surgeon would wish to buy this volume as his individual interest would only be catered for in a relatively small part of the book.

Osteosynthese Praxis. By F. SCHAUWECKER, Tübingen. $9\frac{1}{2} \times 7$ in. Pp. 236+viii, with 517 illustrations. 1972. Stuttgart: Georg Thieme Verlag. DM.98.

THIS is an atlas of internal fixation of fractures by screws, plates, wires, and intramedullary nails. The 236-page book has no less than 517 illustrations which are excellent black-and-white line drawings. The text is limited to a description of the diagrams but at the same time stresses the important technical points in any particular method of internal fixation. The line diagrams are so clear and self-explanatory that a knowledge of German is not essential. In spite of its high cost it should be of considerable interest to orthopaedic surgeons involved in the surgery of trauma.

The Scientific Basis of Medicine. Annual Reviews 1972. Edited by IAN GILLILAND, M.D., F.R.C.P., and JILL FRANCIS. $8\frac{1}{2} \times 5\frac{1}{2}$ in. Pp. 400+ix. Illustrated. 1972. London: The Athlone Press. £4.

IN this volume the British Postgraduate Medical Federation has once again published a selection from the series of lectures on the scientific basis of medicine delivered in the winter of 1970–1. The 19 lectures, all by experts in their fields, cover a wide range of topics illustrating the diversity of modern clinical science. Although many of the subjects covered are outside the range of ordinary surgical practice the book constitutes a fascinating review of the scope of present-day medical research, and all surgeons should find something to stimulate and fascinate them in the variety of subjects discussed. Of particular interest to surgeons are the lectures on transplantation immunology and the haemostatic functions of platelets. The opening lecture, 'Clinical Research: Its Contribution to Biological Thought' by Sir Harold Himsworth is, as would be expected, a masterly dissertation which cannot fail to be of interest to all concerned in this field of activity. The Postgraduate Medical Federation is to be congratulated on an admirable publication, which well merits a place in all medical libraries.

Aktuelle Orthopädie. By P. HINZ, Heidelberg, and R. PLAUE, Heidelberg. $9\frac{1}{2} \times 6\frac{1}{2}$ in. Pp. 60. Illustrated. 1972. Stuttgart: Georg Thieme Verlag. DM.39.80.

THIS is a monograph about club-hand deformity associated with aplasia of the radius. The writer reviews over 100 patients with this deformity most of whom were thalidomide victims. The mechanical problems are presented and the many different types of surgical treatment that have been used are discussed.

This book provides an extensive list of references on this highly specialized subject and, in spite of its relatively high price, should be of great interest to orthopaedic surgeons involved in treating patients with this deformity.

IN BRONCHITIS early optimism confirmed by further clinical experience

❝ On the basis of our earlier experience,[1] we said of trimethoprim that 'we believe it to represent a major discovery and to have far-reaching therapeutic possibilities.' Not only have we had no subsequent reason to alter this belief, but in our view some very promising possibilities have yet to be explored.❞[2]

More effective than ampicillin or tetracycline

In the reduction obtained in sputum volume and purulence SEPTRIN* has been shown to be superior to either ampicillin or tetracycline.[3,4]

Highly active against both primary and secondary invaders

"... not only are the two primary pathogens *Strep pneumoniae* and *H influenzae* sensitive, but so are secondary invaders such as klebsiella which often replace them after antibiotic treatment."[2]

"It is seldom at the completion of a clinical trial that authors are inclined to classify an antimicrobial ..., but in this case, on our results, we feel that the combination of trimethoprim plus sulphamethoxazole can only be considered excellent on the criteria originally specified, namely the elimination of the infecting microorganism."[5]

The Principles of Transurethral Resection and Haemostasis

By J. P. Mitchell, T.D., M.S., F.R.C.S., F.R.C.S.E., *Lecturer in Urology, University of Bristol; Consultant Urological Surgeon, United Bristol Hospitals; Consultant Urologist, Southmead General Hospital.*

This book is based on an essay for which the author was awarded the *Jacksonian Prize*, the oldest and most cherished prize of the Royal College of Surgeons of England.

Transurethral resection is essentially a practical subject in surgery, involving the basic principles of surgical technique, with success depending largely on clinical acumen in diagnosis. Not only urologists and trainee urologists but all surgeons can learn much from this book.

AN INTRODUCTION TO THE
GENERAL
PATHOLOGY
OF
TUMOURS

David J.B. Ashley

By D. J. B. Ashley, T.D., M.D., F.R.C.P.PATH., *Consultant Pathologist, Morriston Hospital, Swansea.*

This book is offered as a contribution to the application of general medical and scientific principles to the understanding of neoplastic disease in the human. It is directed to the clinician, both undergraduate and postgraduate, who is concerned with the care and management of patients suffering from neoplastic disease and who wants a résumé of current knowledge in this field.

120 pages 16 illustrations Paper Covers **£2·00**

ABO Haemolytic Disease of the Newborn

By E. R. Gold, M.D., *Research Fellow, Department of Child Health, University of Bristol*; and N. R. Butler, M.D., F.R.C.P., D.C.H., *Professor of Child Health, University of Bristol.*

This monograph studies in detail ABO haemolytic disease of the newborn, and will be of interest to blood-group serologists, obstetricians, and paediatricians.

216 pages 11 illustrations **£4·00**

6 NEW BOOKS THAT BELONG IN YOUR SURGICAL LIBRARY

MEASURING THE EFFECTIVENESS OF MEDICAL DECISIONS: An Operations Research Approach *by* **Shlomo Barnoon,** *American Society of Internal Medicine, San Francisco, Calif., and* **Harvey Wolfe,** *Univ. of Pittsburgh, Pa.* Needs for measures of effectiveness are discussed. Emphasis is placed upon decisions relating to treatment. Risk associated with the effectiveness of a particular treatment is quantified. Utility theory is used to develop measures of disability and life expectancy. Models are introduced to integrate these measures into decision processes. The measures derived provide a basis for sequential diagnosis and treatment cases. *'72, 248 pp., 20 il., 35 tables,* $*28.00*

ANGIOGRAPHY OF TRAUMA *by* **Whei-Rung Fu,** *Georgetown Univ. School of Medicine, Washington, D.C.* Written for radiologists and those interested in trauma, particularly with multiple trauma. Discusses indications and contraindications for angiography. The technique of angiography is shown to be an integral part of evaluating patients with trauma. A comprehensive chapter on the traumatic rupture of the thoracic great vessels precedes chapters covering areas such as splenic, hepatic, renal, and abdominal trauma. Peripheral vascular injury is concentrated upon. *'72, 116 pp., 76 il.,* $*11.75*

INTERNATIONAL SYMPOSIUM ON MALIGNANT HYPERTHERMIA *edited by* **R. A. Gordon, Beverley A. Britt** *and* **Werner Kalow,** *all of the Univ. of Toronto, Canada. (66 Contributors.)* Presents discussions of the clinical recognition and management of this syndrome, the recognized hereditary and genetic basis of the trait, and reports basic investigations of the mechanisms involved in this syndrome derived from studies of human patients and strains of swine. Elucidation of these basic mechanisms is essential to the recognition and treatment of this disorder, and to the recognition of patients at risk. The contributors all helped in the development of the current knowledge of malignant hyperthermia. *'72, 512 pp., 131 il., 55 tables,* $*22.50*

THE MEDICAL TRANSCRIPTIONIST HANDBOOK *by* **Charles T. McConnico,** *Veterans Administration Hospital, Oklahoma City, Okla. Forewords by* **Margaret C. Cevely** *and* **R. LeRoy Carpenter.** Designed as a self-teaching instrument to enable the student to assume a position as an accurate, productive medical transcriptionist in the shortest possible time. Proper study will provide skills to spell and understand medical words, the content of medical reports, ability to evaluate and understand the meaning of unfamiliar medical terminology by analysis of their elements, the relationship between medical synonyms, and become familiar with surgical instruments and procedures. *'72, 256 pp.,* $*8.75*

NEUROSURGICAL SYNDROMES OF THE BRAIN *by* **Charles W. Needham,** *UCLA School of Medicine, Los Angeles, Calif.* The positive findings of diagnostic tests are itemized to facilitate rapid recognition and early diagnosis of all intracranial lesions amenable to modern neurosurgical therapy. Syndrome analysis is utilized by a development-deficit-deformity technique. A diagnostic template is designed to assist in the correlation of neurological, angiographic, and pneumographic signs. Regional and generalized syndromes are described in detail, along with satellite syndromes, and craniocerebral traumatic syndromes. *'72, 452 pp. (6¾ × 9¾), 104 il.,* $*27.50*

THE HOSPITAL EMERGENCY DEPARTMENT *by* **James H. Spencer,** *Morristown Memorial Hospital, New Jersey. Foreword by* **Robert H. Kennedy.** *(6 Contributors.)* Discusses all aspects of hospital emergency departments. A guide for all concerned with planning, building, equipping, staffing and administering the emergency department in general hospitals. The physical layout, planning, needed equipment and supplies, staffing of the department, cooperation between emergency department staff and other hospital personnel, record-keeping, economic aspects, public relations, and other important topics are thoroughly discussed. *'72, 388 pp., 50 il., 3 tables,* $*18.75*

INJURY

Volume 4/Number 3

The British Journal of Accident Surgery

INJURY provides a focal point of information for all those engaged in the many fields of medicine which accident surgery involves—casualty officers, surgeons concerned with all parts and systems of the body, specialists in orthopaedic and plastic surgery, anaesthetists, nursing staff in accident units, etc. Original articles take up a large section of the journal, and contributions from all over the world are published. Book reviews, abstracts from other publications, and summaries and reports of meetings add to the wide and well-organized coverage which INJURY offers its readers.

Contents

W. H. Rutherford 189 Experience in Accident and Emergency Department, with Royal Victoria Hospital patients from civil disturbances in Belfast 1969–1972, with a review of disasters in the United Kingdom 1951–1971
S. Nade and P. R. W. Monahan 200 Fractures of the calcaneum—a study of the long-term prognosis
P. A. M. Weston 208 First line medical care for the injured
K. Solheim 213 Tibial fractures according to the A.O. method
A. Cargill, C. S. B. Galasko, and A. J. Gunning 221 Pneumopericardium following closed chest injury: a report of two cases
V. Kumar 225 Traumatic pneumopericardium
R. G. Pringle 226 Self-inflicted rotation osteotomy of the tibia
G. D. Lister and I. A. McGregor 229 The groin flap in hand injuries
P. A. Stone 240 Hand burns caused by electric fires—a clinical and surgical review of 90 cases
B. J. S. Grogono 247 Auger injuries
K. F. Rodrigues 258 Traumatic injury of the acetabular epiphysis
D. Davies 261 Patterns in traumatic rupture of the bronchus
P. S. Rasmussen and S. S. Sorensen 265 Tibial condylar fractures

Quarterly *Single copies* £1·85 *Annual subscription* £6·50

UBRETID®

distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.

Full details of **UBRETID** ampoules and tablets are available upon request.

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·83	£3·70	£4·27	£5·70	£5·69	£6·32	£7·74	£8·99
4	3·58	5·19	6·09	7·12	8·07	9·09	10·97	12·97

10/12	9·32	12·72	15·09	17·72	20·34	22·97	28·40	33·05
14/16	10·37	14·34	17·47	20·59	23·72	27·03	33·18	39·55
18/20	14·62	19·47	23·47	27·47	31·78	35·93	44·05	50·89
COVERS	1·94	2·75	3·57	4·38	5·19	6·00	7·63	9·25

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 59. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St Martin's House, 159 Clapham High Street, London, SW4 7SU* (telephone 01-622 9225).

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

IN BRONCHITIS early optimism confirmed by further clinical experience

> “On the basis of our earlier experience,[1] we said of trimethoprim that ‘we believe it to represent a major discovery and to have far-reaching therapeutic possibilities.’ Not only have we had no subsequent reason to alter this belief, but in our view some very promising possibilities have yet to be explored.”[2]

More effective than ampicillin or tetracycline

In the reduction obtained in sputum volume and purulence SEPTRIN* has been shown to be superior to either ampicillin or tetracycline.[3,4]

Highly active against both primary and secondary invaders

"... not only are the two primary pathogens *Strep pneumoniae* and *H influenzae* sensitive, but so are secondary invaders such as klebsiella which often replace them after antibiotic treatment."[2]

"It is seldom at the completion of a clinical trial that authors are inclined to classify an antimicrobial ..., but in this case, on our results, we feel that the combination of trimethoprim plus sulphamethoxazole can only be considered excellent on the criteria originally specified, namely the elimination of the infecting microorganism."[5]

First in Bronchitis

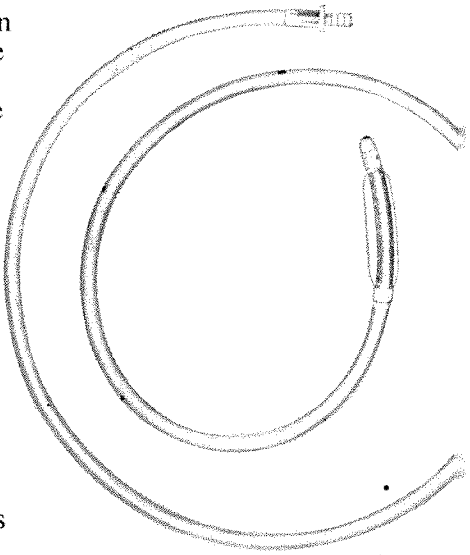
double blockade of bacterial metabolism means resistance is unlikely to develop

Our research is done in close consultation with the medical profession, and as a result we have devised equipment and test procedures where none previously existed. One such is the Portex Flex Test for Intravenous cannulae.

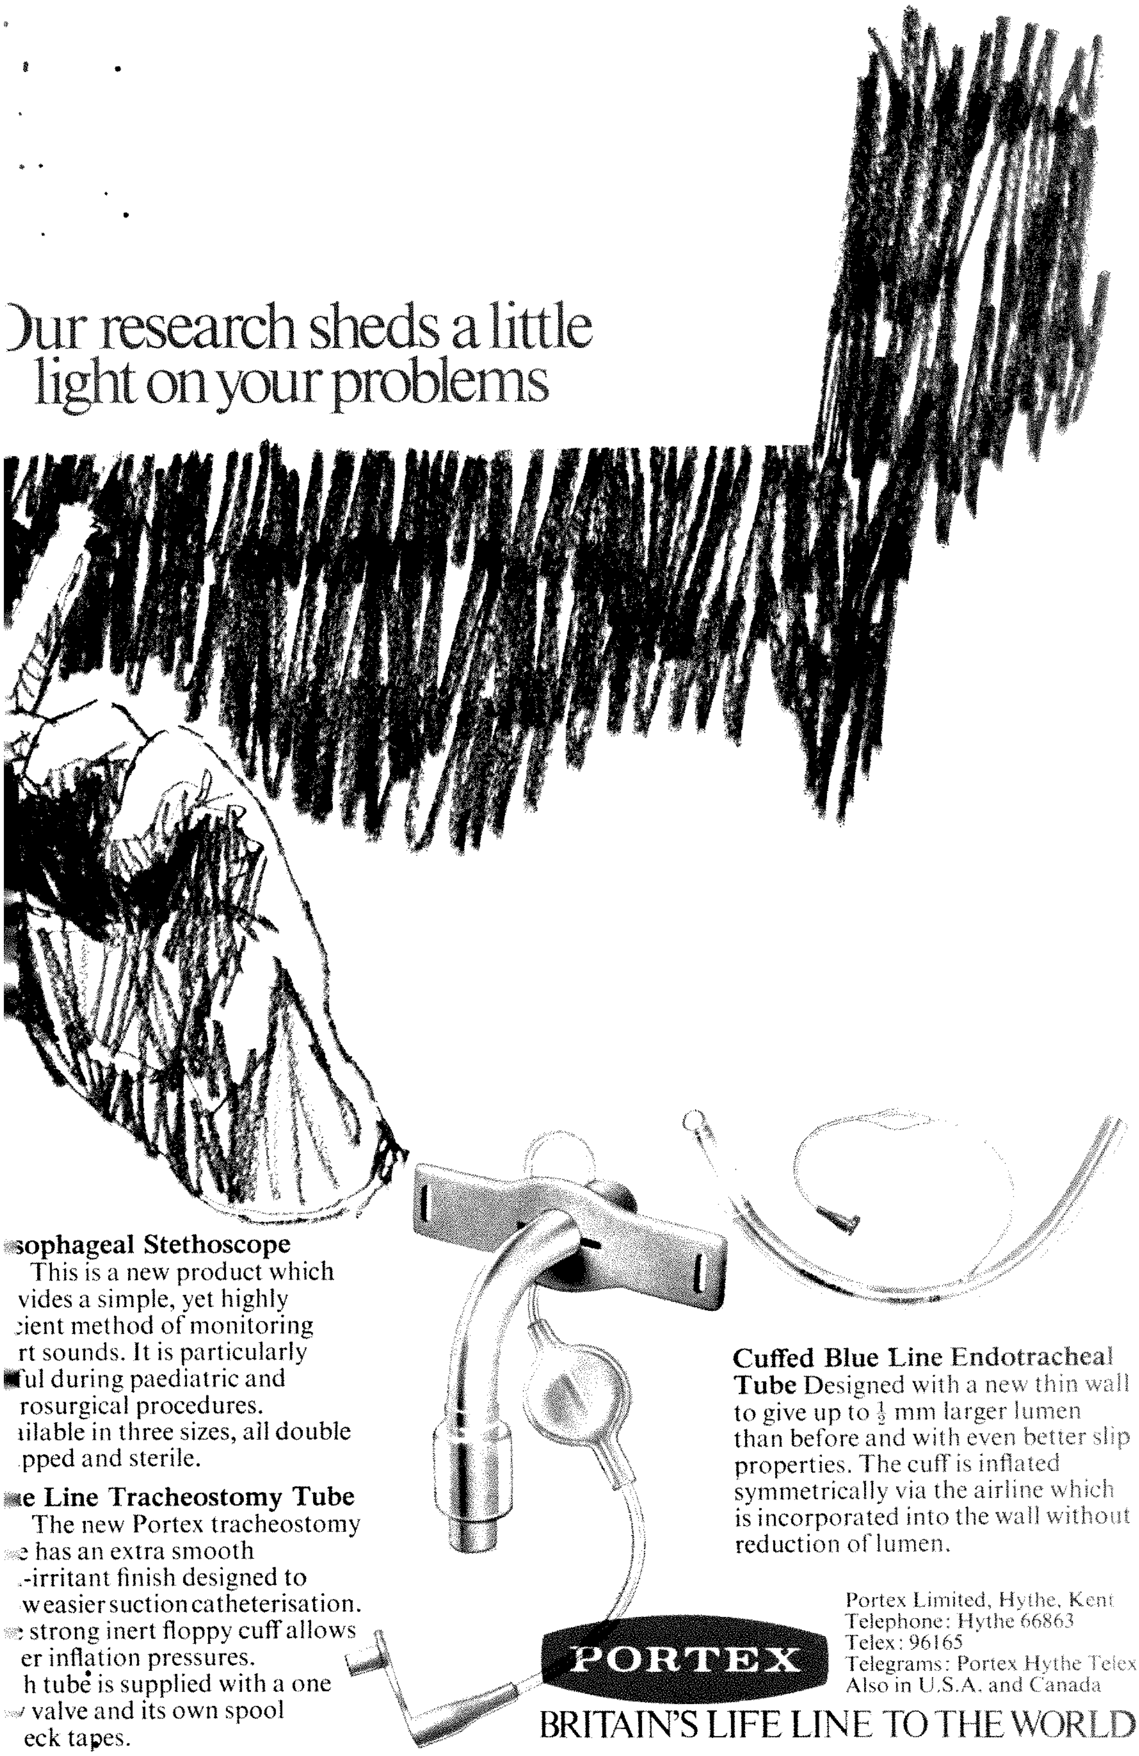
Our new product development programme has made possible significant advances in medical techniques. Like the Atrial Cannula. Like the Salpekar Tracheostomy Tube. Like the Cholangiogram Cannula. And more.

We are also in the forefront of the development of disposable products. This has entailed still further expertise and leadership in sterility procedures, biocompatibility testing, raw materials standards, identity and containment of microbial contaminant levels.

We like to feel that our research supports your search for greater medical advances.



ur research sheds a little
light on your problems



sophageal Stethoscope
This is a new product which
vides a simple, yet highly
ient method of monitoring
rt sounds. It is particularly
ul during paediatric and
rosurgical procedures.
ilable in three sizes, all double
pped and sterile.

e Line Tracheostomy Tube
The new Portex tracheostomy
has an extra smooth
-irritant finish designed to
w easier suction catheterisation.
strong inert floppy cuff allows
er inflation pressures.
h tube is supplied with a one
valve and its own spool
eck tapes.

Cuffed Blue Line Endotracheal Tube Designed with a new thin wall to give up to ½ mm larger lumen than before and with even better slip properties. The cuff is inflated symmetrically via the airline which is incorporated into the wall without reduction of lumen.

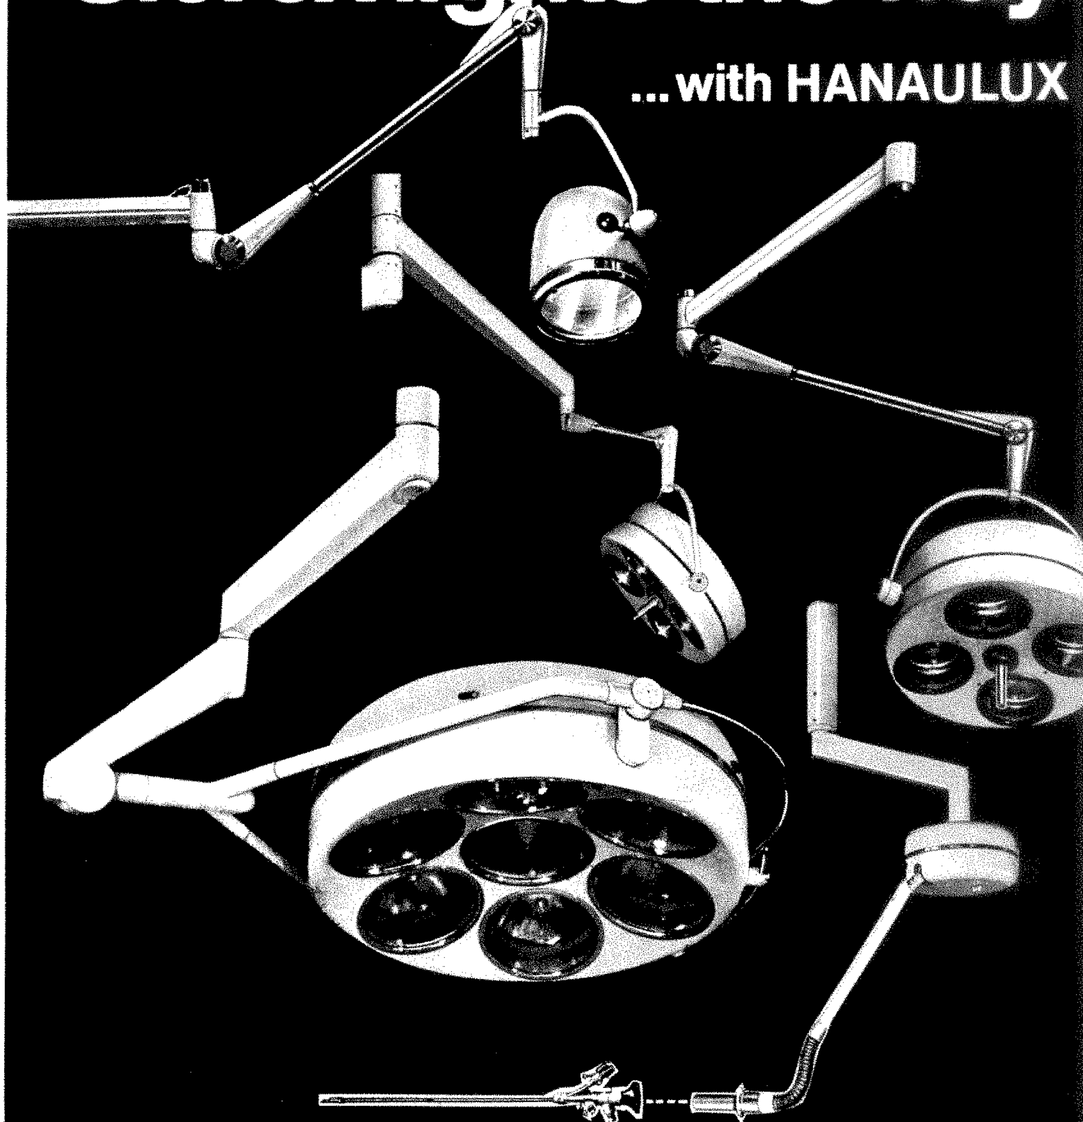
Sierex lights the way

...with HANAULUX



From the cool, highly intensive light provided by the Boston operating lamp to concentrated illumination for cavities from the Glass Fibre Optic Satellite lamp, Sierex can supply the right lighting for all surgical procedures.

Main lighting units, with or without satellites, ceiling mounted, wall mounted or free-standing—it's all the same to Sierex.

You really should see the Hanaulux range before committing yourself. We will gladly supply full technical details on request.

Our head of table is unique.

The Matburn MS is a dramatic addition to our M table series, which are used in more countries throughout the world than any other operating tables.

The MS controls are grouped on a moveable selector arm at the head end to enable all major table movements to be made without disturbing the surgical team or the sterile area.

It's the most advanced table of its kind.

For further details and demonstration, please use the coupon.

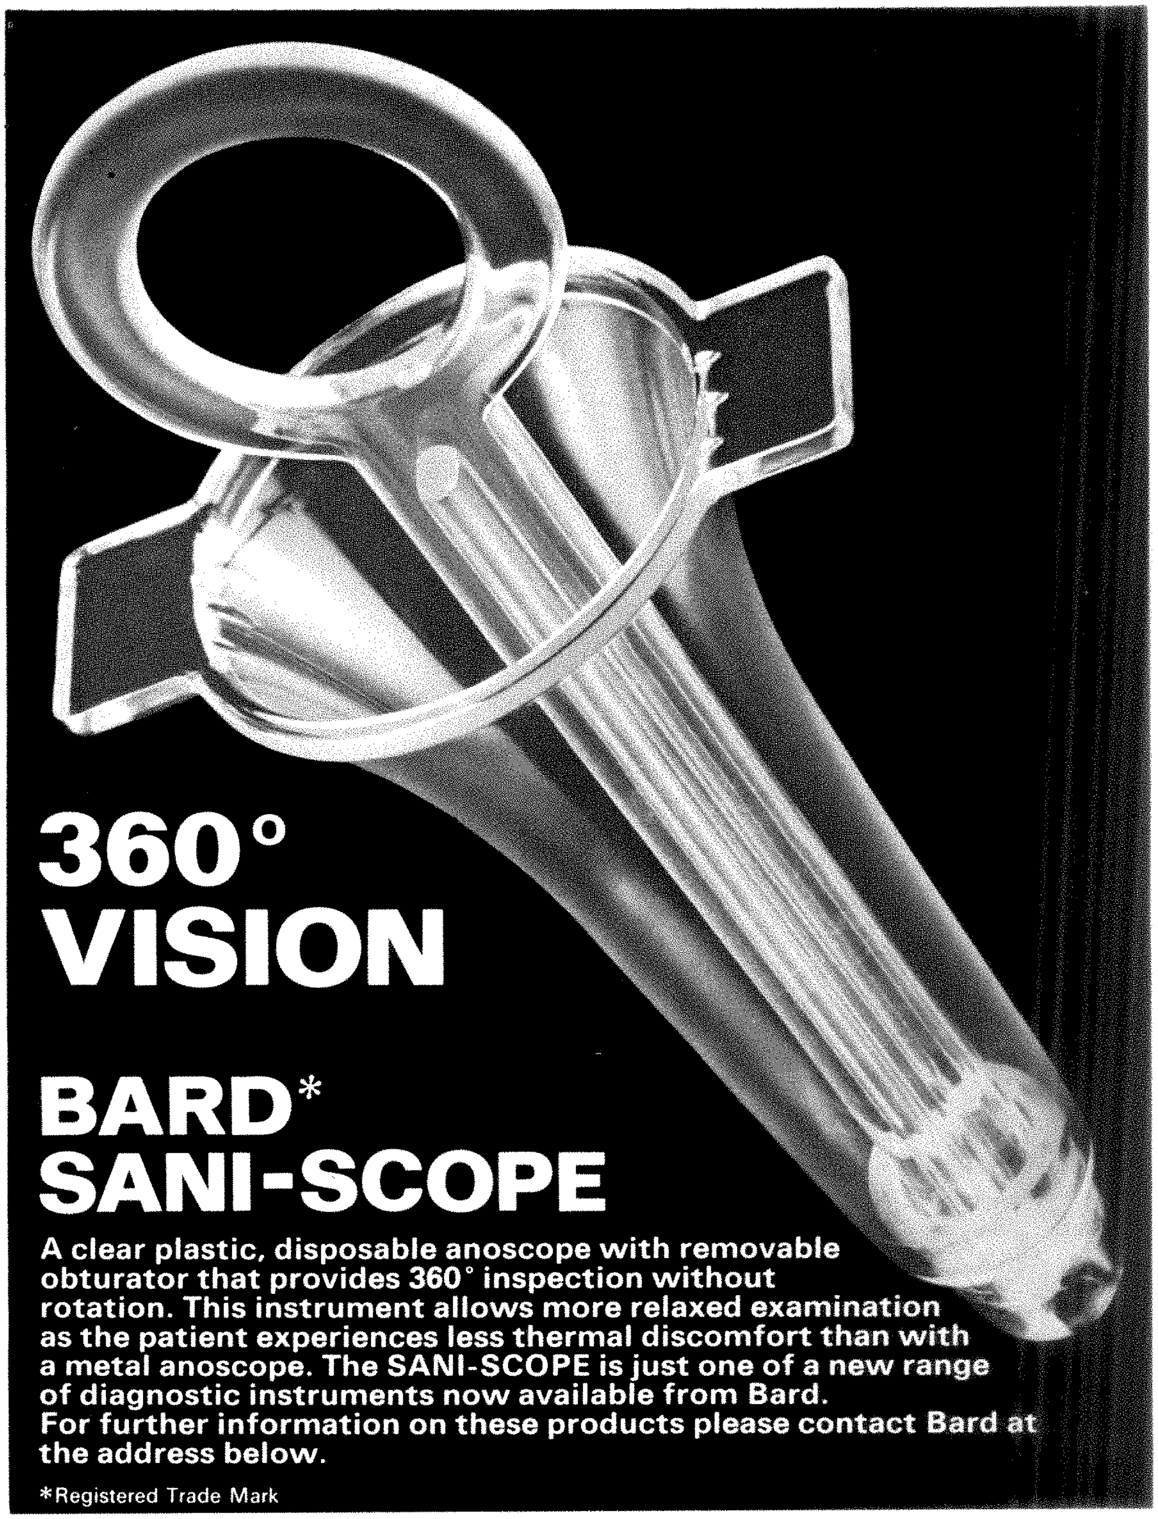
ESCHMANN



360° VISION

BARD* SANI-SCOPE

A clear plastic, disposable anoscope with removable obturator that provides 360° inspection without rotation. This instrument allows more relaxed examination as the patient experiences less thermal discomfort than with a metal anoscope. The SANI-SCOPE is just one of a new range of diagnostic instruments now available from Bard. For further information on these products please contact Bard at the address below.

HAMILTON BAILEY'S EMERGENCY SURGERY. 9th ed.

Edited by T. J. McNair, M.D., F.R.C.S. (EDIN.), F.R.C.S. (ENG.), *Consultant Surgeon, Royal Infirmary of Edinburgh.*

'*Emergency Surgery* has been accepted for many years as the premier textbook for the emergency surgeon. The ninth edition continues this tradition. It is a volume which should be available in the theatre of every hospital and can be thoroughly recommended to all, whether trainee or established consultant who may be responsible for the management of the emergency situation.'—*British Journal of Hospital Medicine.*

998 pages 1155 illustrations **£12·50**

THE PRINCIPLES OF TRANSURETHRAL RESECTION AND HAEMOSTASIS

J. P. Mitchell, T.D., M.S., F.R.C.S., F.R.C.S.E., *Lecturer in Urology, University of Bristol; Consultant Urological Surgeon, United Bristol Hospitals; Consultant Urologist, Southmead General Hospital.*

'This book is founded on a wealth of personal experience both in the use of the resectoscope and the teaching of its use. It spreads beyond its title and covers all aspects of care of the patient before and after the operation, including the management of acute and chronic retention. . . . In summary an extremely worthwhile investment.'—*World Medicine.*

TRAUMA SURGERY: EXCEPTING BONES AND JOINTS

P. Powley, M.B., B.S., F.R.C.S., *Consultant Surgeon, Swindon and District Hospital Group.*

This book is designed for junior hospital staff involved with the reception and initial treatment of the victims of accidents—either road or industrial. It explains in detail the various injuries to the parts of the body other than the main bones and stresses which injuries require specialist treatment from the onset.

136 pages Paper Covers **£1·50**

JOHN WRIGHT & SONS LTD., BRISTOL, ENGLAND BS8 1EX

FOGARTY CATHETERS FOR ACUTE VASCULAR OCCLUSION

FOR: Venous Thrombectomy

Occlusion/Emergency Tamponade

Arterial Embolectomy

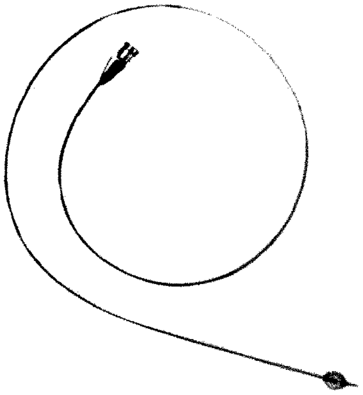
Dilation/Creation of Atrial Septal Defects in Infants

Double Lumen Balloon Catheter/Creation of Atrial Septal Defects in Infants

Biliary Balloon Probe/Exploration and Removal of Debris and Stones

Irrigation

Rugged Universal Hub Fits All Luer-Lok Type Syringes



BALLOON CATHETER CONCEPT

Each catheter has a specially constructed balloon at the distal tip (except Irrigation Catheter). In thrombectomy and embolectomy, when the catheter is introduced into a vein or artery, the instrument follows the path of least resistance and the tip threads itself past the thrombus or plaque. The balloon is then inflated with sterile fluid and the catheter withdrawn, bringing the clot with it. As an emergency tamponade, for dilation, or as a biliary probe, the balloon is similarly inflated.

GENERAL DESIGN FEATURES

1. Tips on the various types are specially designed for the particular procedure; all are soft and atraumatic.
2. Controlled symmetrical balloon geometry.
3. Secure balloon attachment by epoxied suture.
4. Length marked catheter bodies.

ALL FOGARTY CATHETERS ARE SUPPLIED STERILE

New Medical Publications

Acute Ureteric Obstruction: A Clinical and Radiological Study

P. M. Bretland, MD, DMRD, FFR

This book offers a new interpretation of the condition normally diagnosed as 'renal colic'. It sets out the contradictions inherent in some of the current teaching on the subject. The book will also serve to draw attention to some previously unsuspected gaps in the knowledge of the kidney and its behaviour when obstructed.

1972 232pp illustrated 0 407 10200 0 £5·20

Chronic Duodenal Ulcer

Edited by C. Wastell, MS, FRCS

For more than thirty years there has been a steady accumulation of knowledge about chronic duodenal ulcer and the related subject of secretion in the upper gastro-intestinal tract. This book is an attempt to collate some of this information, particularly as it relates to clinical problems. It provides a broad picture of the current state of knowledge and of key areas of research, both patho-physiological and clinical.

1972 294pp illustrated 0 407 13565 0 £8·00

Injuries of the Spinal Cord: The Management of Paraplegia and Tetraplegia

Neville G. Sutton, MB, ChM, DS, FRCS (Eng and Ed), FRACS

A comprehensive review, providing a systematic description of injuries to the spinal cord. It begins with the basic anatomy and physiology of the vertebral column and progresses to the management and care of the patient up to the time of full rehabilitation.

1972 200pp illustrated 0 407 21520 4 £5·50

Laparoscopy and Culdoscopy in Gynecology: Textbook and Atlas

Hans Frangenheim Translated by K. H. Finzer

With the development of the cold-light fibre-optical system, diagnostic laparoscopy and culdoscopy have proved invaluable techniques, to a large extent replacing diagnostic laparotomy. Interest in these procedures is considerable, and is widening rapidly. This book is a pocket-sized manual on the use of these techniques. It is generously illustrated with excellent colour photographs, accompanied by explanatory diagrams.

1972 118pp illustrated 0 407 90100 0 £5·20

Radiological Diagnosis of Digestive Tract Disorders in the Newborn

B. J. Cremin, D(Obst)RCOG, MCRA, FFR, S. Cywes, MMed(Surg), and J. H. Louw, ChM, FRCS

This is the result of the combined ideas of a radiologist who has specialised in this field and of two surgeons who have contributed significantly to progress in paediatric surgery. Clearly illustrated, it supplies all the information needed by those who deal with alimentary disturbances in the newborn infant.

1973 152pp illustrated 0 407 38375 1 £5·80

ORIGINAL PAPERS

ADENOCARCINOMA AND CROHN'S DISEASE

A REPORT OF 2 CASES AND ANALYSIS OF THE LITERATURE

By S. G. DARKE, A. G. PARKS, J. L. GROGONO, and D. J. POLLOCK
THE LONDON HOSPITAL

SUMMARY

Two cases of carcinoma developing in a segment of Crohn's disease are described, one in the large intestine and one in the small intestine. From an analysis of the literature, evidence is advanced with regard to age at the time of developing carcinoma, duration of symptoms attributable to Crohn's disease, anatomical distribution, and observed incidence compared with chance incidence. It is concluded that there is a small but significant risk of carcinoma developing, both in the small and large intestines, in Crohn's disease.

In view of the known predisposition for carcinomatous change in chronic ulcerative colitis it is desirable to know if a similar situation exists for Crohn's disease. This problem was reviewed recently in relation to both the small intestine (Wyatt, 1969) and the large intestine (Hywel Jones, 1969). For the small intestine, where the spontaneous occurrence of carcinoma is rare, it was concluded that there might be a predisposition to carcinomatous change. For the large intestine, however, it was suggested that no significant relationship existed.

Two further cases of carcinoma developing in a segment of Crohn's disease which have recently been seen at the London Hospital are reported in this communication; one in the large intestine and one in the small intestine. Six further cases from the literature are added to those previously reviewed, and further evidence is advanced concerning the relationship between the two conditions.

CLINICAL MATERIAL

All the cases of Crohn's disease seen at the London Hospital since 1948 have been reviewed. *Table I* shows the site of the disease in this series of 167 patients, and indicates the type and distribution of the various malignant tumours found. In 3 cases carcinoma and Crohn's disease occurred at the same site; in 2 this was in the large intestine, while the other was in the small intestine.

Table I.—ANALYSIS OF 167 CASES OF CROHN'S DISEASE PRESENTING AT THE LONDON HOSPITAL BETWEEN 1948 AND 1970

Site of Disease	*No. of Cases*
Total number of cases of Crohn's disease	167
Crohn's disease involving small intestine only	98
Crohn's disease involving small and large intestines	48
Crohn's disease involving large intestine only	21
Carcinoma and Crohn's disease at the same site	3
Carcinoma of colon at different site	2
Lymphosarcoma of small intestine	1
Leukaemia	1
Myeloma	1
Carcinoma of lung	1

CASE REPORTS

Case 1.—Mr. A. K., a 60-year-old clerk, was admitted to the London Hospital in November, 1970, with a 45-year history of attacks of partial small-bowel obstruction. Over the previous 2 years the attacks had become more severe and he had had watery diarrhoea but no rectal bleeding. On examination, he was thin but otherwise fit. There was tenderness in the right iliac fossa and there was a scar from an appendicectomy performed when he was aged 6. Sigmoidoscopy was normal. Haemoglobin estimation showed a mild iron-deficiency anaemia. Although barium-meal, follow-through, and barium-enema examinations were normal a straight radiograph of the abdomen taken during an attack showed several small-bowel fluid levels.

At operation Crohn's disease was found to involve the terminal 38 cm. of ileum. A large faecalith lay immediately proximal to the diseased bowel. There was no macroscopic evidence of malignant disease. An extended right hemicolectomy was performed. The patient's postoperative course was uneventful and when seen 4 months later he was well.

PATHOLOGY.—The right hemicolectomy specimen consisted of 64 cm. of terminal ileum, the caecum, and 13 cm. of ascending colon. The distal 30 cm. of ileum were thickened and matted together by dense adhesions. Two of the loops were connected by a fistula. The colon appeared normal apart from a polyp, 0·7 cm. in diameter, 5 cm. above the ileocaecal valve. The limits of excision were clear of disease. No enlarged lymph-nodes were present.

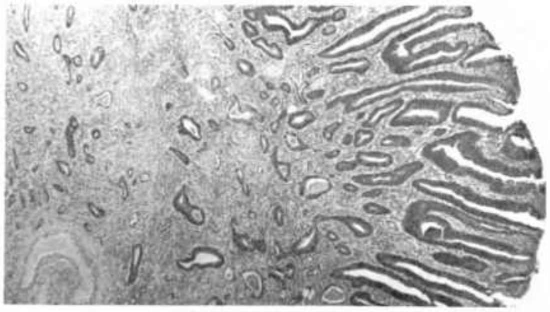

FIG. 1.—*Case* 1. Section of rectal nodule, showing invasion by a well-differentiated adenocarcinoma. H. and E. (× 25.)

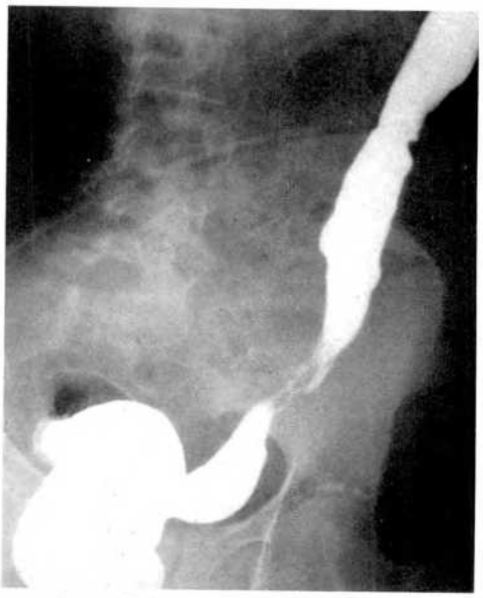

FIG. 3.—*Case* 2. Barium-enema film, showing a smooth filling defect in the sigmoid colon.

Sections showed thickening of the ileum, which was partly due to submucosal fibrosis and partly to muscular hypertrophy. The mucosa was ulcerated with an underlying infiltrate of polymorphs and plasma cells which extended through the muscle coats. Foci of pyloric metaplasia were present. In the submucosa collections of lymphoid tissue were seen. No granulomata were present. A fissure extended through the muscle coat of the bowel at one point. Immediately above this lesion the full thickness of the ileum was infiltrated by a well-differentiated adenocarcinoma (*Fig*. 1). The adjacent bowel showed in situ carcinoma which extended to the opening of the fissure. Lymph-nodes showed reactive hyperplasia only. The appearances were those of Crohn's disease of the terminal ileum with an adenocarcinoma. The colon was normal apart from a benign adenomatous polyp.

Case 2.—A 67-year-old housewife was admitted in November, 1969, with a 2-month history of diarrhoea, rectal bleeding, and weight-loss (13 kg.). She also complained of recent anal pain, and examination revealed a large perianal ulcer approximately 5 cm. in diameter (*Fig*. 2).

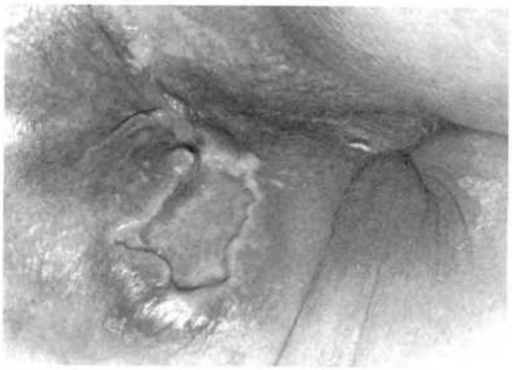

FIG. 2.—*Case* 2. Large perianal ulcer.

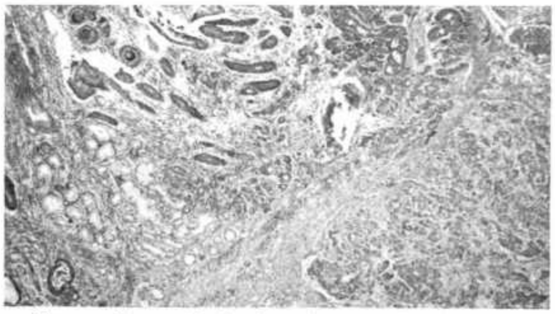

FIG. 4.—*Case* 2. Section from the terminal ileum showing invasion by a quite well-differentiated adenocarcinoma. An area of pyloric metaplasia is present on the left-hand side. H. and E. (× 21.)

At this time her haemoglobin was 8·9 g. A barium-enema examination showed a smooth stricture in the upper sigmoid colon which was consistent with a diagnosis of Crohn's disease (*Fig*. 3).

Laparotomy showed the changes of Crohn's disease from the mid-transverse colon to the rectum. The diseased colon was defunctioned by establishing an end-transverse colostomy. The patient made a good postoperative recovery and her perianal ulcer healed. However, when seen as an out-patient in October, 1970, she complained of dark-red rectal bleeding. On sigmoidoscopy a hard, nodular area was seen at 8 cm. from the anus and biopsy confirmed the presence of invasive adenocarcinoma. An abdominoperineal resection of the rectum and colon distal to the colostomy was therefore performed, from which she made an uneventful recovery.

PATHOLOGY.—Macroscopic examination of the specimen showed four raised irregular nodules 13 cm. from the anus, the largest being 0·6 cm. in diameter. The mucosa around the nodules had a faintly granular appearance. The mucosa 4 cm. above these lesions was irregular. There were mucosal nodules up to 2 cm. diameter with fissures and submucosal fibrosis. The anus was normal.

Sections from the nodules at 13 cm. from the anus showed invasion of the rectum by a well-differentiated adenocarcinoma. The tumour extended through the submucosa to invade the inner muscle coat for a short distance. The surface of the tumour had a villous pattern. The mucosa close to the tumour was mildly atrophic with small areas of ulceration. Sections from the region immediately above the tumour showed extensive ulceration with fissures extending through thickened submucosa into the muscle coat. There was a transmural infiltrate of lymphocytes and plasma cells. Foci of lymphocytes, sometimes with germinal centres, were present at all levels including the serosa. No granulomata were present. Occasional crypt abscesses were seen near areas of ulceration only. Sections of lymph-nodes showed reactive changes only with no granulomata or tumour cells. There were no premalignant epithelial changes. The presence of transmural inflammation and fissures strongly supported the clinical diagnosis of Crohn's disease of the colon with adenocarcinoma in the same segment (*Fig.* 4).

REVIEW AND ANALYSIS OF THE LITERATURE

The literature on Crohn's disease and carcinoma involving the same segment of intestine is shown in *Table II* for the small intestine (25 cases) and *Table III* for the large intestine (20 cases). The analysis of data relating Crohn's disease and carcinoma is considered separately for the small and large intestine.

Small Intestine.—

Age Incidence.—The average age at the time of diagnosis of carcinoma in a segment of Crohn's disease ('Crohn's carcinoma') is 46 years. This contrasts with an average age of 61 in a group of 119 cases of small-bowel carcinoma unassociated with Crohn's disease (carcinoma *de novo*) from the Birmingham Cancer Registry (Wyatt, 1969, from Brookes, Waterhouse, and Powell, 1968). This is shown in histogram form in *Fig.* 5 and the difference between the two groups is statistically significant ($P < 0{\cdot}01$).

Duration of Symptoms.—The duration of symptoms in the patients with 'Crohn's carcinoma' prior to surgery tended to be longer than that in patients coming to surgery for simple Crohn's disease in a series of 86 cases described by Cornes and Stetcher (1961); this is shown in *Table IV*. However, there is no statistical difference ($P > 0{\cdot}2$). It is unlikely that the carcinomas were responsible for long-standing symptoms; of 45 cases of unassociated small-bowel carcinoma described by Brookes and others (1968), 43 cases had symptoms of less than 2 years' duration.

Distribution through the Intestine.—The anatomical distribution of 'Crohn's carcinoma' through the intestine is shown in *Table V*. This is compared with a series of 321 small-bowel carcinomas collected between 1920 and 1960 from the world literature (Rocklin and Longmire, 1961). The 'Crohn's carcinoma' cases occurred mainly in the terminal ileum, and the carcinoma *de novo* cases were evenly distributed through the intestine. There is a statistically significant difference between this distribution ($P < 0{\cdot}01$).

Table IV.—DURATION OF SYMPTOMS PRIOR TO SURGERY IN PATIENTS WITH 'CROHN'S CARCINOMA' COMPARED WITH THOSE WITH SIMPLE CROHN'S DISEASE OF THE SMALL INTESTINE

DURATION OF SYMPTOMS (yr.)	SMALL-BOWEL CROHN'S DISEASE (Cornes and Stetcher, 1961)		'CROHN'S CARCINOMA' (Present series)

Carcinoma of the small bowel *de novo* (Rocklin and Longmire (1961)	113	37	108	34	98	29

Table VI.—REPORTED INCIDENCE OF 'CROHN'S CARCINOMA' OF THE SMALL INTESTINE

Author and Centre	*Reported Incidence*
Sheil, Clark, and Goligher (1968). Leeds General Infirmary	1 : 240
Crohn and Yarmis (1966). Mount Sinai Hospital	1 : 676
Present series (1973). London Hospital	1 : 146
Average	1 : 354 (0·3 per cent)
Estimated chance incidence	$1 : 10^9$

Incidence.—The incidence of adenocarcinoma of the small intestine may be estimated from two sources (Ackerman and del Regato, 1962; Haffner and Semb, 1969). A comparable figure of approximately 0·3 per 100,000 population per year is obtained from both sources after correction for survival rates and intercurrent deaths. The prevalence of Crohn's disease at all sites is 9 per 100,000 (Evans and Acheson, 1965). The chance of the diseases occurring together is therefore more than 1 in a thousand million. The chance is smaller still if allowance is made for both diseases affecting the same segment of intestine. *Table VI* shows the observed incidence in various reported series and the average for these is 0·3 per cent.

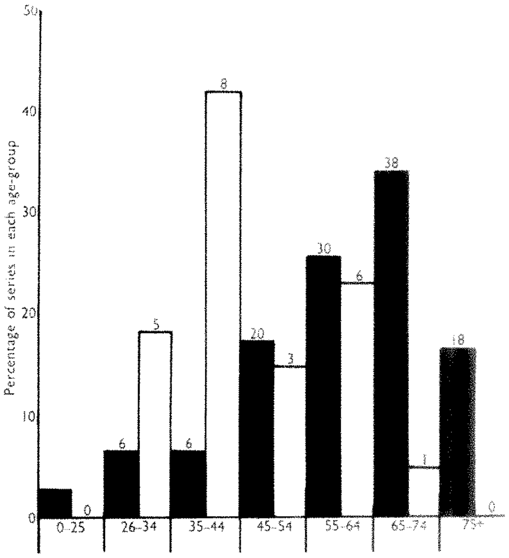

FIG. 5.—Age distribution of patients with 'Crohn's carcinoma' (white) compared with that for patients with carcinoma *de novo* (black) of the small intestine. Figures at the top of each column are the actual number of cases in each age-group.

Large Intestine.—

Age Incidence.—The age at diagnosis of 'Crohn's carcinoma' of the large bowel was compared with a series of 1171 cases of carcinoma of the large bowel occurring *de novo* (Goligher, 1941). There was no statistical difference.

Duration of Symptoms.—The duration of symptoms at the time of diagnosis fell into two groups. Nine patients had a history of under 1 year and an average age of 59 years. Five patients had a much longer history, averaging 18 years, but in spite of this their average age was only 44.

Distribution through the Intestine.—The anatomical distribution of 'Crohn's carcinoma' in the colon is shown in *Table VII* and compared with a large series of cases of carcinoma *de novo* from Leeds (Smiddy and Goligher, 1957). There is a statistically significant difference in the distribution ($P < 0{\cdot}01$), carcinoma *de novo* occurring mainly distally and 'Crohn's carcinoma' more proximally. The sex incidence in these two groups is comparable.

Incidence.—The prevalence of large intestinal Crohn's disease, including the caecum, can be estimated from the fact that the large intestine is involved to some extent in 55 per cent of cases of Crohn's disease (Avery Jones, Gummer, and Lennard Jones, 1968). The prevalence is therefore 6 per 100,000 population (Evans and Acheson, 1965). The average age of the present series of 'Crohn's carcinoma' is 53 years. For a population of this age the death-rate from carcinoma of the colon and rectum is 36 per 100,000 (Registrar General, 1969). However, the corrected 5-year survival is 42 per cent (Cutler and Lourie, 1964), suggesting an incidence of approximately 60 per 100,000. An estimate of a chance association is therefore greater than 1 in ten million. The chances of the two diseases occurring at the same site is smaller still. In the present series there are 2 cases of large intestinal carcinomas anatomically discrete from a coexistent segment of Crohn's disease. Two similar cases are reported in the literature (Davis and Caley, 1960; Hawk and Turnbull, 1966). *Table VIII* shows the observed incidence in various reported series and the average of these is 1·8 per cent.

DISCUSSION

The evidence that Crohn's disease predisposes to carcinoma is based on three points:—

1. The age of the patient at the time of diagnosis of 'Crohn's carcinoma' compared with that for carcinoma *de novo*.
2. A comparison of the anatomical distribution between these two groups.
3. A comparison of the estimated chance incidence and observed incidence.

'Crohn's carcinoma' of the small intestine occurs in a younger age-group and more frequently in the ileum than carcinoma *de novo*. These two findings are statistically significant. That this age difference and distribution simply reflect the group sampled is unlikely. A comparable incidence of other small-bowel malignant tumours would be expected, but only 3 cases have been reported—a lymphosarcoma in this series and 2 cases of reticulum-cell sarcoma (Hughes, 1955; Wyburn-Mason, 1968). There is also a sparsity of tumours in other sites; in this series only 6 other malignant conditions were found, and in a series from King's College Hospital, London, there were 6 cases out of 302, none of which was in the bowel (Murray, 1968).

For the large intestine a statistically significant difference has been shown between the anatomical distribution of 'Crohn's carcinoma' and carcinoma *de novo*. Again this may simply reflect the group sampled. However, although carcinoma of the large intestine is common, only 4 cases of coexistence with Crohn's disease have been reported (*vide supra*).

No difference in age in the two groups exists for the large intestine, but large intestinal Crohn's disease tends to occur later in life and requires surgical treatment at an earlier stage (Cornes and Stetcher, 1961). It is interesting to note, however, that the 'Crohn's carcinomas' in the large intestine fall into two subgroups: one having a long history at a younger age, and the other a short history at an older age. A long history of inflammatory disease preceding the development of carcinoma, as found in ulcerative colitis, is suggestive of a predisposition. However, as in the small intestine, the figures relating to duration of symptoms are too small to reach statistical significance.

On considering the pathological features of Crohn's disease, it would seem unlikely to predispose to carcinoma. It is predominantly a submucosal disease involving short segments of intestine and, unlike ulcerative colitis, premalignant changes are not a feature (Dawson and Pryse-Davies, 1959; Morson and Pang, 1967; Lee, 1971). Steiger and Dudrick (1970) draw attention to Schuman's (1970) case, which is the seventh report of carcinoma occurring in a defunctioned loop of Crohn's disease, and Lennard Jones and Morson (1969) wondered if bacterial stasis might have a carcinogenic effect on the bowel. On the other hand, these might represent the conditions under which Crohn's disease could continue chronically active yet not actually precipitating further surgery. An individual predisposition to both diseases could be invoked, perhaps based on an immunological abnormality common to both diseases, and this would explain coexistent carcinomas.

It is important to have some assessment of the risk of malignant change in Crohn's disease. For ulcerative colitis the practical risk in an Oxford Survey was 3·5 per cent (Edwards and Truelove, 1964), but under certain circumstances it may reach 25 per cent (De Dombal, Watts, Watkinson, and Goligher, 1966). For Crohn's disease the observed risk of adenocarcinoma is 0·3 per cent for the small intestine and 1·8 per cent for the large intestiine. Although the risk is less for the small intestine, the evidence for a causal relationship, as previously described, is greater.

The development of carcinoma in the presence of Crohn's disease presents difficult problems in diagnosis and management. Both diseases frequently present with altered bowel habit, symptoms of obstruction, and anaemia. Preoperative diagnosis of the carcinoma is most unlikely in the small intestine, and improbable in the large intestine, except when within sigmoidoscopic or colonoscopic range (e.g., *Case* 2 in the present series). In the small intestine the carcinoma is most commonly found by the pathologist; of 14 cases operated for intestinal obstructions, in only 4 was the carcinoma itself causing the obstruction. The tumour had frequently spread, 14 out of the 18 small-intestine cases in which data are available having lymph-node metastases, and in a previously defunctioned loop the danger of spread before surgery is even greater.

THE USE OF IMMUNIZED PIG LYMPH-NODE CELLS IN THE TREATMENT OF PATIENTS WITH ADVANCED MALIGNANT DISEASE

By M. O. SYMES and A. G. RIDDELL
DEPARTMENT OF SURGERY, UNIVERSITY OF BRISTOL, ROYAL INFIRMARY, BRISTOL

SUMMARY

The treatment of 14 patients with advanced malignant disease by the infusion of pig lymph-node cells pre-immunized against the appropriate tumour is described.

Marked tumour necrosis was seen in 7 cases and 4 of the patients obtained definite clinical benefit.

It is suggested that the therapy may be of most value when used in conjunction with other forms of treatment.

MITCHISON (1954) demonstrated that it was possible to transfer immunity against a mouse lymphoma by injecting cells from the lymph-nodes draining an allogenic tumour transplant into a second mouse which was isogenic with the first. Subsequently Mitchison (1955) repeated this observation using a mouse sarcoma. He found that the optimal time for cell transfer was at 5–10 days after immunization against the tumour.

This evidence for the importance of cell-mediated immunity in resistance to tumour growth led Woodruff and Symes (1962) to treat A-strain mouse mammary carcinomata, transplanted subcutaneously to isogenic hosts, by sublethal whole-body irradiation and intravenous injection of CBA spleen or lymph-node cells from animals pre-immunized against the appropriate tumour. Marked tumour necrosis was produced, but apparently complete tumour destruction was invariably associated with the induction of fatal graft versus host (G v H) disease. However, it was subsequently found that marked tumour regression could be produced, without accompanying G v H disease, by treating intraperitoneal tumour transplants by intraperitoneal injection of immunized spleen cells. It was suggested that early intimate contact between lymphoid and tumour cells contributed to the selective anti-tumour effect.

Another means of focusing the attack of immunized immunologically competent cells on the tumour rather than on the host was suggested by the work of Symes (1967). He found that in splenectomized mice there was a positive correlation between tumour size and the degree of anti-tumour effect produced by a given number of immunized spleen cells.

At a clinical level Woodruff and Nolan (1963) treated 8 patients by intravenous or intraperitoneal injection of normal lymphoid cells from other patients and in every case they noted some evidence of tumour necrosis. Nadler and Moore (1965) cross-immunized pairs of patients against the tumour of the other and then transfused immunized lymphocytes in the opposite direction. Tumour regression was observed in 3 out of 14 patients.

The *in vivo* immunization of a patient against the tumour of another patient raises difficult ethical problems. Therefore in order to potentiate the anti-tumour effect Symes, Riddell, Immelman, and Terblanche (1968) and Symes, Immelman, Peacock, Riddell, and Rhys Davies (1970) investigated the use of mesenteric lymph-node cells, from pigs immunized by the implantation of multiple fragments from the appropriate tumour into the mesentery, in the treatment of 5 patients with advanced malignant disease. Four of these patients showed definite, though temporary, regression of the tumour which was most marked in 2 of the 3 cases where the pig cells were infused into the arterial blood-supply of the tumour.

The present paper describes further experience in the treatment of advanced malignant disease with immunized pig cells.

MATERIALS AND METHODS

Selection of Patients.—In all 14 cases treated the patient had symptoms due to incurable malignant disease. Furthermore, the patients had either not responded, or seemed unlikely to respond, to the other methods of therapy currently available.

Immunization of the Pigs.—In each case several pieces of the tumour to be treated (of approximately 3 ml. total volume) were obtained. Multiple fragments of viable tumour were then prepared (each about 0·1 ml.) and implanted singly into separate pockets made in the small-bowel mesentery of the pig. Where the tumour had been obtained from a site liable to be infected the pig was treated systemically with an appropriate antibiotic.

For the retreatment of 1 patient a bull calf was immunized in a similar manner.

Preparation of Lymph-node Cell Suspensions.—Aseptic precautions were used throughout. The hyperplastic lymph-node chain was removed *in toto* 7 days after the implantation of the appropriate tumour fragments. The capsule was removed from the nodes. They were then cut into small pieces with fine scissors and the pieces were further reduced to a cell suspension in Medium 199 (Wellcome) using a hand-operated glass-piston blender. The cells were strained by gravity through a stainless-steel mesh of reducing pore size (30, 100, and 200 mesh). Finally, the cell suspension was centrifuged in an M.R.C. blood-transfusion bottle at 580 *g* for 5 minutes and resuspended in 100 ml. of fresh Medium 199. Total and in some cases 'viable' (using 0·165 per cent trypan blue exclusion) cell counts were performed on the cell suspension. The percentage cell viability in *Cases* 6, 7, 8, 10, 11, 12, 13, and 14 was 78, 86, 76, 87, 60, 56, 87, and 91 per cent respectively. The viability of the bull-calf lymph-node suspension used in *Case* 11 was 69 per cent.

Administration of Pig Lymph-node Cells.—In order to minimize the risk of a hypersensitivity reaction to pig protein each patient received 25 mg. of Phenergan i.m. 30 minutes before cell infusion, which was carried out over a period of 15 minutes under general anaesthesia. Two patients (*Cases* 4 and 10) experienced mild reactions (*see* Symes and others, 1970, and the Results for details). Otherwise the infusion of cells was uneventful.

RESULTS

A synopsis of the 14 patients treated is presented in *Table I*.

Table I.—Synopsis of Patients with Advanced Malignant Disease treated by Infusion of Pig Lymph-node Cells immunized against the Appropriate Tumour

Case No.	Age and Sex	Diagnosis	Treatment given	Survival after Treatment (d.)
1*	40 M.	Malignant melanoma	Day −7: Splenectomy Day −2: Melphalan, 30 mg. i.v. Day 0: Pig cells, 3·5 × 10⁹ i.v.	15
2	43 F.	Malignant melanoma	Day −7: Splenectomy Day −2: Melphalan, 30 mg. i.v. Day 0: Pig cells, 7·86 × 10⁹ i.v. Day 12: Autoplastic stored spleen cells, 2 × 10⁹ i.v.	56
3*	64 F.	Adenocarcinoma of ovary with hepatic secondaries	Day −2: Melphalan, 18 mg. i.v. Day 0: Pig cells, 6·50 × 10⁹ via aorta	12
4†	40 M.	Adenocarcinoma of colon with hepatic secondaries	Day 0: Pig cells, 12·4 × 10⁹ via hepatic artery	151
5‡	56 F.	Adenocarcinoma of pancreas with hepatic secondaries	Day 0: Pig cells, 22·4 × 10⁹ via coeliac axis	63
6	48 M.	Adenocarcinoma of bladder with hepatic secondaries	Day 0: Pig cells, 5·2 × 10⁹ via hepatic artery	1
7†	49 M.	Adenocarcinoma of rectum	Day 0: Pig cells, 4·6 × 10⁹ via internal artery	42
8	51 M.	Adenocarcinoma of colon with hepatic secondaries	Day 0: Pig cells, 5·06 × 10⁹ via hepatic artery Day 22: 5-F.U. via hepatic artery	35
9*	58 F.	Adenocarcinoma of colon with hepatic secondaries	Day 0: Pig cells, 8·75 × 10⁹ via hepatic artery	5
10‡	62 F.	Adenocarcinoma of breast with multiple metastases	Day 0: Pig cells, 1·67 × 10⁹ i.v.	32
11†	62 M.	Transitional-cell carcinoma of bladder	Day 0: Pig cells, 2·5 × 10⁹ via aorta Day 181: Bull-calf cells, 7·52 × 10⁹ via aorta	322
12‡	64 M.	Adenocarcinoma of bladder	Day 0: Pig cells, 5·75 × 10⁹ via aorta Day 30: Total cystectomy	52
13†	74 M.	Transitional-cell carcinoma of bladder	Day 0: Pig cells, 4·80 × 10⁹ via aorta	100
14‡	62 M.	Adenocarcinoma of bladder	Day 0: Pig cells, 5·05 × 10⁹ via aorta	86

* Patients showing massive tumour necrosis which may have contributed to early death.
† These patients obtained definite clinical benefit.
‡ No evidence of tumour regression was seen.

The patients may be divided into three groups according to the outcome of treatment:—

1. Cases in which definite clinical benefit was obtained (*Cases* 4, 7, 11, and 13).
2. Patients showing massive tumour necrosis in which clinical and pathological evidence suggested that this had occurred following treatment and which probably contributed to early death (*Cases* 1, 3, and 9).
3. Patients in whom there was no evidence of tumour regression, as judged clinically and pathologically (*Cases* 5, 10, 12, and 14).

In 3 patients (*Case* 6, who died on the day following treatment, and *Cases* 2 and 8) it was not possible to evaluate the outcome. Autopsy on *Case* 6 suggested that death was due to tumour progression and was not related to the injection of foreign cells.

Illustrative cases in each group are presented below.

CASE REPORTS

Group 1.—

Case 4.—This patient has been reported previously (Symes and others, 1970) and therefore will be mentioned in outline only. He presented with a carcinoma of the sigmoid colon and hepatic enlargement due to secondary tumour deposits. Following excision of the primary tumour, part of which was used to immunize the pig, the lymphocytes were infused over a period of 30 minutes into a catheter placed in the hepatic artery. During the next 70 days the patient's general condition improved, his liver decreased markedly in size as shown by clinical examination and a technetium scan (*see* Symes and others, 1970), and he returned for a time to light activity. By day 110, however, tumour growth had recommenced and was associated with inferior vena caval obstruction. He died on day 151 and at autopsy large areas of the hepatic secondaries were found to be calcified.

Case 7.—This man had an inoperable carcinoma of the rectum which had not responded to radiotherapy. Tumour tissue for the immunization of the pig was obtained through a proctoscope. On day 13 following cell infusion, examination under anaesthesia was carried out independently by two surgeons, who both reported the tumour to be approximately half its pretreatment size. At this time it was felt that the tumour was on the borderline of being resectable and the patient was therefore discharged in the hope that some further regression would permit surgical excision. The patient was reported to be well for the next 6 weeks, during which time he took a holiday. However, when he was re-examined on day 53 the tumour showed evidence of massive regrowth. It was now filling the pelvis and a fistula was present opening on to the anterior abdominal wall. The patient died on day 67.

Case 11.—This patient had a 9-month history of transitional-cell carcinoma of the bladder, which had failed to respond to a course of radiotherapy given 4 months previously.

Cytoscopy in April, 1971, showed a large tumour occupying the left wall of the bladder, and rectal examination revealed a left-sided pelvic mass fixed to the pelvic wall. At this time an intravenous pyelogram (*Fig.* 1) confirmed the presence of a filling defect in the left half of the bladder and showed a non-functioning left kidney.

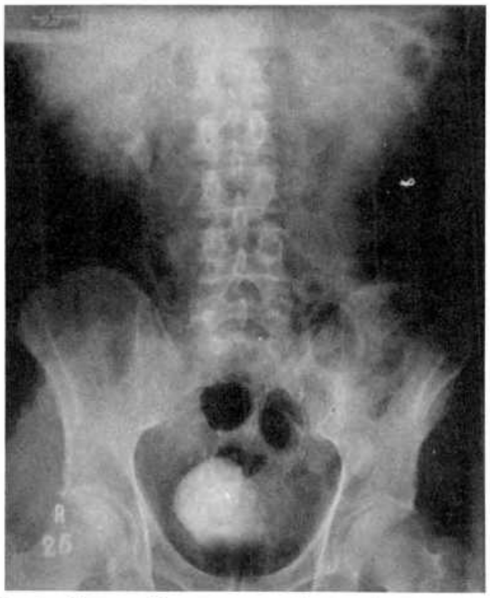

FIG. 1.—*Case* 11. Pretreatment pyelogram, showing a large filling defect in the bladder and a non-functioning left kidney.

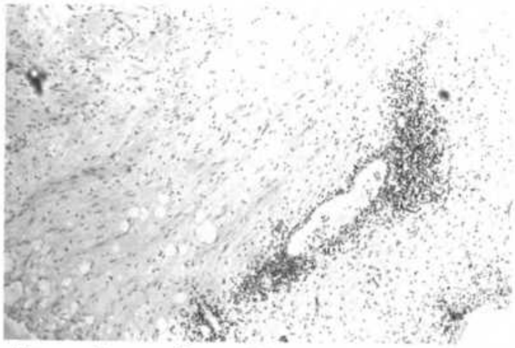

FIG. 3.—*Case* 11. Tumour biopsy 14 days after treatment. There is extensive tumour necrosis and marked lymphocytic infiltration. H. and E. (× 35.)

On day 14 after the infusion of pig cells a biopsy of the tumour showed marked necrosis and lymphoid-cell infiltration (*Figs.* 2 and 3), whilst no filling defect in the bladder was seen on the intravenous pyelogram. The pelvic mass was also smaller. At cystoscopy on day 48 the tumour appeared as a flat ulcer and radiological evidence of left kidney function was obtained (*Fig.* 4). On day 83 a small recurrence of the tumour in the bladder was resected; otherwise the patient remained well.

However, by day 154 there had been a massive recurrence of the tumour and this was treated by a second infusion of immunized lymphocytes obtained from a bull calf to avoid the risk of sensitivity to pig antigens. There was again evidence of marked tumour necrosis following therapy at cystoscopy on day 195. Following this the patient remained well until the end of 1971, but thereafter his condition deteriorated and he died on day 322.

At autopsy the primary tumour was seen to be almost totally necrotic, but there was evidence of massive recent involvement of the liver by secondary tumour.

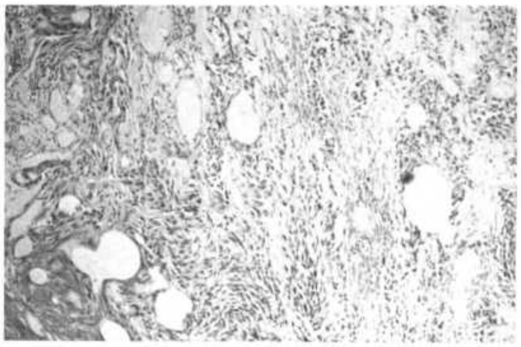

FIG. 2.—*Case* 11. Pretreatment biopsy of the transitional-cell carcinoma of the bladder. H. and E. (× 35.)

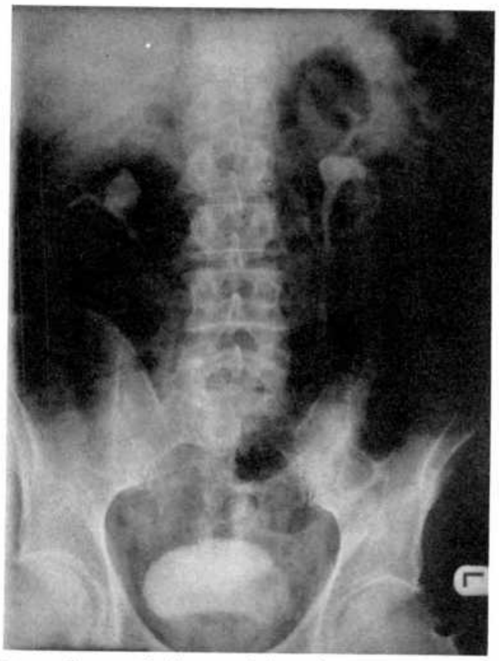

FIG. 4.—*Case* 11. Pyelogram 48 days after treatment, showing return of left kidney function.

Case 13.—This man presented in August, 1969, with haematuria due to an invasive transitional-cell carcinoma of the bladder. Radiotherapy given between October, 1969, and May, 1970, was associated with regression of the tumour. However, haematuria recurred in October, 1970, and the tumour grew steadily for the next 15 months.

At cystoscopy in January, 1972, the patient had a large left-sided bladder tumour and there was also a hard extravesicular mass fixed to the left pelvic wall. An intravenous pyelogram showed a non-functioning left kidney. On day 14 following the infusion of pig lymphocytes cystoscopy revealed massive haemorrhagic tumour necrosis which was confirmed histologically. The patient has remained well since, being active at a home, and has had only a single episode of haematuria. Cystoscopy on day 84 showed oedematous necrotic tumour on the left bladder wall (confirmed histologically) and pelvic examination at that time revealed some thickening on the left pelvic wall but no mass.

GROUP 2.—

Case 9.—This woman had a carcinoma of the sigmoid colon removed by anterior resection in June, 1969. In October, 1970, she was readmitted with liver secondaries. At laparotomy the diagnosis was confirmed and a catheter was inserted into the hepatic artery. A portion of the tumour was removed from the liver and used to immunize a pig. Histology confirmed that the tumour in this biopsy was a viable mucus-secreting adenocarcinoma.

On day 2 following the infusion of immunized lymphocytes into the hepatic artery the patient developed abdominal distension and marked ankle oedema. On day 5 the patient inhaled vomit and died, following the onset of rapidly progressive weakness. At autopsy the liver, which weighed 3480 g., was found to contain multiple deposits of tumour most of which had a necrotic appearance and some of which were surrounded by areas of hyperaemia. Histology confirmed the presence of large areas of tumour necrosis.

Cases 1 *and* 3.—These patients have previously been reported (Symes and others, 1970). Seven days before the infusion of pig lymphocytes both patients were subjected to splenectomy. They were given Melphalan intravenously 2 days before infusion as an immunosuppressant to promote the survival of the pig cells. Over approximately the next fortnight both patients showed massive tumour necrosis. In *Case* 1 this affected multiple subcutaneous melanoma deposits, some of which became cystic. In *Case* 3 the pelvic mass comprising the primary ovarian tumour and the liver, colonic, lung, and subcutaneous secondaries became almost totally necrotic. Both patients died at the height of this necrosis.

GROUP 3—

Case 10.—This woman presented with an 18-year history of carcinoma of the breast. Previous treatment had been radical mastectomy, radiotherapy, and hyposectomy.

In February, 1971, she was admitted with multiple subcutaneous tumour deposits, one of which was excised to immunize the pig. A total of 88 ml. of a suspension containing immunized pig cells was infused intravenously over a period of 15 minutes. At the end of the infusion the patient appeared flushed and complained of headache, which reaction began to subside after 10 minutes.

Following treatment there was no detectable regression in the tumour deposits and she died on day 32 from progression of her disease. Autopsy confirmed that there was no abnormal tumour necrosis.

DISCUSSION

It has been widely contended that to attempt immunotherapy for advanced malignant disease is probably a waste of time (*see* Alexander, 1970, for example). This is certainly true where the object of the therapy is to increase the patient's resistance to his tumour. However, in the present study an attempt has been made to 'import' an immunological response, induced in a pig, by the adoptive transfer of lymph-node cells. In theory the lymph-node cells may attack the patient (graft versus host, G v H) or the tumour (graft versus tumour, G v T) or both. The problem is to obtain the maximum G v T and the minimum G v H effects. We have sought to do this by administering pig lymphocytes into the arterial blood-supply of the tumour, thus facilitating contact between the lymphocytes and the tumour cells. In addition, the magnitude of the immunological response by the pig cells to a particular antigen may depend on the amount of the antigen present. Thus, the presence of a large tumour may accentuate the G v T effect and protect the patient from G v H reaction. Experimental evidence to support this idea has been provided by Symes (1967).

An alternative approach to eliminating the G v H effect would be to extract nucleic acids from the immunized pig cells and to administer these to the patient (Alexander, Delorme, Hamilton, and Hall, 1967). However, this method depends on there being tumour-specific antigens present against which the foreign lymphocytes could be specifically immunized. Such a condition may not obtain in advanced tumours.

From the present series of patients there would seem to be satisfactory evidence that the infusion of immune pig lymphocytes can result in tumour necrosis. This was observed in a number of different tumour types. By contrast in no case was there any evidence that tumour growth was enhanced.

The importance of direct lymphocyte–tumour-cell contact is emphasized by the superior results from intra-arterial as compared with intravenous infusion of pig cells (*Table I*).

The administration of an immunosuppressant before infusing the pig cells resulted in massive necrosis and early death in 2 cases (*Cases* 1 and 3) of the 3 so treated and the practice was therefore discontinued.

An important but perhaps obvious conclusion is that the greatest benefit to the patient is likely to result from the treatment of a tumour at a site where extensive necrosis will not produce a catastrophic effect on body function, for example, *Cases* 7, 11, and 13.

Owing to the presence of one or more clones of resistant tumour cells (*see*, for example, *Cases* 7 and 11) it is probable that this therapy will not in itself ever prove curative except in a tiny percentage of cases. Its place is, therefore, as an adjunct to other types of treatment. For example, following the infusion of pig cells an inoperable tumour may for a short time become resectable (*Case* 7). Also the possibility of giving radiotherapy or a cytotoxic drug after cell infusion might be considered. In *Case* 14 the tumour showed increased vascularity and lymphoid infiltration in spite of its high viability. This patient is therefore to receive radiotherapy.

Acknowledgements.—We should like to thank Miss Teresa Lai and Dr. Jennifer Rees for their assistance in this project. We are grateful to Mr. D. C. Bodenham, Dr. H. Eckert, Mr. R. C. L. Feneley, and Professor J. H. Peacock for referring cases to us.

The advice of Mr. G. W. Sweetnam and his staff in matters of animal welfare is gratefully acknowledged.

THE EFFECT OF INNERVATION, DENERVATION, AND MUSCLE TYPE ON THE REUNION OF SKELETAL MUSCLE

BY P. WEBB

DEPARTMENT OF ANATOMY AND EMBRYOLOGY, UNIVERSITY COLLEGE, LONDON

SUMMARY

The left plantaris and soleus and the right and left sternohyoid muscles of rats were transected surgically and cross-repaired to form conjoined muscle bellies composed of two innervated muscles, two denervated muscles, and one denervated and one innervated muscle.

Subsequent maceration of the conjoined muscle belly showed that regeneration had taken place by inoculation of the growing tips of the regenerating fibres in the doubly denervated muscle belly and in the innervated–denervated muscle belly but not in the case of the doubly innervated muscle belly.

Muscle type was not found to influence this process.

The significance of these findings is discussed.

THE ability of mammalian skeletal muscle to recover following damage has been known since 1865 (Waldeyer, 1865). A variety of techniques have been used to induce damage including chemical toxins (Walton and Adams, 1956), ischaemia (Clark, 1946), direct percussion (Allbrook, Baker, and Kirkaldy-Willis, 1966), crush lesions (Clark, 1946; Saunders and Sissons, 1953; Hall-Craggs, 1971), and surgical division of muscle bellies (Clark, 1946; Jones, 1949; Gay and Hunt, 1954). Saunders and Sissons (1953) and Hall-Craggs (1971) examined the effect of denervation on the process of regeneration. In both these studies damage was induced by crushing the muscle bellies transversely between the blades of a haemostat.

Surgical exposures, however, often involve the complete division of muscle bellies at right-angles to the direction of the fibres. This procedure thus isolates a portion of the muscle from its parent innervated muscle belly. The fate of the isolated portion following such a procedure is of interest surgically. The present study was undertaken (1) to confirm previous reports of end-to-end anastomosis of severed muscle-fibres (Gay and Hunt, 1954) and to explore its nature; (2) to examine the effects of innervation and denervation on this process (Saunders and Sissons 1953, Hall-Craggs, 1971), and (3) to find out whether the processes of repair are comparable when reunion is attempted between muscles of different physiological types.

METHODS

Surgical Procedures.—Wistar rats of both sexes weighing between 150 and 275 g. were used. Two series of operations were performed under general anaesthesia, which was induced and maintained by 4 per cent chloral hydrate (1 ml. per 100 g) introduced intraperitoneally. A prophylactic dose of 0·3 ml. of Intramycetin was administered intramuscularly to each rat postoperatively.

In the first series of operations a vertical dorsal incision was made between the bellies of the left gastrocnemius exposing the plantaris and soleus. The proximal half of the soleus and the distal half of the plantaris were excised and the cut surfaces of the remaining muscle bellies were then joined with three 000000 silk sutures.

Of the 18 rats which were subjected to this procedure, both the plantaris and soleus were denervated in 6 by the removal of a 1·5-cm. segment of the tibial nerve. In a further 6 animals the soleus alone was denervated by the division of its motor nerve, which was then buried in the lateral head of the gastrocnemius. In the final 6 rats the nerve-supply of both the soleus and plantaris was preserved.

In the second series of operations a vertical median incision was made in the neck to expose the sternohyoid muscles. The muscle bellies were divided surgically; on the right just caudal to the superior motor end-plate. The cranial portion of the right muscle and the caudal portion of the left were then cross-repaired. The remaining muscle on the right was allowed to retract into the neck and that on the left was excised. Eighteen rats were subjected to this procedure. In 6 rats both the right and left sternohyoid muscles were denervated by division of the superior motor nerve at its point of entry into the muscle belly. The nerve was then buried in the subjacent omohyoid to prevent reinnervation. In 6 rats the right muscle alone was denervated, and in the final 6 rats the nerve-supply of both the right and left sternohyoid muscles was retained.

The conjoined muscle bellies of both series of operations were removed and examined after 3 weeks by maceration, histochemical, and histological techniques. For each technique 12 rats were used (2 from each of the three groups of the two series).

Maceration.—The muscle bellies were fixed in 10 per cent formol–saline and macerated in 20 per cent nitric acid at room temperature for up to 56 hours. Individual fibres or bundles of fibres were then teased out under a dissecting microscope, mounted in glycerin, and examined using phase microscopy. This technique represents a modification of that used by Gay and Hunt (1954).

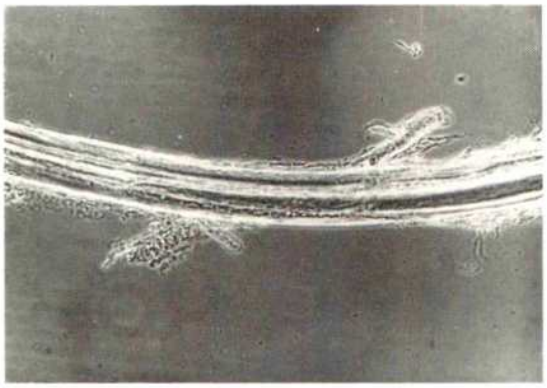

FIG. 1.—Junctional zone of three macerated fibres from a conjoined muscle belly composed of innervated plantaris and denervated soleus. (× 60.)

Histochemistry.—The excised muscle bellies were plunged into *n*-hexane cooled to -70° C. by a mixture of solid CO_2 in acetone. Blocks were prepared of the experimental muscle and of the control muscle from the contralateral leg in the first series and the adjacent sternomastoid in the second. Transverse sections were cut at 10 μm. at sites away from the site of reunion and stained for diphosphopyridine nucleotide-tetrazolium reductase (DPNH-TR) (Engel and Brooke, 1966).

Histology.—The muscle bellies were fixed in 10 per cent formol-saline and embedded in paraffin wax. Longitudinal sections were cut at 15 μm. and stained using Weigert's hematoxylin and Van Geison's picric acid.

RESULTS

In both series the conjoined muscle bellies appeared to have joined when examined macroscopically after 3 weeks. After maceration a variable number of fibre bundles could be followed across the join.

It was observed that when the conjoined muscle belly was composed of two denervated muscles or of an innervated and a denervated muscle the majority of fibre bundles could be so traced. Individual fibres were teased from a bundle and mounted on a slide so that the observed junctional zone was opposite a diamond scratch mark on the surface of the slide. Under the phase microscope the junctional zone (*Fig.* 1) was seen to be composed of mature fibre which was practically indistinguishable from the fibre away from the join. However, some of the fibres ended by bifurcating into one or two collateral 'buds' (*Fig.* 2) which appeared to join with similar buds from the other side of the join. Longitudinal splitting (Hall-Craggs, 1970) was observed in several of the mounted fibres.

When the conjoined muscle belly was composed of two innervated muscles only a few individual fibres could be traced across the join. The majority ended by dividing into several collaterals which were long and thin and which interwove in a complex manner with similar buds from the other side (*Fig.* 3). It was not possible to identify with certainty the anastomosis of fibres.

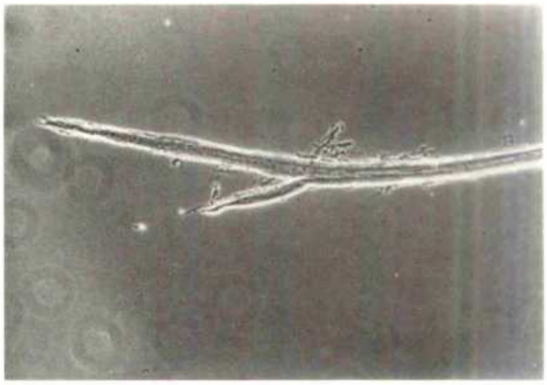

FIG. 2.—Isolated end of an innervated sternohyoid muscle-fibre macerated from a doubly innervated conjoined muscle belly, showing a collateral sprout. (× 60.)

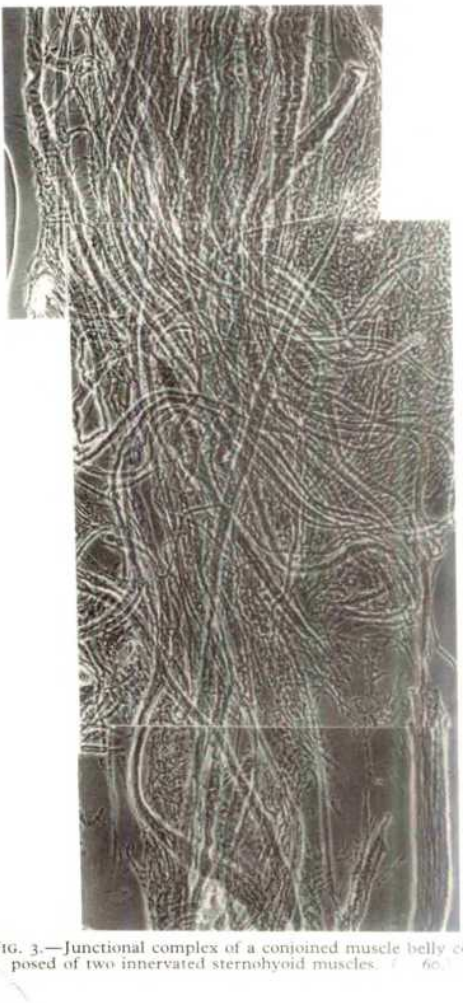

FIG. 3.—Junctional complex of a conjoined muscle belly composed of two innervated sternohyoid muscles. (× 60.)

Longitudinal sections revealed a variable amount of connective tissue. More was present in the doubly innervated muscle belly. Transverse sections cut cranial and caudal to the join were examined to check the effectiveness of the denervation procedure and the completeness of innervation. Sections cut through a denervated muscle belly showed almost uniformly decreased fibre diameter and enzyme staining. Sections through the innervated muscle bellies showed occasional areas of decreased fibre diameter, indicating that some fibres had been denervated during the operative procedure.

DISCUSSION

Regeneration of striated muscle through or across a region of damage has been investigated by several authors. One of the difficulties of interpretation of the findings has been the non-uniformity of the damage produced. Saunders and Sissons (1953) claimed complete destruction of the muscle-fibres but stated that the degree of damage to the sarcolemmal tubes was not the same in all parts of the crushed areas. In some areas the tubes remained more or less intact while in others they were completely destroyed. For this reason it was decided to transect the muscle bellies surgically. The plantaris and soleus and the right and left sternohyoids were chosen for the experiment because in both situations the muscles are of similar size, adjacent to each other, and have an accessible motor nerve, thus facilitating the approximation of the transected muscle bellies and allowing denervation to be achieved readily. The plantaris and soleus are physiologically fast and slow muscles respectively while the sternohyoid is a fast muscle.

The present study confirms the earlier reports that regeneration of striated muscle across a surgical division is possible and not interfered with by simultaneous denervation. Individual fibres of two conjoined denervated muscles and conjoined innervated and denervated muscles were traced from one side through the junctional zone to the other side and in some cases individual fibres were traced from tendon to tendon of the conjoined muscle belly. Collateral buds at the tips of regenerating fibres from both denervated and innervated muscle were seen. Clark (1946) claimed that regenerating tips are capable of a growth maximum of 1–1·5 mm. per day, which raises the possibility that regeneration could take place by the growing buds replacing the isolated portion of the muscle by substitution down the existing sacrolemmal tubes in a manner reminiscent of peripheral nerve repair. However, in the present study growing tips were only seen at the junctional zone and arising from fibres on both sides of the join and on several occasions the growing tips of one muscle were seen in the process of anastomosing with those of the opposite muscle, when the conjoined muscle belly was composed of at least one denervated muscle, thus confirming the previous report (Gay and Hunt, 1954) that regeneration is achieved by the reunion of the damaged ends of the muscle-fibre.

There was a quantitative difference in the number of growing tips seen. When the conjoined muscle belly was composed of at least one denervated muscle the majority of fibre bundles were composed of mature fibres, only a few of the fibres ending in growing tips with collateral sprouts. When the muscle belly was composed of two innervated muscles the majority of the fibres on both sides of the join ended in growing tips interweaving with each other without making contact. The fact that they did interweave suggests that contraction of the muscle had not interfered with the possibility of contact. It is thought that the few fibres that did cross the join were regenerated fibres formed by union between an innervated fibre and a fibre denervated accidentally during operation.

It is suggested that the production of growing tips with collateral sprouts is a general response of the striated muscle-fibre to injury and that when the potential for anatomical union has been achieved by inosculation between the opposing growing tips, which occurs when at least one of the fibres is denervated, the sprouting of collaterals is inhibited. Thus, in the present series when innervated muscle was confronted by innervated muscle there was profuse sprouting of collaterals but anastomoses were not observed. Whether this is because contraction of muscle-fibres on both sides of the join was sufficiently disrupting to prevent the earlier delicate changes of union taking place or whether there was some more profound influence of the nerve is not yet understood. Hall-Craggs (1971), using rat sternohyoid muscle, demonstrated that the altered fibre pattern produced by crushing the motor nerve 3 weeks before crush transection of the muscle belly was in due course transferred to isolated fibres on their recovery. It seems, therefore, that innervated muscle will adopt an uncommitted portion of another muscle, whether of the same physiological type or not, and incorporate it into a functional unit under the control of one motor nerve, but that when two functional units are confronted the processes of regeneration are impeded and continuity of the muscle belly is restored by the fibrous tissue repair.

Acknowledgements.—My thanks are due to Dr. E. C. B. Hall-Craggs for his constant help and advice with all stages of the experiment, to Mr. J. Sheppard for the preparation of histological material, and to Mr. D. Gunn for the photographic work.

THE ARTERIAL COMPLICATIONS OF POLYCYTHAEMIA VERA

By A. P. BARABAS, D. N. OFFEN, and E. A. MEINHARD

DEPARTMENTS OF SURGERY AND MORBID ANATOMY, HAMMERSMITH HOSPITAL, LONDON

SUMMARY

Of 200 patients referred for management of polycythaemia vera, 98 (49 per cent) had presented with vascular complications and 68 (34 per cent) of these involved arteries. Transient but recurrent cerebrovascular accidents and digital artery occlusions were the typical arterial complications. If polycythaemia was not promptly treated there was a risk of permanent hemiplegia, monocular blindness, and severe ischaemia of the leg.

Embolism may have accounted for some of the arterial complications. A possible source for emboli —a proximal mural thrombus—was demonstrated in all 5 patients who were examined with femoral arteriography and in 2 patients who underwent surgery. In selected cases thrombectomy may be indicated to prevent further embolism.

In 1903 William Osler first drew attention to the vascular complications of polycythaemia. Brown and Giffin in 1930 and Norman and Allen in 1937 reported a total of 198 patients with polycythaemia from the Mayo Clinic, a third of whom had vascular complications. In 250 autopsies of patients dying with polycythaemia Chievitz and Thiede (1962) found vascular catastrophes to be the commonest cause of death.

In the present paper the vascular complications in 200 patients with polycythaemia vera are reported and the arteriographic and microscopic appearances of the arterial lesions in the limbs are described. Arterial embolism is suggested as a possible cause of some of the complications.

CASE MATERIAL

The case records of 200 in-patients of Hammersmith Hospital who were treated between the years 1952 and 1972 were studied. All were referred to the Radiotherapy Department of Hammersmith Hospital for the management of polycythaemia vera. The diagnosis of polycythaemia vera was made on the peripheral blood-picture and in doubtful cases confirmed by the estimation of the red-cell volume and bone-marrow puncture. All received radioactive phosphorus treatment.

VASCULAR COMPLICATIONS

Of the 200 patients, 98 (49 per cent) presented with vascular complications; these were arterial in 68 cases (34 per cent), venous in 57 (28 per cent), and both arterial and venous in 27 (13 per cent). In all, therefore, there were 144 different vascular complications in 98 patients (*Table I*).

Comparison between the 98 patients who presented with vascular complications and the 102 patients without such complications revealed no significant difference in age; the average age for the patients with complications was 61 years, while that for those without complications was 59 years. The sex distribution was also comparable in the two groups; the incidence of males in the group with complications was 60 per cent, while that in the group without complications was 56 per cent.

Table I.—Vascular Complications at the Time of Diagnosis of Polycythaemia Vera in 200 Cases

Type of Complication	No. of Patients Affected	
Cerebrovascular accident	39*	78 different arterial complications in 68 patients†
Coronary artery disease	10*	
Peripheral artery disease	25	
Monocular blindness	4	
Superficial thrombophlebitis	30	66 different venous complications in 57 patients†
Deep-vein thrombosis	25	
Pulmonary embolization	4*	
Portal-mesenteric thrombosis	5*	
Subclavian vein thrombosis	1	
Priapism	1	

* One fatal incidence occurred in each group.
† 27 patients had both arterial and venous complications.

Cerebrovascular Accidents. — Thirty-nine patients had cerebrovascular accidents; 9 of these were hypertensive, while the remainder had a diastolic blood-pressure of below 100 mm. Hg. Twenty-six of the 39 patients had suffered symptoms and signs consistent with temporary cerebral ischaemia, such as transient hemiplegia, facial weakness, or aphasia, lasting from half an hour up to 2 weeks, and in some cases recurring. Thirteen patients had permanent neurological loss, 6 of these having suffered one or more transient attacks before these permanent signs had developed. One patient died of a further cerebrovascular accident soon after admission and before treatment of the polycythaemia could be started.

Monocular Blindness.—Four patients had suffered attacks of transient blindness (amaurosis fugax). After several episodes 1 of these patients had become permanently blind in one eye because of retinal artery occlusion.

Coronary Artery Disease.—This was present in 10 patients.

Peripheral Artery Disease.—Twenty-five patients had symptoms of arterial disease affecting the limbs. In 15 of these the digital arteries only were involved, causing sudden ischaemia of a single finger or toe. By the time that the diagnosis of polycythaemia was confirmed, 10 patients had already undergone amputations of one or more digits. These local amputations healed well as the main arteries were patent and all the peripheral pulses were present (*Fig.* 1). Three further patients had had toes amputated in the past but presented with femoral artery occlusion, 2 of whom required a through-knee amputation. In the remaining 7 patients femoral artery occlusion occurred without preceding ischaemia of the toes. None of these required amputation or arterial surgery.

Mortality.—Four deaths—all the result of vascular complications—occurred during investigations and treatment, the cause of death being cerebrovascular accident in 1, myocardial infarction in 1, pulmonary embolism in 1, and mesenteric vein thrombosis in 1.

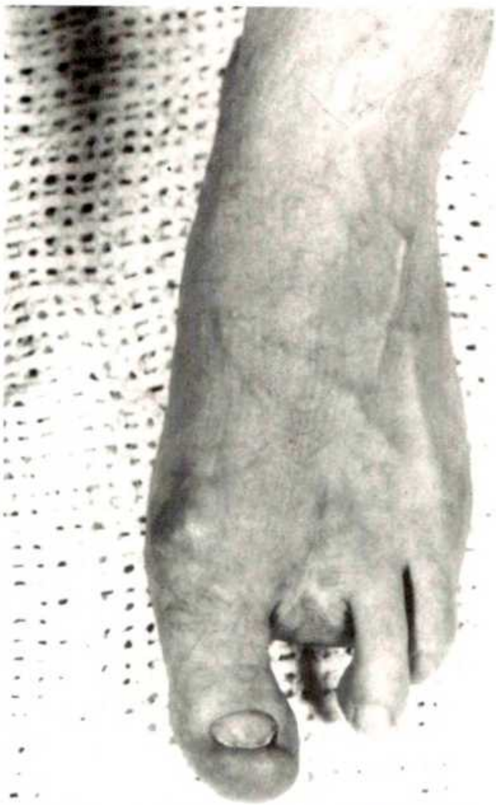

FIG. 1.—*Case* 2. Left foot with the second and third toes amputated.

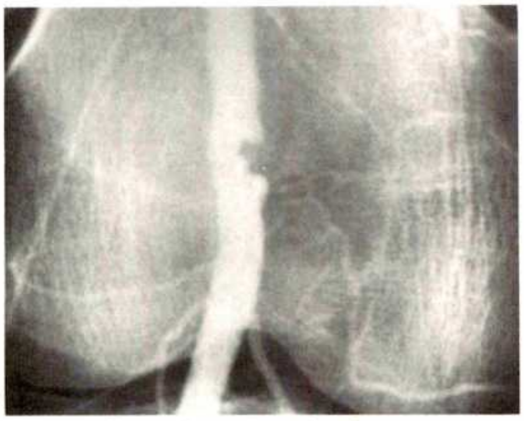

FIG. 3.—*Case* 2. Femoral arteriogram.

ARTERIOGRAPHIC FINDINGS

In 5 of the 15 patients with digital ischaemia but with palpable pulses at the ankle, femoral arteriograms were done. In all cases short localized segments of narrowing were found in the femoral or popliteal arteries. Apart from these narrowed segments, the main arteries appeared free from disease (*Figs.* 2, 3). The digital arteries were not sufficiently visualized on the radiographs for comment. Arterial surgery was carried out in 2 of the 5 patients who had had femoral arteriograms done and in both the narrowed segments were found to be due to mural thrombus.

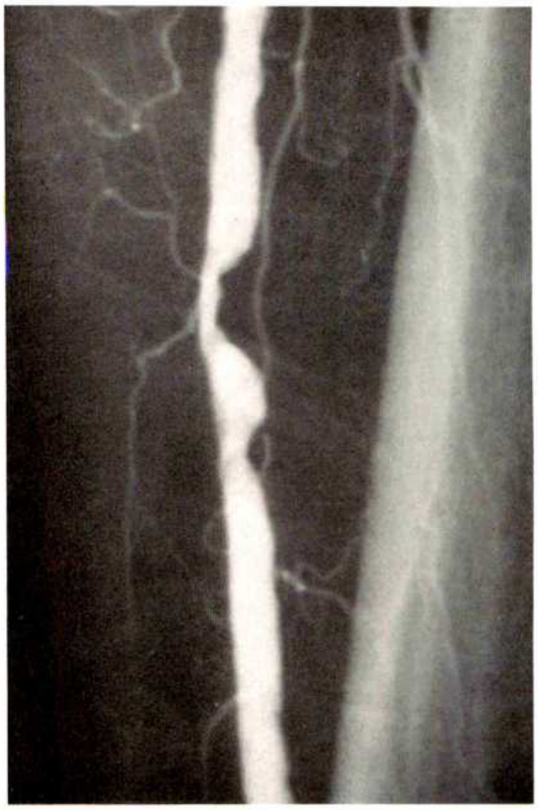

FIG. 2.—*Case* 1. Femoral arteriogram.

CASE REPORTS

Case 1.—A 66-year-old female was discovered to have polycythaemia when she presented with a painful ulcer on the sole of the left foot (*Fig.* 4). She also complained of tiredness, a burning sensation of her face and feet, and headaches.

On examination her face was flushed, and she had a palpable spleen and a blood-pressure of 180/80. All peripheral pulses, including those of left foot, were easily palpable. Blood investigations revealed the following: haemoglobin, 16·7 mg. per 100 ml. (114 per cent); packed-cell volume, 57·1 per cent; white-blood count, 11,000; platelets, 602,000 per c.mm. Her red-cell volume was 39 ml. per kg. and the bone-marrow showed generalized cellularity.

An intravenous pyelogram and other investigations were unremarkable. Two pints of blood were withdrawn and 5 m.c. of radioactive phosphorus were given intravenously. During the following 6 weeks her general health improved but she continued to complain of continuous pain in the left foot and developed ischaemia of the tip of the second and fourth toes. At this time her blood-count was normal: haemoglobin, 13·6 g. per 100 ml., platelets, 150,000 per c.mm. A femoral arteriogram showed no general arterial disease, but near the adductor opening there were two well-demonstrated narrowings (*Fig.* 2). On exploration these lesions proved to be focal mural thrombi with firm pale edges. The central portions had the appearance and consistency of red-currant jelly. Microscopy of the endarterectomy specimen (*Figs.* 5, 6) showed only a moderate amount of atheroma in the vessel wall. Much of the mural thrombus was organized. Seven well-defined elastic laminae indicated separate episodes of thrombosis. The central portion of the thrombus (*Fig.* 6) was recent and unorganized.

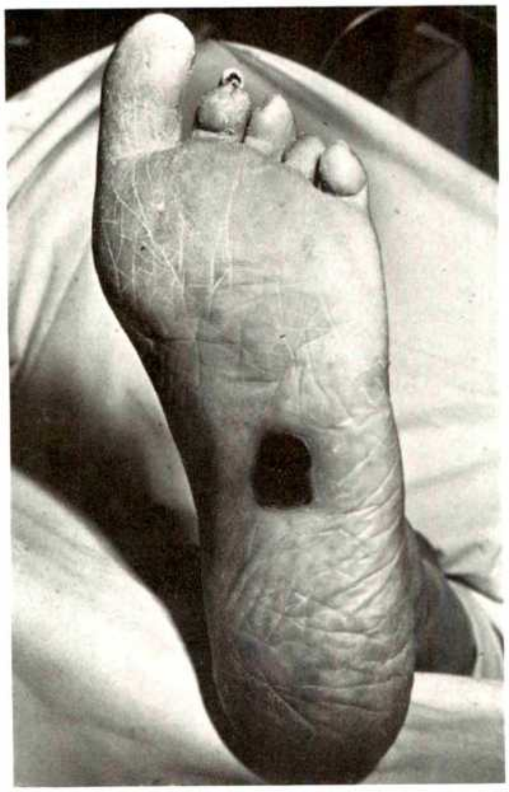

FIG. 4.—*Case* 1. Ischaemic ulcer on the sole of the foot. Note the loss of the tip of the second toe.

After discharge the patient developed no further vascular complications over a period of 2 years.

Case 2.—A 56-year-old male had had the second and then the third toe of his left foot amputated because of the sudden onset of ischaemia $2\frac{1}{2}$ years before the diagnosis of polycythaemia was made (*Fig.* 1). On these occasions his haemoglobin had been 16·1 and 16·5 g. per 100 ml., respectively, but no further investigation had been carried out at that time. Two years later after the sudden onset of left hemiplegia he was referred to the Hammersmith Hospital. Blood investigations on this occasion revealed the following: haemoglobin, 19 g. per 100 ml.; white-blood count, 12,000; platelets, 640,000 per c.mm. His blood-volume was increased and the bone-marrow was hypercellular but other investigations were unremarkable. Two pints of blood were withdrawn and radioactive phosphorus was given. His blood-count returned to normal, but while receiving intensive physiotherapy when he was making good recovery from his hemiplegia he complained of continuous pain in his left foot and was referred to the peripheral vascular clinic.

On examination the blood-pressure was 180/110 and all the peripheral pulses including those of the left foot were

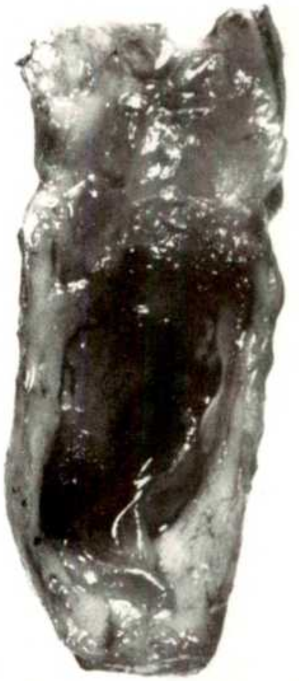

FIG. 5.—*Case* 1. Cross-section of the endarterectomy specimen. Note the multiple laminations of organized mural thrombus on the left, with an area of unorganized thrombus on the right.

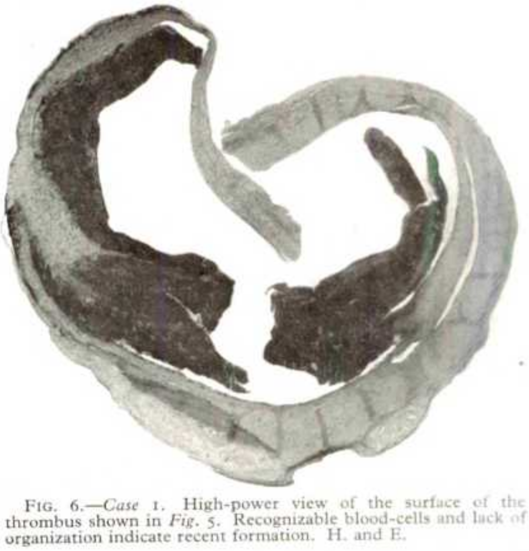

FIG. 6.—*Case* 1. High-power view of the surface of the thrombus shown in *Fig.* 5. Recognizable blood-cells and lack of organization indicate recent formation. H. and E.

palpable. The amputation sites of the second and third left toes were well healed, but the left big toe was cold and ischaemic. A left femoral arteriogram showed narrowing of the popliteal artery (*Fig.* 3). He was placed on the waiting list and admitted later for endarterectomy. By this time his haemoglobin had risen again to 16 g. per 100 ml. and platelets to 400,000 per c.mm. During surgery, therefore, blood-loss was not replaced, allowing a deficit of about 2 pints to occur. The arteries showed moderate atheroma and the narrowed segment proved to be due to focal, organized, laminated mural thrombus. On the third and twentieth days after surgery he had two haemorrhages from the site of the arteriotomies. There was no infection in the wound. At the time of the second haemorrhage the popliteal artery was found to be thrombosed and a Fogarty catheter was used to clear it. Foot pulses did not return but there was no clinical increase of the ischaemia in the foot for about a year, when severe claudication and rest pain developed and despite a further attempt to clear the popliteal artery a Gritti-Stokes amputation became necessary.

DISCUSSION

Untreated polycythaemia vera carries a high risk of intravascular thrombosis. Brown and Giffin (1930) and Norman and Allen (1937) reported an incidence of vascular thrombosis of about 30 per cent. In our 200 cases there was a higher rate of almost 50 per cent. This may be explained by the higher average age in the present series (60 years) as opposed to that in the two series reported above which was 52 and 57 years, respectively.

The initial vascular symptom may be relatively trivial: superficial thrombophlebitis, ischaemia of one toe or finger, minor and transient cerebral or visual disturbances. Nevertheless, the recognition of the underlying polycythaemia is important because, if left untreated, more severe complications may follow. This was shown in 13 patients with permanent hemiplegia about half of whom had suffered minor transient 'strokes'; also 2 patients who required amputation of the leg had had ischaemic toes amputated without diagnosis of the underlying polycythaemia, and 1 patient became blind in one eye after attacks of transient blindness.

The diagnosis of polycythaemia may be difficult on clinical signs, as not all patients have plethora, injected conjunctivae, and a palpable spleen. Also routine haemoglobin estimation may show only a relatively minor increase—no more than 17 g. per 100 ml.—which may be because in polycythaemia occult blood-loss sometimes occurs from the gastro-intestinal tract, and, paradoxically, may even lead to anaemia (Szur, 1971).

The treatment of polycythaemia vera, namely the suppression of bone-marrow with radioactive phosphorus (Szur, Lewis, and Goolden, 1959), may take up to 8 weeks to become fully effective. In a patient with vascular complications, therefore, urgent reduction of blood-volume and red-cell mass is important. Cranley, Fogarty, Krause, Strasser, and Hafner (1963) reported improvement in ischaemic symptoms in polycythaemia after phlebotomy. This improvement is only temporary so that elective, as opposed to emergency, surgery should always await long-term radio-isotope control. Wasserman and Gilbert (1963) found an increase in haemorrhagic and thrombotic complications in patients undergoing surgery with untreated, or insufficiently controlled, polycythaemia. Our experience with *Cases* 1 and 2 seems to support this conclusion as no complications occurred in *Case* 1 with well-controlled polycythaemia, but in *Case* 2, whose polycythaemia was insufficiently controlled, both bleeding and clotting complications occurred.

Although the diagnosis and treatment of polycythaemia are well established, the pathogenesis of its arterial complications is uncertain. The earliest hypothesis to explain arterial occlusions was put forward by Oppenheimer in 1929. He wrote: 'The great viscosity of blood causes increased wear and tear on the vessels, thus favouring the development of arteriosclerosis in much the same way as high blood-pressure does in hypertensive patients.' There is no pathological evidence to support Oppenheimer's hypothesis. Also we found the pattern of arterial involvement to be different from that in arteriosclerosis: in polycythaemia cerebrovascular accidents were four times (39 cases) more common than in coronary artery disease (10 cases), while in patients with arteriosclerosis the reverse is true (Taylor and Calo, 1962); in polycythaemia ischaemia of the toes and fingers commonly occurs before claudications (18 out of 25 cases), while in arteriosclerosis proximal artery occlusion usually precedes ischaemia of digits. In polycythaemia women and men are almost equally affected, while in arteriosclerosis males predominate (*Table II*).

Table II.—COMPARISON OF ARTERIAL COMPLICATIONS IN ARTERIOSCLEROSIS AND POLYCYTHAEMIA VERA

	POLYCYTHAEMIC ARTERIAL LESIONS*	ARTERIOSCLEROTIC ARTERIAL LESIONS†
Coronary artery disease : cerebrovascular accident	1 : 4	4 : 1
Distal peripheral artery disease : proximal peripheral artery disease	3 : 1	1 : 4
Sex ratio:— Male : female	3 : 2	9 : 1

* In the present 98 cases.
† In the 450 cases of Taylor and Calo (1962).

The sudden occlusion of small distal vessels in polycythaemia is generally thought to be due to local thrombosis (Millikan, Siekert, and Whisnant, 1960). We believe that at least in some, if not in all, embolism is the cause. First, in 18 of our patients sudden ischaemia occurred in a single digit, and although other digits of the same limb became ischaemic at later dates, in no case were several digits simultaneously involved. This episodic and asymmetrical course suggests embolism rather than local thrombosis. Secondly, in all 5 patients examined with arteriography a possible source of emboli—a proximal mural thrombus—was found. Thirdly, the surgical removal of the fragile thrombus of red-currant jelly texture prevented further distal ischaemia in *Case* 1.

In the lower limb, therefore, we believe that there is radiological and histological support for embolism being the cause of ischaemia. This evidence is not available as yet for patients with attacks of cerebral ischaemia. However, transient cerebral symptoms have been shown to be caused by micro-emboli in the non-polycythaemic patient (Pickering, 1964) and there may well be a similar mechanism in polycythaemia.

Embolism from mural thrombus would imply the possibility of prevention by thrombectomy. In cases where polycythaemia was well controlled this was successful, but in *Case* 2, who in retrospect would seem ill suited for surgery, it led to complications.

In conclusion, patients with distal arterial lesions should be examined for evidence of polycythaemia, and if this is found, for a possible source of emboli, but surgery should only be undertaken after full medical control of the underlying polycythaemia.

Acknowledgements.—We wish to thank Dr. L. Szur and Mr. Peter Martin for allowing us to study their patients and for their help in the preparation of this paper. We are also grateful to Mrs. Margaret Buttery of the Medical Records Department, Hammersmith Hospital, and to Mr. W. Hinks and Mr. A. M. Moreman for their help with the photography.

HIGH BLOOD VISCOSITY: AN AETIOLOGICAL FACTOR IN VENOUS THROMBOSIS

BY JOHN A. DORMANDY AND JOY B. EDELMAN

ROYAL FREE HOSPITAL, LONDON, AND DEPARTMENT OF PHYSIOLOGY, INSTITUTE OF BASIC MEDICAL SCIENCES,
ROYAL COLLEGE OF SURGEONS OF ENGLAND

SUMMARY

This is a preliminary report on a prospective study of 52 general surgical and gynaecological patients designed to investigate a possible relationship between a high blood viscosity and the development of deep venous, thrombosis (D.V.T.). The blood viscosity of the patients was measured immediately before operation and the development of venous thrombosis was monitored with the radioactive fibrinogen technique. The 11 patients who developed a D.V.T. had a blood viscosity, prior to operation, 21 per cent higher than the patients who did not develop venous thrombosis. The difference was 29 per cent if correction was made for variation in the haematocrit. It was found that a general surgical patient, over 40 years of age, with a preoperative blood viscosity above 4·3 cP (corrected to a haematocrit of 45 per cent) will have a 73 per cent chance of developing a D.V.T. after operation.

VIRCHOW (1846) first described the relationship between pulmonary 'thrombi' and deep venous thrombosis (D.V.T.), and its importance has been appreciated, the thrombi now being termed 'emboli', and confirmed since then. The problem of pulmonary embolism and clinically silent thrombosis has been recognized for many years. Recently, with the introduction and widespread use of ^{125}I-labelled fibrinogen for the detection of D.V.T., it has been shown to be particularly common in postoperative patients, where an incidence of D.V.T. of 30–35 per cent has been found (Hobbs and Davies, 1960; Atkins and Hawkins, 1965; Kakkar and Flanc, 1968; Flanc, Kakkar, and Clarke, 1968; Negus, Le Quesne, Brown, and Chapman, 1968; Kakkar, 1969; Howe, 1970).

Knowing this high incidence of D.V.T., attempts have been made, using the new diagnostic methods, to reinvestigate the aetiology of this condition. In addition, a search has been made to find a screening test which may delineate the group of patients at particular risk of developing D.V.T., so that special preventive measures may be concentrated on this group.

According to Virchow's (1846) triad, the factors predisposing to thrombosis are stasis, increased coagulability of the blood, and changes in the vessel wall. Damage to the intima of the vein in situations other than direct trauma is unlikely and therefore can be discounted as a frequent cause of the deep venous thrombosis. There has, however, been considerable emphasis in the past on changes in the constituents of the blood, particularly the platelets, at the time of surgery. It has been shown that increased platelet adhesiveness occurs in the postoperative period, in the puerperium (Wright, 1942), in recurrent venous thrombosis, as well as in thromboembolic pulmonary hypertension (Hirsh and McBride, 1965). However, in a prospective study no correlation was observed between changes in platelet adhesiveness and the development of D.V.T. (Negus, Pinto, and Brown, 1969). Changes in platelet adhesiveness were of no value in the prediction of postoperative venous thrombosis.

There is much more circumstantial evidence relating postoperative D.V.T. to perioperative venous stasis. McLachlin, McLachlin, Jory, and Rawling (1960) demonstrated that reduced flow occurs in patients in the horizontal supine position, and Clark and Cotton (1968) showed that during general anaesthesia popliteal and external iliac vein flow is reduced by at least 50 per cent. This has led to the trial of a number of techniques designed to reduce perioperative stasis, and thus thrombosis. There has, however, been no indication why in a group of patients subjected to similar conditions of reduced venous flow some develop D.V.T. but not others. An abnormal increase in blood viscosity may give rise to a situation of relative stasis. Blood viscosity, which has long been recognized as one of the primary determinants of blood-flow, has been studied very little in a clinical context, although there have been isolated reports of abnormal blood viscosity in a number of conditions associated with poor blood-flow (Dormandy, 1970; Dintenfass, 1971).

FIG. 1.—Wells-Brookfield microviscometer.

The present authors have studied patients with established D.V.T. confirmed by ^{125}I-fibrinogen studies and phlebography, and found them to have a higher blood viscosity than normal control subjects (Dormandy and Edelman, 1971). It was decided, therefore, to carry out a prospective study of patients undergoing operation, with reference to their blood viscosity and the subsequent development of venous thrombosis.

MATERIALS AND METHODS

Fifty-two patients admitted for elective general surgical or gynaecological operations were studied. Their ages ranged from 20 to 82 years. Patients were excluded if the operation was to be on the legs, groin, or thyroid gland, or if they had a history of a recent thrombotic episode. The thyroid was blocked with sodium iodide and 100 μc. of ^{125}I-labelled human fibrinogen were given intravenously preoperatively. The legs were scanned pre- and postoperatively on the day of operation and on the first, third, fifth, seventh, and ninth postoperative days. In most cases with positive scans confirmatory phlebography was performed.

Blood viscosity was measured with a Wells-Brookfield microviscometer (*Fig.* 1) which is an adaptation of an industrial machine and has previously been used extensively for studying blood (Dormandy, 1970). A conical disk is rotated in the small rhodium cup containing the blood sample by a variable-speed motor, through a beryllium-copper spring connexion. The drag on the rotating cone which is due to the viscosity of the sample can then be measured by the torque on the spring suspension. Although the difference in velocity between the rotating cone and the cup increases towards the periphery the distance between the two surfaces also increases. Therefore, with a cone of the correct angle the velocity gradient or shear rate will be kept constant throughout the sample. Thus, viscosity in centipoises (cP) can then be calculated from the dimensions of the chamber, the rotational speed of the cone, and the torque in the spring suspension. The cup is surrounded by a water-jacket to keep the sample at 37° C. because viscosity is critically dependent on temperature.

The viscometer was calibrated on each day of use with a fluid of known viscosity. The viscosity was estimated at a shear rate of 230 sec.$^{-1}$ as this is thought to be in the physiological range (Whitmore, 1967; Dormandy, 1970). Immediately preoperatively 10 ml. of venous blood were anticoagulated with 125 I.U. solid lithium heparin and the viscosity was measured on 1-ml. samples. The same heparinized venous samples were used to estimate the haematocrit because of the important relationship between viscosity and red-cell concentration. Although a high haematocrit is often accompanied by a high viscosity, many patients with a markedly raised viscosity may not have an abnormally high haematocrit (Dormandy, 1970).

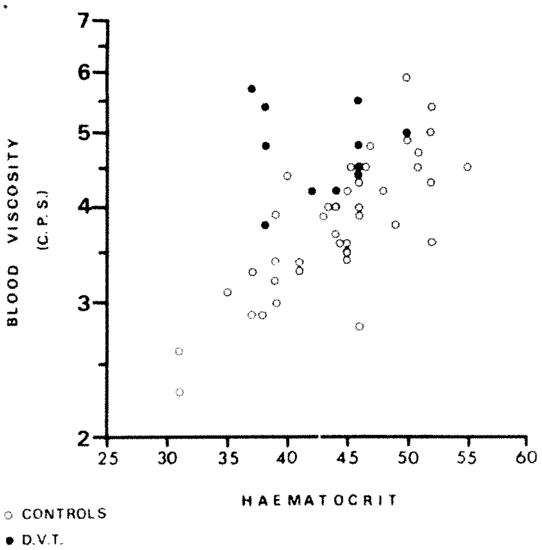

FIG. 2.—Preoperative blood viscosity plotted on a logarithmic scale against the haematocrit.

Table I.—OPERATIONS PERFORMED IN THE PRESENT SERIES

Operation		*No. of Patients*
Major thoracic		
Thoracotomy		2 (1)
Lobectomy		1 (1)

Hysterotomy		2
Incisional hernia		2
Dilatation and curettement		1
Salpingostomy		1
	Total	18

Figures in parentheses refer to the patients who developed post-operative D.V.T.

RESULTS

Eleven out of 52 patients developed D.V.T. following surgery. Further details of the patients are given in *Tables I* and *II*. The comparatively low incidence of D.V.T. was probably due to the fact that all patients above the age of 20 years were included in the trial; in fact none of the 14 patients under 40 years developed D.V.T. The patients who developed D.V.T. had a measured blood viscosity before operation 21 per cent higher than those patients who did not develop D.V.T.

It has previously been shown that there is a direct linear relationship, in the physiological range, between the red-cell concentration and the logarithm of the blood viscosity (Dormandy, 1970). This relationship can be seen in *Fig.* 2, where the blood viscosity (using a logarithmic scale) is plotted against the haematocrit. To allow a direct comparison between the blood viscosity of individual patients differences in the haematocrit have to be eliminated. Using a regression line calculated from the control results, the measured viscosities were converted to a standard haematocrit of 45 per cent. *Fig.* 3 shows the result obtained. If differences in the haematocrit of the various samples are eliminated in this way the preoperative blood viscosity of patients who later developed a D.V.T. was 29 per cent higher than the viscosity of patients who did not develop a D.V.T.

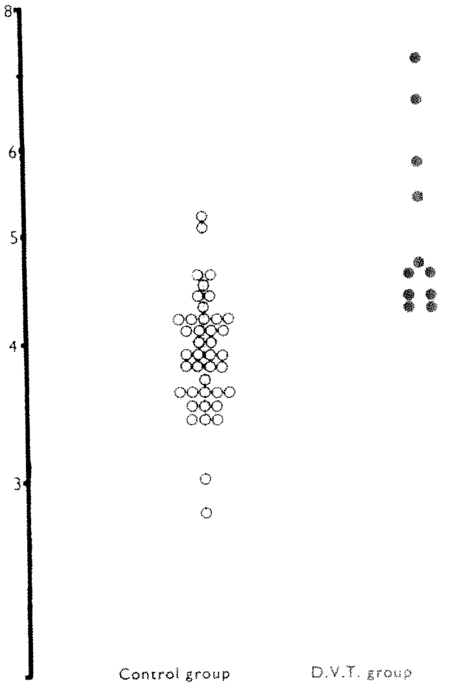

FIG. 3.—Preoperative blood viscosity in 52 patients corrected to a standard haematocrit of 45 per cent ($t = 5{\cdot}5$; $P < 0{\cdot}001$).

Table II.—DETAILS OF PATIENTS WHO DEVELOPED DEEP VENOUS THROMBOSIS

AGE AND SEX	DISEASE	OPERATION
65 M.	Carcinoma of stomach	Gastrectomy
68 F.	Gall-stones	Cholecystectomy
45 F.	Menorrhagia	Hysterectomy
54 M.	Bladder stone	Cystotomy
66 M.	Carcinoma of stomach	Gastrectomy
62 M.	Papilloma of rectum	Anterior resection
64 M.	Carcinoma of lung	Lobectomy
65 M.	Gall-stones	Cholecystectomy
66 F.	Prolapse	Hysterectomy
60 F.	Prolapse	Vaginal repair

Table III summarizes these results. Patients who developed postoperative D.V.T. had a blood viscosity prior to surgery 21 per cent higher at the measured haematocrit and 29 per cent higher at a standard haematocrit than control subjects who did not develop D.V.T. These differences were significant at the level of $P = 0{\cdot}005$ and $P = 0{\cdot}001$ respectively. All the patients who developed D.V.T. had a preoperative blood viscosity above 4·3 cP when corrected to a standard haematocrit of 45 per cent. Only 7 of the patients who did not develop a D.V.T. had a blood viscosity above this level, and 3 of these patients were under 40 years of age.

Table III.—SUMMARY OF THE RESULTS IN THE PRESENT SERIES

	NEGATIVE D.V.T.	POSITIVE D.V.T	DIFFERENCE	SIGNIFICANCE OF DIFFERENCE
Haematocrit (per cent)	44·6	42·8	−1·8	Not significant
Measured viscosity (cP)	3·93	4·75	+0·82	$P = 0{\cdot}005$
Corrected viscosity (cP)	3·95	5·12	+1·17	$P = 0{\cdot}001$

It thus appears that if a surgical patient over 40 years of age has a blood viscosity above 4·3 cP (corrected to a haematocrit of 45 per cent) before operation, he has a 73 per cent chance of developing a D.V.T. following surgery.

DISCUSSION

Although the number of patients studied was small, an important finding has emerged from this preliminary trial: an elevated blood viscosity before operation is significantly associated with the development of postoperative D.V.T. This appears to be the first physicochemical, as opposed to clinical (such as previous thrombotic episodes or age), predisposing factor to have been found in this disease. It could be used as a screening test to select patients for perioperative radioactive fibrinogen scanning or for the application of any special prophylactic measures which may be available.

While continuing with the present trial, the investigations are being extended to try to discover the reason for the high viscosity in some patients. At present very little is known about the causes of elevated blood viscosity other than a high haematocrit. There is known to be a general relationship between fibrinogen and blood viscosity (Chien, Usami, Dellenback, Gregerjen, Nanninga, and Guest, 1967; Merrill and Pelletier, 1967) and there may be a relationship between viscosity and blood-lipid patterns. An extended project, including investigation of these and other aspects, is now being undertaken.

The ideal prophylactic treatment of patients found to have a high blood viscosity prior to surgery would be direct treatment of the high viscosity; unfortunately no suitable therapy is yet available for this purpose. Low-molecular-weight dextran has been suggested as a possible agent for reducing blood viscosity; however, it has recently been shown to have no specific effect on blood viscosity other than by simple haemodilution (Dormandy, 1971). A recent *in vitro* study using small doses of heparin (Negus, Pinto, and Slack, 1971) demonstrated not only decreased platelet adhesiveness but increased lipoprotein-lipase activity after its administration. It may be that the clearing lipase activity might reduce blood viscosity by reducing the lipid level.

MECHANICAL SUTURES IN SURGERY

By FELICIEN M. STEICHEN AND MARK M. RAVITCH

DEPARTMENTS OF SURGERY OF THE UNIVERSITY OF PITTSBURGH AND THE MONTEFIORE HOSPITAL, UNIVERSITY OF PITTSBURGH HEALTH CENTER,
PITTSBURGH, PENNSYLVANIA

SUMMARY

Following the original introduction of an automatic stapling instrument producing B-form staples by de Petz (1924, 1927), there has been derived from the very important first generation of Soviet stapling instruments a second generation of American stapling instruments characterized by: (1) the use of pre-loaded, pre-sterilized, and disposable staple cartridges; (2) the adaptability of one instrument to a variety of cartridges for use in a variety of tissues and operative situations; (3) the transfer from the instrument itself to the disposable cartridge of delicate and fragile moving parts simplifying the maintenance and operation of instruments. The instruments have found wide and satisfactory application in numerous areas of thoracic, vascular, gastro-intestinal, and gynaecological surgery.

MECHANICAL suture is the method of closing or anastomosing soft tissues in which the suture is made semi-automatically with a stapling apparatus activated by the surgeon's hand. The first useful stapling instrument was developed by the Hungarian de Petz (1924, 1927). Another Hungarian, Hültl (1911), had actually preceded de Petz in the development of a stapling device. Of Hültl's instrument, we know that it was extremely cumbersome, weighed 5 kg., and took 2 hours to assemble. De Petz's instrument (*Fig.* 1) provided a leak-proof, haemostatic but crushing closure of the stomach, duodenum, and colon. However, the gross staples of German or new silver, in spite of their correct B formation, were never relied upon for definite closure of the bowel. Friedrich in 1934 (*Fig.* 2), Sandor in 1936, Tomoda in 1937, and Nakayama in 1964 (*Fig.* 3) improved on de Petz's initial idea with modifications or instruments of their own.

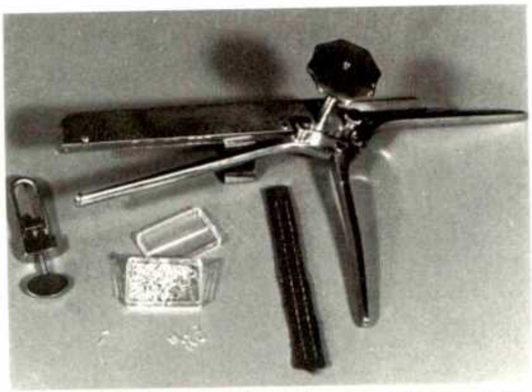

FIG. 1.—The de Petz stapler. After positioning and closing the instrument, the free ends are kept tight by the application of a U-shaped clamp shown at the left-hand side of this picture. The staples of German silver are introduced by turning the knob at the upper right-hand side of the figure in an anti-clockwise direction, thus activating a 'crémaillère' introducing one staple at a time. A double-row, finished staple line is also shown.

As interest in mechanical sutures grew, their use was extended beyond the gastro-intestinal tract. Gudov in 1951 devised an instrument for vascular anastomosis and subsequently a great impetus to mechanical suture devices was given by the Institute for Experimental Surgical Apparatus and Instruments in Moscow (Androsov, 1956, 1963, 1970; Amosov and Berezovsky, 1961; Goldman, 1964; Betts and Takaro, 1965; Gritsman, 1966; Lagache and Vankemmel, 1970) (*Figs.* 4, 5).

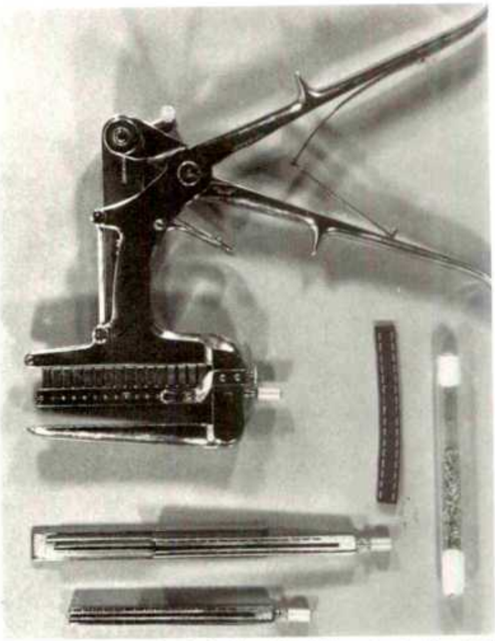

FIG. 2.—The stapler devised by Friedrich using similar staples to those of de Petz. However, exchangeable magazines are provided. Compression of the tissues to be sutured is achieved by squeezing the handle of the instrument once, approximating the jaws. A safety catch is then released and a second compression of the jaws drives the staples home.

Elsewhere Busto and Bucherl (1954) described the experimental use of staples in the closure of bronchial stumps, and Samuels in 1955 reported the use of metal clips in experimental end-to-end anastomoses of arteries. Vogelfanger and Beattie (1958) in Canada and more recently Nakayama (1964) in Japan devised instruments for vascular anastomoses, but their application is essentially limited to the suturing of non-atherosclerotic vessels since everted flanges of the opposing vessels are needed for the procedure.

Cooper, Malina, and Tolins (1967) devised and used an elegant repeating stapler, introducing one staple at a time. Their instrument is especially helpful in areas where larger instruments cannot be accommodated.

Our earlier experience with the original Soviet instruments convinced us of their potentialities (Ravitch, Brown, and Daviglus, 1959; Ravitch, Steichen, Fishbein, Knowles, and Weil, 1964; Ravitch, Rivarola, and Van Grov, 1966). Interest by American designers and manufacturers resulted in the creation of a family of six staplers; four of them were developed from the basic principles worked out by the Institute in Moscow, one was derivative only in its purpose, and one was wholly different and unique (U.S. Surgical Corp., N.Y.).

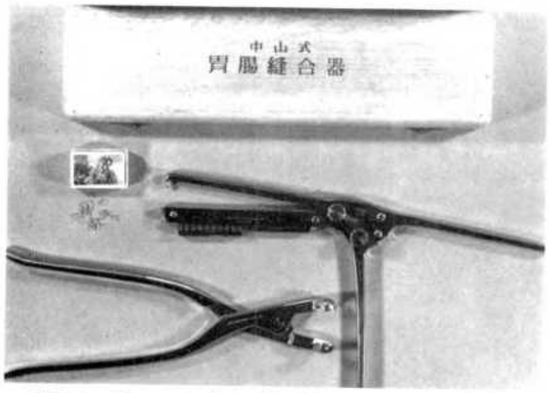

FIG. 3.—The stapler devised by Nakayama. This consists in essence of a simplified de Petz clamp. The staples are introduced by compressing the two cartridges with the heavy forceps seen at the lower left-hand side of the picture.

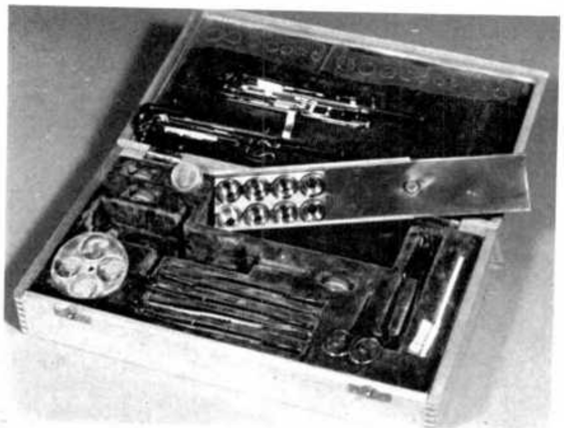

FIG. 5.—The Soviet ASTS instrument devised for the end-to-end anastomosis of vessels. While the vascular instruments do provide perfect everting sutures in healthy vessels, they are composed of many parts, their use is complicated, and the technique is applicable essentially only in normal vessels.

INSTRUMENTS

The development of pre-loaded, pre-sterilized, disposable cartridges together with disposable anvils and the incorporation of all the small moving parts in the disposable cartridge has done away with the technical limitations and the cumbersome hand-loading of the original Soviet instruments.

The very fine stainless-steel staples used as sutures are essentially non-reactive in the tissues. The size and disposition of the staples within each cartridge and the design of the corresponding anvil are adapted to the recognized need in suturing a given structure, viz., vessels, bronchus, stomach, intestines, or lung. Each instrument can accommodate a variety of cartridges so as to reduce the required number of instruments to a minimum.

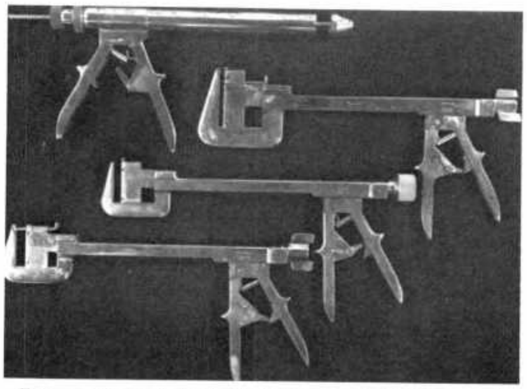

FIG. 4.—Three of the instruments of the UKB (25, 40, 60) variety devised by the Institute for Experimental Surgical Apparatus and Instruments in Moscow are seen superposed from left to right. In the upper left-hand side of the figure is shown the PKS which is used for end-to-end inverting anastomoses in low anterior rectal resections. The instrument is introduced through the anus. For oesophagogastric or oesophagojejunal anastomoses it has to be introduced through a stab wound in the bowel.

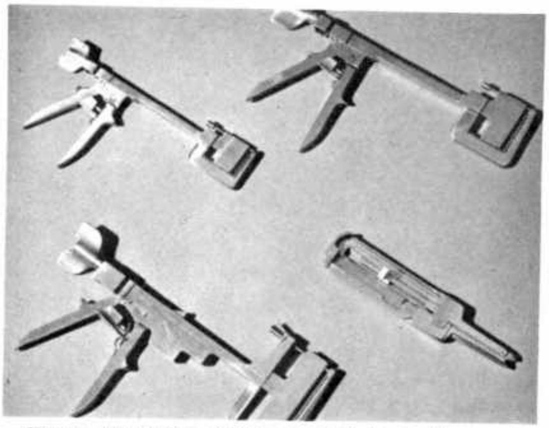

FIG. 6.—From left to right in an anticlockwise direction are shown the TA-90, TA-30, TA-55, and GIA. The TA instruments are used for linear sutures and closures in gastro-intestinal, pulmonary, gynaecological, and vascular surgery. The GIA instrument is employed for transection and simultaneous closure of the intestine and lung, as well as for anastomoses in the gastro-intestinal tract.

The six instruments are used for: (1) linear sutures and closures in gastro-intestinal, pulmonary, gynaecological, and vascular surgery; (2) transection and simultaneous closure of the intestine; (3) anastomoses in gastro-intestinal surgery; (4) ligating and dividing vessels; (5) closing skin and fascia. There are three linear suture instruments (the TA-30, 55, 90), one anastomosing instrument (the GIA), one ligating and dividing instrument (the LDS), and one instrument for closing of fascia and skin.

With the three TA or linear instruments (*Fig.* 6) the tissues to be sutured are first gently compressed between the jaws of the clamp. An entire suture line is then driven home, the size of the staples and the length and pattern of the suture line depending upon the cartridge employed. The designations 30, 55, and 90 refer to the length in mm. of the double staggered row of staples inserted, these instruments placing simultaneously 11, 18, and 33 staples repeatedly.

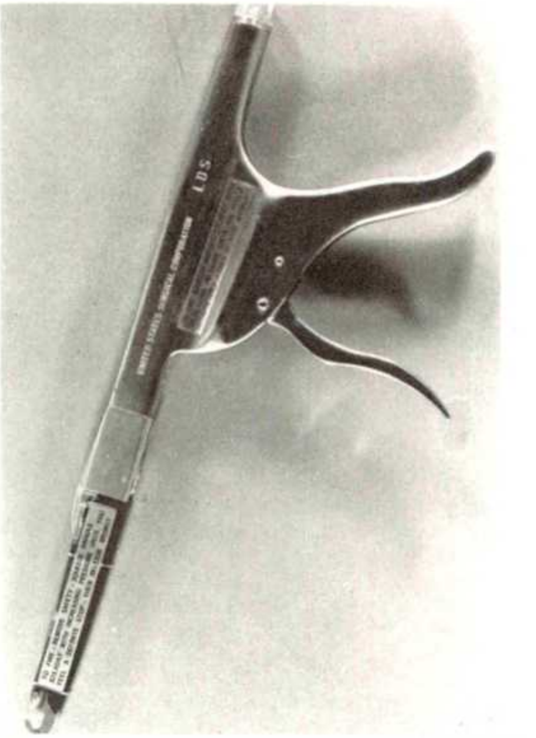

FIG. 7.—The LDS stapler with cartridge. In one operation this instrument doubly ligates and divides between staples tissue contained within the hook located at the tip of the cartridge, which can be operated thus 15 times before reloading.

The GIA (*Fig.* 6) consists of two interlocking halves forming a flat handle with two projecting limbs. With the instrument open, its limbs grasp between them the walls of the organs to be anastomosed or of tissue to be sutured and transected. The basic anastomosis is serosa to serosa and side to side. The cartridges provide two double rows placed simultaneously, thus avoiding the need for the reinforcing sutures required in the single-row Russian instrument. The staggering of the pushers for the introduction of the double rows of staples, the disposable knife, and the transfer of the innumerable tiny staple drivers into the disposable cartridge make the instrument easy to activate and maintain.

One of the most interesting instruments is the LDS (*Fig.* 7), which is the product of 8 years of hard work and innumerable models based on a wide variety of principles, as regards staple design, jaw design, and method of activation (Ravitch, Hirsch, and Noiles, 1973). The instrument as used with a pre-loaded, pre-sterilized, and disposable magazine does the following things: (1) it isolates safely within it by a positive mechanism whatever tissue is delivered to it, not relying on the operator to judge the amount of tissue which might or might not be safely grasped; (2) it doubly ligates this tissue with absolute security whether it is a tiny delicate isolated vein or a mass of fat and blood-vessels; (3) when the handle is squeezed the instrument doubly staples the tissue enclosed and divides it between the staples in the same operation.

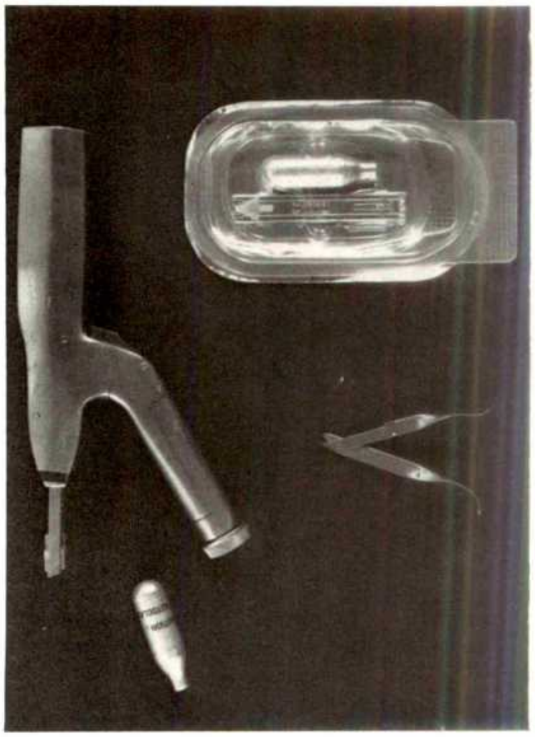

FIG. 8.—The skin stapler is shown together with a cartridge containing 25 staples and the staple remover, which is not unlike the one used for the removal of Michel clips. The sterile package contains a small CO_2 cylinder which provides the driving force in the instrument, as well as the staple cartridge.

A totally different kind of instrument in conception and historical background is the skin stapler (*Fig.* 8). This instrument is powered by a CO_2 cartridge. The disposable, pre-loaded, pre-sterilized magazine contains 24 staples which when closed form in a complete rectangle. The time-saving obtained with this instrument is substantial.

SURGICAL TECHNIQUES

With increasing experience and confidence in the instruments, we have found that they can be used in a wide variety of operative procedures. In the Billroth-II type of gastric resection (Ravitch and Steichen, 1973) the LDS is used for the ligating and dividing of vessels along the curvatures, the duodenum and stomach are closed with the TA instruments, a side-to-side gastrojejunostomy is performed with the GIA, and the stab wounds used to introduce the limbs of the GIA are closed with a TA instrument. We prefer an antecolic anastomosis placed on the anterior wall of the stomach (Ravitch and others, 1964), although retrocolic and posterior anastomoses can be performed with equal ease.

If a Billroth-I reconstruction is contemplated the gastroduodenal continuity may be established by a triangulating, partially inverting, partially everting, end-to-end anastomosis with the help of the TA-55 stapler (McGinty, 1970; Ravitch and Steichen, 1973) after the proximal portion of the stomach has been sealed by a double staggered staple row applied by the TA-90 and a portion corresponding to the width of the duodenum has been excised from this closure along the greater curvature. Another elegant technique for this reconstruction is Reynolds's (1973) application of the GIA instrument to Poth's (1950) technique of gastrectomy and gastroduodenostomy, in which a 'step-like' resection of the body of the stomach, starting at the lesser curvature, results in the creation of a tube along the greater curvature. This tube is fashioned so as to present a circumference matching the one of the duodenum and it may then be anastomosed to the duodenum manually or by using the triangulating, partially inverting, partially everting, end-to-end anastomosis.

For the excision of a gastric ulcer the TA-90 has been used (Ravitch and Steichen, 1973). If the ulcer is situated on the posterior wall of the stomach, for instance, the vessels along the greater and lesser curvatures are cleared with the LDS instrument sufficiently to allow for mobilization of the stomach. The gastric wall is then grasped with Babcock clamps on either side of the ulcer; the ulcer and surrounding normal gastric wall are introduced between the jaws of the TA-90 instrument. An elliptical resection results, leaving a transverse closure of the posterior wall of the stomach. The TA-55 serves admirably for everting, mucosa-to-mucosa, non-obstructing transverse closure of the Heineke-Mikulicz pyloroplasty, while the GIA is used routinely for Finney pyloroplasty and gastro-enterostomy (Ravitch and Steichen, 1973).

In small- and large-bowel surgery a special type of functional end-to-end anastomosis—previously described in a manual suture technique by Poth (1950)—in which the cut ends of two loops of bowel are placed together in a shotgun fashion, the septum between them is divided with this instrument, and then the open end of the bowel is closed over with the TA-55, or sometimes the TA-90 is utilized (Steichen, 1968). Currently, we usually divide the small and large intestines between the arms of the GIA instrument, thus closing at the moment of transection each end with two rows of the extremely fine staples, whatever might be the ultimate plan of anastomosis or resection (Ravitch and Steichen, 1973). The anastomotic clamp also serves very well to divide the spur of a Mikulicz enterostomy or of the Duhamel operation for Hirschsprung's disease in one stage and at the same time as the original operative procedure (Steichen, Talbert, and Ravitch, 1968).

With the use of these instruments there is an important saving of time in such extensive procedures as colon by-pass, colon interposition with lower oesophagectomy, and especially colon replacemen and total oesophagectomy in one stage (Steichen 1971). In the latter procedure double suture line and transection of the gastric fundus, functiona end-to-end colocolostomy or ileocolostomy, end-to-side cologastrostomy, end-to-side cervical or thoracic oesophagocolostomy, and incidental appendectomy are all performed with the help of staplers In patients undergoing oesophagogastrectomy the stomach is mobilized along the greater and lesser curvatures with the LDS and the body of the stomach is transected between two TA-90 suture lines Intrathoracic end-to-side oesophagogastrostomy is then performed with the GIA. We have used the TA-55 instrument in the closure of oesophageal and pharyngeal diverticula and the GIA in the creation of a reversed gastric tube for the palliative by-pass o inoperable oesophageal carcinoma (Ravitch and Steichen, 1973).

In thoracic surgery the TA-90 or TA-55 instrument is used in the excision of emphysematous blebs (Steichen, 1971). The individual bleb is grasped and held up with Babcock clamps and then slipped into the jaws of the stapling instrument at the junction of the bleb with the relatively normal lung tissue. Following the stapling of the neck of the bleb, the latter is removed distal to the instrument, obtaining a haemostatic and air-tight closure. The very narrow suture line does not encroach on the expansion of the underlying lung tissue. Wedge and segmenta resections may be performed similarly, by holding the wedge or segment to be resected and introducing the TA-90 or TA-55 instrument proximal to the lesion to be excised (Steichen, 1971). Following staple closure of the lung at the elected site of resection a tangential excision of the specimen may then be performed. If this excision represents all or most of a given segment, ligation of the corresponding segmental artery is advisable. In wedge resections the GIA instrument may also be used in a double application, producing a pie-shaped excision of the specimen and surrounding tissue with automatic transection and closure of both the remaining lung and the specimen (Steichen, 1971).

The TA-30 instrument using cartridges containing the 4·5-mm. staples is employed in the closure of the main bronchus after pneumonectomy, and the same instrument using staples of 3·8 mm. in the closure of lobar bronchi (Dart, Scott, and Takaro, 1970 Steichen, 1971). A third cartridge containing very fine staples may be used with the same instrument in the closure of the pulmonary artery after pneumonectomy and the pulmonary vein(s) after lobectomy or pneumonectomy (Steichen, 1971). A not-anticipated use of the TA-90 or TA-55 instrument is the division of an incomplete pulmonary fissure in pulmonary lobectomy; the GIA instrument may also be used for this purpose (Steichen, 1971). Following control of the hilus after closure and transection o the vessels and the bronchus, the remaining bridge between the two lobes, the dissection of which results so frequently in an oozing and bubbling surface, is closed with a row of staples. This suture line is narrow and avoids any compromise of the expanding remaining lobe.

The vascular staples contained in one of the fou cartridges that fit the TA-30 have been used fo closure of the patent ductus arteriosus and more recently for closure of the Potts aortopulmonary anastomosis (Leand, Bender, Martz, Crisler, Agnew, and Gott, 1971) at the time of the definitive open-heart correction of the tetralogy of Fallot. The vascular staples are equally useful in the closure of the hepatic end of the portal vein in end-to-side portacaval shunts (Steichen, 1971). The TA-30 instrument accommodates a special cartridge for the compartmentation of the inferior vena cava in the prevention of pulmonary embolism (Ravitch, Snodgrass, McEnany, and Rivarola, 1966).

Table I.—OVER-ALL EXPERIENCE WITH AUTOSUTURE INSTRUMENTS DURING THE PERIOD FROM 6 JUNE, 1967, TO 15 SEPTEMBER, 1971

TYPE OF SURGERY	NO. OF PATIENTS	NO. OF OPERATIONS	NO. OF PROCEDURES	NO. OF COMPLICATIONS	NO. OF DEATHS
Gastric	69*	70	167	6	—
Intestinal	60†‡	62	120	3	—
Oesophageal	15	15	55	2	—
Pulmonary	49§	50	104	6	1
Vascular	14	14	16	—	—
Gynaecological	8	8	8	—	—
Miscellaneous	3*	3	7	—	—
Total	218	222	477	17	1

Four patients were operated on twice with autosuture instruments:—
* Inguinal herniorrhaphy and gastrectomy.
† Closure of fistulae and ileocolectomy.
‡ Ileocolectomy and Duhamel procedure.
§ Staged bilateral resection of pulmonary blebs.

In gynaecological operations we have used the TA-55 for the closure of the vaginal cuff in abdominal hysterectomies (Kahn, 1968) and the GIA for the suturing of the broad ligament in vaginal hysterectomies.

INSTRUMENT AND STAPLE CHARACTERISTICS

Mechanical suturing assures many of the factors which are desirable in a bowel anastomosis or tissue closure, such as: fixation and coaptation of the structures to be sutured; avoiding the shifting and minimal tearing that occur in even the most carefully hand-performed suture; needle and suture holes that are of the same fine calibre, since the staple is both a needle and a suture; speed and neatness resulting in minimal trauma to and oedema of the wound edges; and finally minimal inflammation and necrosis because of the non-strangulating nature of the tissue closure involved in the B shape of the closed staple. The quality of the actual suturing depends little on the surgeon's experience and skill, although he still has to learn when and how to use the instruments, how to prepare the tissues, etc. As in other areas of human endeavour, machines cannot replace or improve man's thinking; if used properly they can, however, add precision, neatness, and speed in the execution and completion of his decisions.

Studies have shown that the tissues distal to the staple line remain viable, and that in the gastro-intestinal tract the mucosa-to-mucosa approximation does not require inversion or reinforcement (Ravitch, Lane, Cornell, Rivarola, and McEnany, 1966; Ravitch and Rivarola, 1966; Steichen, 1968). Healing is accelerated because of minimal trauma and oedema and the non-reactive nature of the stainless-steel staples. Staples have not been deformed or damaged over the 4-year period that we have been able to follow some of our patients. The staples have not shifted, with the exception of those in inverting intestinal anastomoses which may be eliminated into the bowel lumen with time. In gastric and intestinal surgery we have been consistently impressed with the immediate patency of anastomoses and the early return of intestinal transit (Weil and Steichen, 1970; Steichen, 1971). Air-leaks or haemorrhagic oozing following pulmonary blebectomy, wedge resection, segmentectomy, and division of an incomplete fissure have been virtually eliminated by the stapling techniques.

RESULTS

From June, 1967, to September, 1971, a total of 218 patients have undergone 222 operations (*Table I*). These amounted to 477 individual staple procedures. The definition of a 'staple procedure' is best illustrated by a Billroth-II gastrectomy, in which four stapling procedures would be involved: (1) ligating and dividing vessels, (2) duodenal closure, (3) gastric closure, and (4) gastrojejunostomy. In addition, the skin was closed with the staples in some 150 patients.

In these 477 staple procedures we encountered 13 complications related to the use of the instruments (*Table II*). There was postoperative anastomotic bleeding in 5 patients, 3 of whom required reoperation. There were 5 suture-line leaks, of which 4 were temporary and self-limiting. One occurred some 3 weeks after an emergency gastrectomy for bleeding from a duodenal ulcer. In this patient the duodenal stump had been drained, which is not our usual technique. Leakage of bile occurred at a time when the patient was already at home and eating a regular diet. The leak was limited and healed spontaneously. In the second patient, a 10-day-old baby with a right colectomy for in utero caecal perforation and neonatal obstruction from the resulting inflammatory mass, a small amount of faeces was discharged from the wound on one occasion at a time when normal transit was already established. Seventeen days later the child demonstrated the classic picture of Hirschsprung's disease; hence the anastomosis had been performed proximal to a mechanical obstruction. In 1 patient who had a total oesophagectomy and oesophagocologastrostomy performed in one stage there was a small and temporary discharge of saliva through the neck incision. One leak in a heavily irradiated colon was manifested after 2 weeks with no complications and apparent recovery following colostomy closure. The radiation had been given 12 years previously for treatment of an adenocarcinoma of the uterus. At that time, severe radiation colitis had resulted; however, evaluation prior to closure of the colostomy did not contra-indicate an attempt at reconstructing normal bowel passage. Finally, a leak occurred after a technically difficult colorectal anastomosis. It was treated by local drainage alone. The patient left the hospital with a healed and well-functioning anastomosis.

Table II.—COMPLICATIONS RELATED TO THE USE OF AUTOSUTURE INSTRUMENTS

COMPLICATION	OPERATION	NO. OF COMPLICATIONS	
		Related	Questionable
Suture leak			
Late	Duodenal closure	1	—
Small	Ileocolic anastomosis	1	—
	Oesophagocolic anastomosis	1	—
Post-irradiation	Colocolic anastomosis	1	—
Limited	Colorectal anastomosis	1	—
Postoperative bleeding			
Reoperation (2)	Gastrectomy	4	—
	Cologastrostomy	—	1
Limited	Wedge gastrectomy	1	—
	Pulmonary wedge	—	3
Air leak			
Limited	Pulmonary wedge	2	—
Bronchopleural fistula			
Expired	Pulmonary lobectomy	1	—
	Total	13 (5·8 per cent)	4 (1·8 per cent)

Pulmonary air leaks for 24–36 hours were observed in 2 patients with a wedge resection. A bronchopleural fistula after a right lower lobectomy for pulmonary suppuration in advanced Wegener's granulomatosis was fatal in 1 patient.

In another 4 patients the postoperative complications were questionably related to the use of the instruments. In 3 of these patients there was some postoperative bleeding through chest tubes after a pulmonary wedge resection, 2 of these patients having had, in addition, extensive decortications.

In the fourth patient there was presumed slow intraperitoneal bleeding over a 24-hour period following a tangential wedge resection of the stomach for a posterior penetrating ulcer. No blood was aspirated through the nasogastric tube in this patient and he recovered without reoperation.

DISCUSSION

Mechanical suture instruments do not make a virtuoso out of a tiro and do not make difficult surgery possible for the unskilled or untrained. Nor is it possible to use these instruments in all situations and on all patients or on all lesions. Nevertheless, the suturing and anastomosing instruments, for instance, deliver their staples with a uniform degree of compression, with a uniform spacing in a manner that the best of us cannot achieve manually, and without the trauma involved in picking up bowel bronchus or blood-vessels with a forceps, penetratir it with a needle, pulling through the thread, takir it up again, and penetrating it once more. In tl Soviet Union where distances between hospitals a great and transportation of very sick patients difficult at times, these instruments were original created partly in order to increase technical abili and safety in the hands of the isolated surgeon pe forming major operations only occasionally. In con paring large series of gastrectomies Gritsman in 19 reported a mortality of 3·2 per cent in gastrectomi performed manually for gastric and duodenal ulce as compared with 1 per cent if staplers were use Mortality in gastrectomy for carcinoma was 10·4 ar 3·6 per cent respectively. The number of new ar ingenious ways in which these instruments can l employed is becoming apparent as they are beir used more widely, and satisfaction with them seen to be general.

THE EFFECT OF ANTRAL ACIDIFICATION ON ACID SECRETION STIMULATED BY PENTAGASTRIN*

By M. H. WHEELER, R. J. PRESCOTT, and A. P. M. FORREST
DEPARTMENT OF CLINICAL SURGERY, UNIVERSITY OF EDINBURGH

SUMMARY

In 6 dogs with innervated antral pouches (4 with vagally innervated fundic pouches and 2 with vagally denervated fundic pouches) the effect of irrigating the antral pouches with acid on the pentagastrin-induced secretion from the fundic pouches was assessed. A range of doses of pentagastrin (0·25–8·0 μg. per kg. body-weight per hour) was given by intravenous infusion for 3 hours at a constant rate, each dose being given on six occasions in separate experiments carried out on separate days. No consistent inhibition of secretion was observed in either preparation. The results do not support the concept of either an inhibitory hormone or an inhibitory neural reflex of antral origin active against pentagastrin-stimulated acid secretion.

Previous studies from the Surgical Unit, Royal Infirmary, Cardiff, suggested that a neural reflex might be responsible, in part, for the inhibition of pentagastrin-induced gastric secretion by antral acidification in the dog (Williams and Forrest, 1969). Similar conclusions were reached by Coelho, Bombeck, Pissidis, and Nyhus (1971) in respect of both meat and pentagastrin.

The experiments of Williams and Forrest (1969) were carried out in dogs with vagally innervated and denervated fundic pouches and vagally innervated antral pouches of the stomach. The stimulus of gastric secretion was pentagastrin given in sequential doses in a single experiment. Inhibition by perfusion of the antral pouch with acid was observed only in dogs with vagally innervated fundic pouches stimulated by submaximal doses of pentagastrin.

The studies now reported extend these observations in dogs in which varying doses of pentagastrin were given, each in a single test.

MATERIALS AND METHODS

The studies were carried out in 6 mongrel dogs with body-weights ranging from 9 to 13 kg. Four were prepared with vagally innervated (mucosal septal) fundic pouches (Hollander and Jemerin, 1938; Thomas, 1942) using the modifications described by Gregory, Hallenbeck, and Code (1942). The remaining 2 animals were prepared with vagally denervated (separated) fundic pouches (Heidenhain, 1879). The presence or absence of vagal nerve-supply to the pouch was confirmed by an insulin test, which was performed once in each dog (Jemerin, Hollander, and Weinstein, 1943). The total acid output in the 3 hours following an intravenous injection of 0·5 U. of insulin per kg. body-weight ranged from 2·9 to 13·0 mEq. in the case of the innervated preparations and was zero in the denervated pouches.

At a second operation performed 4 weeks later an innervated antral pouch was made by the construction of a mucosal septum between the body and the antrum (Forrest, 1956), gastro-intestinal continuity being re-established by gastroduodenostomy. The distal end of the antrum was exteriorized to form a mucocutaneous fistula. Definition of the junction between the body and the antrum at operation was made using *p*H-indicator paper after a subcutaneous injection of 1 mg. histamine dihydrochloride, as described by Olbe (1963). A strip of mucous membrane, 1–2 cm. wide, was excised along both sides of the junction in order to be as certain as possible that the antral pouch contained no parietal cells. No oxyntic cells were seen in random biopsies taken from the margins of the remaining antral mucosa in any of the dogs. As further confirmation, *p*H measurements of the antral contents were made during experiments in which gastric secretion was stimulated. In all the dogs it remained above *p*H 7·0. Confirmation of the absence of duodenal mucosa in the distal antrum was also obtained by histological examination.

---

* Based on a communication to the Surgical Research Society in July, 1971.

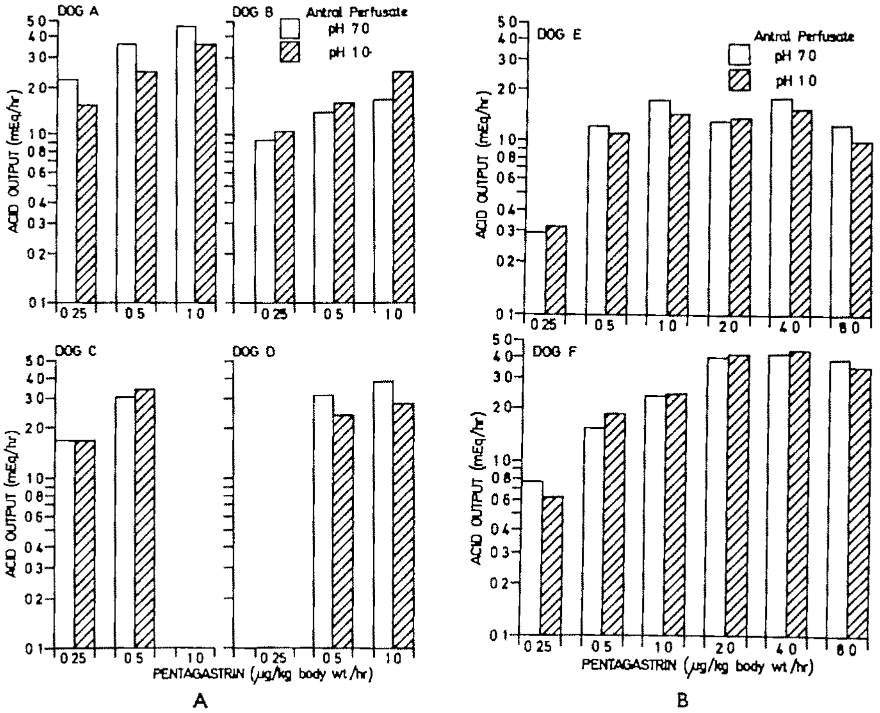

FIG. 1.—Acid secretory responses to intravenous infusions of pentagastrin in (A) 4 dogs with vagally innervated fundic pouches and (B) 2 dogs with vagally denervated fundic pouches during antral pouch perfusion with (i) isotonic saline at *p*H 7·0 and (ii) isotonic saline at *p*H 1·0. Each column represents the mean of the final hour outputs of acid for each dose obtained in a 3-hour test performed three times in each animal. The mean acid outputs have been plotted on a logarithmic scale. Three doses of pentagastrin were employed in dogs A and B, two doses in dogs C and D, and six doses in dogs E and F.

The septal integrity of all the mucosal septal pouches was established by feeding the animals milk on at least three occasions. Tests of secretion were commenced 6 weeks after operation. Before each test the animals were fasted for at least 18 hours and a rest of 48 hours was allowed between tests. Any test in which an animal vomited or showed excess restlessness or salivation was terminated.

The acid secretory response to a range of doses of pentagastrin (Peptavlon, I.C.I. 50, 123, Imperial Chemical Industries Ltd.) was determined. Each dose of pentagastrin was given in a separate experiment by intravenous infusion for 3 hours. The doses of pentagastrin were 0·25, 0·5, and 1·0 µg. per kg. body-weight per hour in the dogs with innervated fundic pouches, and 0·25, 0·5, 1·0, 2·0, 4·0, and 8·0 µg. per kg. body-weight per hour in those with denervated fundic pouches.

The infusion was injected into a foreleg vein at a rate of 6·7 ml. per hour, irrespective of the dose, using a Palmer slow-infusion pump (C. F. Palmer, London).

Fifteen minutes before the start of the pentagastrin infusion and after the collection of at least one 15-minute basal specimen of gastric juice, perfusion of the antral pouch was commenced with isotonic saline at *p*H 7·0 or an isotonic solution of HCl in saline at *p*H 1·0 and continued throughout the test. Confi mation of equal osmolality of the two solutions was l estimation of the depression of the freezing poir using a semi-micro osmometer (Knauer, Berlin).

The antral perfusate was delivered by a peristalt pump (Type MHRE, Watson-Marlow Ltd., Marlo Bucks.), at a rate of 1 ml. per minute via the narro inner lumen of a double-lumen Kay gastroston tube (J. G. Franklin and Sons Ltd., London). fluid escaped from the antrum through the wide out lumen of the tube and as the balloon of the cathet was not inflated, distension of the antrum w avoided. At hourly intervals the *p*H of the perfusa returning from the antrum was measured; it nev varied from that of the entering fluid.

Three tests were performed on each dog for ea dose of pentagastrin and at each *p*H of the ant perfusate, i.e., 6 tests for each dose of pentagastri The antral perfusate used in any one experiment w selected randomly.

During the tests the gastric juice was collected 15-minute samples. The volume was measured in n and the concentration of acid determined by titrati with 0·01 NaOH to a *p*H of 7·0 using an EIL Model Titrimeter (Electronic Instruments Ltd., Richmon Surrey). From these estimations the acid output w calculated in mEq. per 15 minutes.

The results were analysed by a statistical compa son of the outputs of acid during the last hour (mE per hour) of the tests when the antrum was perfus at *p*H 7·0 with the outputs when the *p*H of t perfusate was 1·0. As acid outputs appear to follow a log-normal distribution (Forrest and Code, 1954) the logarithms of the individual values for each test were used in the analysis (Gaddum, 1945). In a further analysis the outputs during the third half-hour (mEq. per 30 minutes) of each test were similarly compared. The latter period was chosen as it coincided with that which appeared in the data presented by Williams and Forrest (1969) and which was found to give the greatest differences.

Table I.—EFFECT OF ANTRAL ACIDIFICATION ON THE ACID SECRETORY RESPONSE TO PENTAGASTRIN ADMINISTERED BY CONTINUOUS INTRAVENOUS INFUSION

DOG	DIFFERENCE BETWEEN LOG ACID OUTPUT DURING ANTRAL PERFUSION AT pH 7·0 AND pH 1·0		
	Mean	± S.E.M.	*P*
A	0·138	0·024	< 0·001

Group I − group II	0·012	0·066	N.S.

* Calculated from between-dog variation as this group of dogs differed significantly in response among themselves.

† Calculated from within-dog variation in the absence of significant between-dog variation.

N.S., Not significant ($P > 0·05$).

The initial analysis was to determine if any effect of antral acidification was dose-dependent. Differences between fundic-pouch outputs during antral perfusion at pH 7·0 and 1·0 were examined over the whole range of pentagastrin doses and the results compared by an analysis of variance.

Since no dose-dependence was demonstrated, the mean difference in acid output obtained from all the doses was used in the main analysis. The standard errors of these differences were calculated from a pooled variance obtained from all the doses and their significance assessed by *t*-tests.

RESULTS

The mean acid output during the final hour of the 3-hour tests on the individual dogs is shown in *Fig.* 1 at each dose of pentagastrin and with each perfusate.

As one would expect, the dose of stimulant had a noticeable effect on the level of acid output; increasing the dose increased acid secretion. Nevertheless, the difference between acid output from the fundic pouches during perfusions of the antrum at pH 7·0 and 1·0 was not substantially affected by the dose of pentagastrin. The absence of a statistically significant effect of dose on this difference was shown by an analysis of variance. In no dog was the result significant at even the 20 per cent level.

In the absence of any apparent dose effect comparisons of response to antral perfusion at individual doses were not worth while. Instead, the mean difference between acid output during antral perfusion at pH 7·0 and 1·0 obtained from all doses was considered for each dog. *Table I* shows the mean difference for each dog together with the standard error of this difference. Neither of the animals with denervated fundic pouches exhibited significant inhibition.

Table II.—EFFECT OF ANTRAL ACIDIFICATION ON THE ACID SECRETORY RESPONSE TO PENTAGASTRIN ADMINISTERED BY CONTINUOUS INTRAVENOUS INFUSION

DOG	DIFFERENCE BETWEEN LOG ACID OUTPUT DURING ANTRAL PERFUSION AT pH 7·0 AND pH 1·0

* Calculated from between-dog variation.

† Calculated from within-dog variation.

N.S., Not significant ($P > 0·05$).

Two of the dogs with innervated fundic pouches showed significantly lower acid output when the antrum was perfused at pH 1·0 as compared with pH 7·0. However, 1 dog in this group showed a higher output at pH 1·0 which reached significance at the 10 per cent level. The dogs with the innervated fundic pouches considered as a group did not demonstrate significant inhibition.

A comparison of the mean effect of antral acidification on the acid output of the dogs with denervated fundic pouches and of the dogs with innervated fundic pouches failed to demonstrate any statistically significant difference between the two groups (*Table I*).

A similar analysis was applied to the third half-hour of each test instead of the final hour. This is summarized in *Table II*. Although the results of this analysis were less precise, because of a greater degree of variation leading to larger standard errors, the conclusions matched those described above.

DISCUSSION

Since pentagastrin has the same active terminal tetrapeptide and physiological properties as gastrin (Tracy and Gregory, 1964), its action should be inhibited by any mechanism which inhibits gastrin-stimulated secretion. The demonstration of such inhibition would indicate that acidification of the antrum inhibits gastric secretion by a mechanism other than suppression of gastrin release. In vagally denervated fundic pouches this could only be by a hormonal mechanism.

Our failure to demonstrate inhibition in this preparation is further evidence against the existence of such an antral inhibitory hormone. These findings are in agreement with those of Williams and Forrest (1969), who also used pentagastrin-stimulated secretion, and of Gillespie and Grossman (1962), Andersson and Olbe (1964), and Rheault, Semb, Harkins, and Nyhus (1965), who stimulated secretion with hog gastrin.

Contrary findings were reported by Coelho and others (1971) using pentagastrin to stimulate gastric secretion, and by Thompson, Davidson, Miller, and Davies (1964), who used hog gastrin. Both these groups of workers claimed that antral acidification inhibited the secretion from denervated fundic pouches. Full details of the experiments of Coelho and others have not yet been published.

The studies of Olbe (1964) suggested that the 'resting' innervated antral pouch releases small quantities of gastrin which might influence the secretory response of a fundic pouch to other stimuli. If this is so, then antral acidification, by reducing this subthreshold gastrin release, would result in a diminished response of a fundic pouch. Clearly the case for the antral chalone diminishes when this argument is evoked. However, Andersson and Grossman (1966) did not think that the amount of gastrin released spontaneously from the excluded innervated antrum was sufficient to increase significantly the response of a fundic pouch to exogenous gastrin.

In the present study there was no consistent inhibition of pentagastrin-induced acid secretion from innervated fundic pouches following acidification of the innervated antral pouch. The doses of pentagastrin chosen were those which gave the maximal inhibition previously noted (Williams and Forrest, 1969). Although 2 dogs did show some inhibition, the extent of this was less than that observed in the earlier study and there was no difference in the means of the 4 dogs considered as a group.

Our failure to demonstrate consistent inhibition in the animals with innervated antral and innervated fundic pouches is in agreement with the results of Preshaw (1967). Preshaw was also interested in the possibility of a neural inhibitory mechanism triggered by antral acidification and carried out studies in which he irrigated innervated antral pouches with 50 m*N* and 100 m*N* HCl in dogs with gastric fistulae. No inhibition of gastrin-stimulated secretion was observed. In these animals inhibition of a sham-feeding response was noted, indicating that antral acidification could suppress the release of vagally stimulated gastrin.

The experiments described here were undertaken in an attempt to confirm our previous findings. In the tests which we reported earlier (Williams and Forrest, 1969) sequential doses of pentagastrin were given in a single experiment and antral perfusion was performed using a gravity-feed system. In the current studies each dose of pentagastrin was given in a single test on different days, and a constant-rate perfusion system employing a peristaltic pump was used. Whether these differences explain our inability to confirm the inhibition observed previously, we do not know. Certainly, we have failed to obtain further evidence for a possible neural reflex of antral origin active against pentagastrin-induced acid secretion.

Acknowledgements.—This work was supported by the Wellcome Trust, from whom M. H. Wheeler received a full-time grant.

The authors are grateful to Mrs. M. Coyle for her technical assistance.

The pentagastrin used in this study was generously supplied by Imperial Chemical Industries Ltd., England.

THE CONTROLLED USE OF VASODILATOR DRUGS IN THE MANAGEMENT OF HYPOVOLAEMIA COMPLICATED BY DIMINISHED CARDIAC FUNCTION

By K. M. PAGLIERO, A. K. YATES, AND D. G. HILL
THORACIC SURGICAL UNIT, GUY'S HOSPITAL, LONDON

SUMMARY

The fundamental importance of precise measurement of cutaneous temperature rather than the cursory assessment with the back of the hand in cases of shock or diminished tissue perfusion has been well described by Ross, Brock, and Aynsley-Green (1969). They showed examples where core/toe temperature gradients reflected hypovolaemia in postoperative cardiac surgical patients and further showed how this information could be used to guide α-blockade therapy to overcome peripheral vasoconstriction, thus allowing rapid correction of hypovolaemia by transfusion.

One criticism levelled by antagonists to this form of treatment is that α-blockade drugs cause hypotension. This article shows that with careful control α-blockade should not cause significant hypotension. Furthermore, in patients with hypotension of cardiogenic origin, α-blockade may be safely used in the treatment of coincidental hypovolaemia.

PERIPHERAL cutaneous temperature is dependent on the degree of cutaneous vasoconstriction and will therefore in standard environmental conditions reflect the degree of increased peripheral resistance found in shock, whatever its cause. Peripheral resistance can be calculated knowing the cardiac output and systemic pressure. However, measurement of cardiac output at the bedside is tedious, costly, and beyond the scope of all but the most sophisticated of units. Measurement of cutaneous temperature, on the other hand, is easy to perform, inexpensive, and non-invasive. Conceivably, the skin could be vasodilated in the presence of vasoconstriction in other organs. Cutaneous temperature measurement would therefore be of no value. However, our clinical findings show that a warm periphery (as measured in the big toe) corresponds to generalized vasodilatation with normal consciousness, good urinary output, and maintenance of normal acid-base balance which indicates that the degree of overall peripheral resistance is reflected by the cutaneous temperature.

α-Blockade is used to overcome vasoconstriction resulting from the physiological output of adrenaline and noradrenaline, this physiological response being the same for any form of shock whether cardiogenic, hypovolaemic, or peripheral in type (Block, Pierce, Manesc, and Lillehei, 1965). In the Thoracic Surgical Unit at Guy's Hospital chlorpromazine, 2·5–5 mg. intravenously, is used in repeated doses if an initial lack of response makes them necessary. Chlorpromazine has been reported by Dietzman and Lillehei (1968) as a 'moderately' effective α-blocking agent with a central nervous depression effect which is not always desirable in shock. Accordingly, Dietzman and Lillehei use phenoxbenzamine. Our own experience is that chlorpromazine is satisfactory and we have never needed to resort to more powerful drugs. Any associated mild cerebral sedation appears to be beneficial.

The vasodilatation caused by α-blockade is initially reflected by a fall in venous pressure corresponding with the increase in volume of the vascular bed. There will therefore be a concomitant fall in arterial pressure. The undesirable effect of this hypotension can be avoided by simultaneous intravenous transfusion to maintain the venous pressure.

CASE REPORTS

Case 1.—*Fig.* 1 shows the parameters for the first 5 postoperative hours of a 53-year-old woman who had undergone mitral valve replacement. On her return from the operating theatre she had poor peripheral perfusion and required an intravenous infusion of isoprenaline (0·2 mg. per cent at 4 drops per minute) to maintain her cardiac output at acceptable levels. Two doses of 2·5 mg. of chlorpromazine were given to initiate vasodilatation. Simultaneous transfusion, however, was not sufficient to maintain the central venous pressure. Each injection was followed by a fall in the central venous pressure and arterial blood-pressure with no improvement in the haemodynamic state. A fall of 30 points of blood-pressure is noteworthy in this patient and had the original pressure been 80–90 mm. Hg systolic could have been catastrophic.

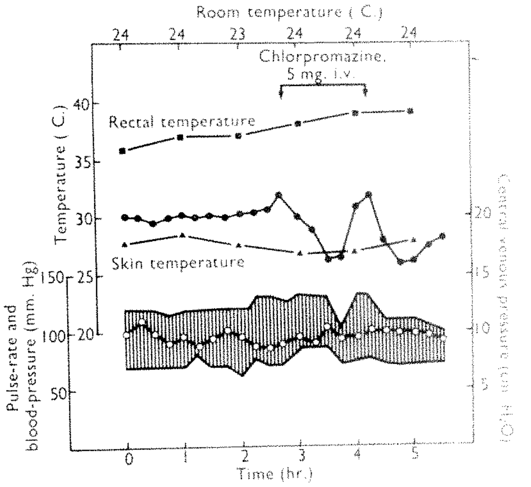

FIG. 1.—*Case* 1. Chart of the parameters for the first 5 hours after mitral valve replacement.

A patient with cardiogenic shock will be particularly susceptible to a fall in the central venous pressure. Hypovolaemia must nevertheless be corrected and therefore attention must be paid to expanding the effective blood-volume at the same time as inducing peripheral vasodilatation by α-blockade. Expansion of the blood-volume is achieved by transfusion at such a rate that the central venous pressure does not fall. Minute-by-minute monitoring of the venous pressure may be necessary. The vasodilator effect of intravenous chlorpromazine is usually seen within 2 or 3 minutes if the dose is adequate. If these criteria are satisfied there will be no fall in the central venous pressure, no reduction in venous return to the heart, and no hypotension. The following cases illustrate these points.

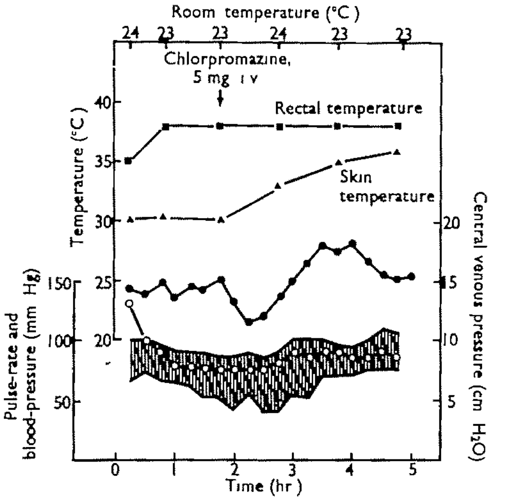

FIG. 2.—*Case* 2 Chart of the parameters for the first 5 hours after aortic valve replacement.

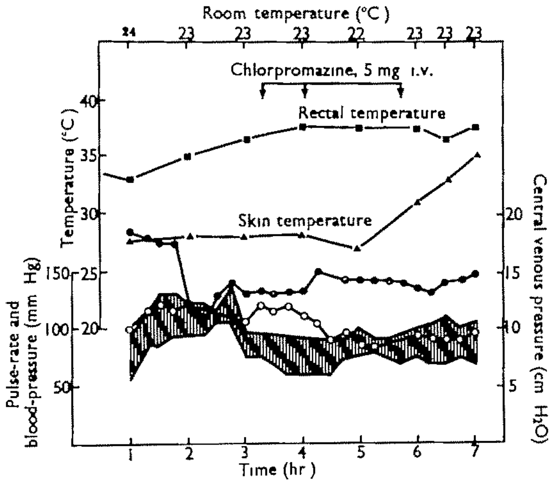

FIG 3—*Case* 3 Chart of the parameters for the first 7 hours after mitral valve replacement

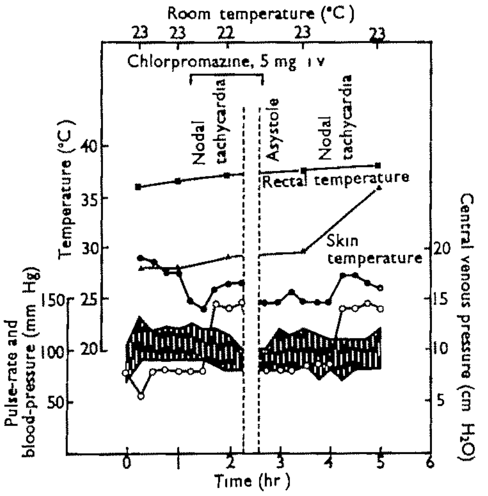

FIG. 4—*Case* 4. Chart of the parameters for the first 5 hours after mitral valve replacement

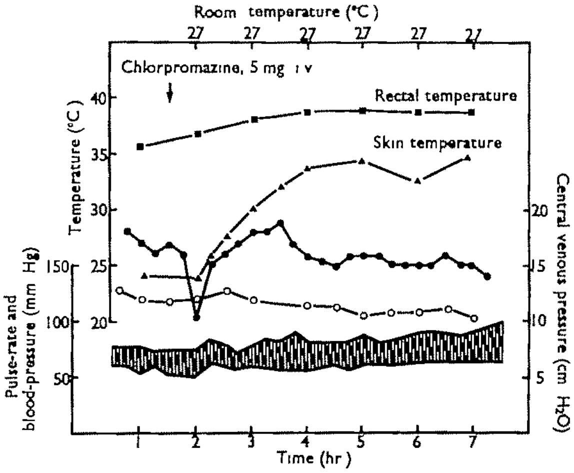

FIG 5—*Case* 5. Chart of the parameters for the first 7 hours after emergency aortic valve replacement.

Case 2.—*Fig.* 2 shows the parameters of a man of 50 years who had undergone aortic valve replacement for aortic stenosis while in severe cardiac failure. For 2½ hours after operation there was a declining blood-pressure. The peripheral temperature of 30° C. indicated vasoconstriction despite a central venous pressure maintained at 14–15 cm. water. Chlorpromazine, 5 mg. i.v., was therefore given while the venous pressure was maintained by increased blood transfusion. The blood-pressure showed progressive improvement with increasing peripheral perfusion, as indicated by a decreasing core/toe temperature gradient.

This case illustrates that the controlled administration of chlorpromazine at a systolic blood-pressure of 85 mm. Hg resulted in no further hypotension.

Case 3.—*Fig.* 3 is the chart of a 45-year-old woman who had undergone mitral valve replacement for mitral regurgitation. The initial picture is one of instability: peripheral vasoconstriction and low urinary output indicated low cardiac output and hypovolaemia. In addition, heat-loss during the 6-hour operation had caused depression of the central temperature to 33° C. In this case chlorpromazine was withheld until metabolic heat had produced a rise in the central temperature to 37° C. (Although vasodilatation risks loss of heat and depression of the central temperature, chlorpromazine may be safely given to patients with central hypopyrexia if an adequate environmental temperature is maintained.) Three separate intravenous injections of 5 mg. of chlorpromazine were necessary before a vasodilator response was gained, as indicated by the need for rapid transfusion to maintain the central venous pressure. Subsequently, vasodilatation and normovolaemia were indicated by a satisfactory rise in the peripheral temperature, increase in urinary output, and return of consciousness. Despite the three doses of chlorpromazine there was no significant change in the systolic blood-pressure, which remained at 90–100 mm. Hg throughout this period of treatment.

In retrospect vasodilator therapy should have been initiated earlier in the postoperative period and the injections of chlorpromazine should have been repeated more rapidly, e.g., at 15–20-minute intervals until the vasodilator response was obtained.

Case 4.—*Fig.* 4 shows the chart of a 51-year-old man who underwent mitral valve replacement. He returned to the ward with a satisfactory blood-pressure, venous pressure, and pulse-rate; however, vasoconstriction persisted, indicating concealed hypovolaemia. There was no response to an initial dose of chlorpromazine. Half an hour later a nodal tachycardia occurred and the blood-pressure dropped to 100 mm. Hg systolic. Subsequently, myocardial instability persisted and a period of asystole occurred. Despite the precarious situation, having achieved a return of heart-beat it was considered essential to correct the hypovolaemia. A further dose of chlorpromazine was given together with increased transfusion to maintain the venous pressure. Over the next 1½ hours this treatment was rewarded by vasodilatation with no adverse effect on the cardiovascular state.

Case 5.—*Fig.* 5 is the chart of a man of 52 years who underwent emergency aortic valve replacement. His postoperative condition was critical and his blood-pressure was only 70 mm. Hg systolic despite cardiac stimulants and vasopressors. Concealed hypovolaemia was indicated by a low peripheral temperature and therefore the patient was given chlorpromazine, 5 mg. i.v., despite his hypotension. A fall in the venous pressure was corrected by transfusion and was maintained at a satisfactory level. Peripheral vasoconstriction relented, urine excretion became satisfactory, and the patient became conscious. The blood-pressure continued to be low, indicating reduced cardiac function, but this was not aggravated by our treatment.

CONCLUSION

The use of α-blockade to facilitate and to allow speedy correction of hypovolaemia has been previously recommended by Ibsen (1967). Other workers (Block and others, 1965; Dietzman and Lillehei, 1968) have advocated the use of vasodilators in cardiogenic shock. Although this latter treatment is far from universally accepted, it would, however, seem a reasonable and safe policy to combine these two treatments to aid the correction of hypovolaemia in the presence of cardiogenic and other forms of shock.

The cases illustrated in this article serve as examples of this policy. At no time have we had cause to regret its use. However, it cannot be overemphasized that α-blockade without careful attention to the central venous pressure and central temperature can be highly dangerous. Its indiscriminate and uncontrolled use could result in dangerous degrees of hypotension or central hypothermia.

Once again, the measurement of the core/toe temperature gradient has been shown to be of value in the understanding and management of shock.

FURTHER PROGRESS WITH RECONSTRUCTION OF THE EXSTROPHIED BLADDER

BY D. INNES WILLIAMS AND JAMES E. KEETON
THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET, LONDON, AND THE ST. PETER'S GROUP OF HOSPITALS, LONDON

SUMMARY

Two series of primary reconstructions of the classic exstrophied bladder are reviewed and a brief description of the operative procedure is given.

There has been a significant improvement in the results since 1963 and a discussion of the possible reasons is given along with a policy for the future.

EXSTROPHY of the urinary bladder continues to be a formidable problem in paediatric urology. This paper brings up to date the treatment of this condition under the care of the senior author (D. I. W.) at the Hospital for Sick Children, Great Ormond Street, and the St. Peter's Group of Hospitals, London. The last reported results from these hospitals cover a period from 1949 to 1963 (Williams and Savage, 1966). During this period 80 cases of exstrophy of the urinary bladder were treated, with primary closure of 51 cases. The late follow-up shows that 5 cases have acceptable continence. This is a dismal result but is better than when we first reported this series (Williams and Savage, 1966). At the time of the initial report a policy for the future was decided upon. We decided to be more selective in the choice of which exstrophied bladder to reconstruct. This depended mainly upon the size, suppleness, and condition of the bladder. Also less attempt was made to obtain a tight closure of the bladder neck and the closure was done at a later age. In the first series the average age of closure was 8–12 months, whereas in the second series it was 16 months.

PRESENT SERIES

From July, 1963 to July, 1969, 36 cases of classic exstrophy of the bladder have been treated. This report is limited to the common complete form of exstrophy of the bladder. Epispadias, ectopic cloaca, and the split-symphysis variants are excluded. Clearly the incomplete forms of exstrophy are more amenable to reconstruction and their inclusion in this series would give a false impression of the results to be expected.

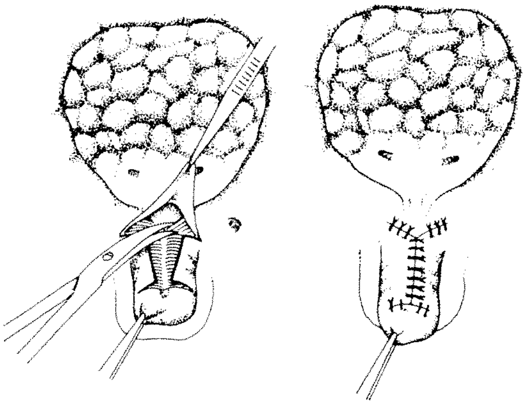

FIG. 1.—Urethral lengthening procedure. A, A V-shaped incision is based near the verumontanum and has its apex near the coronal sulcus. The urethra is dissected back and the dorsal fibrous attachments of the corpora cavernosa are freed. B, Skin closure is in the form of a Y.

The sex distribution was in the ratio of 2 males to 1 female, which has changed from that of the original series of 3 males to 1 female. Of the 36 cases, 17 were considered unsuitable for closure because of the small size and rigidity of the bladder. These 17 cases had a urinary diversion, of which 11 were ileal conduits, 5 were sigmoid conduits, and 1 was a cutaneous ureterostomy. Nineteen cases were primarily reconstructed and the details of these cases are reported here.

OPERATION

The basic procedure is unchanged from that of the earlier series and has been described in detail in the previous article (Williams and Savage, 1966). The essential features are as follows.

In the male infant upward chordee correction is performed about 6 months prior to the actual closure of the bladder. The simplest method of chordee correction is by elongation of the urethra based on a V–Y plasty, bringing around preputial skin (*Fig.* 1). After a transverse or V-shaped incision in the urethral strip the proximal end is dissected off the corpora cavernosa up to the point at which these separate from one another. The corpora are then laid bare on either side and traced upwards until the bands which tether them to the pubic tubercles can be severed. The defect in skin cover created by correction of the chordee may be corrected by the use of preputial flaps, either brought around the side or over the top with a button-hole method, but in some cases there is insufficient preputial tissue and one has to use scrotal skin. An opening is made in the skin of the anterior scrotal wall and the skin of the penis is then circumcised. The whole penis is displaced under this anterior scrotal skin and the glans is brought up through the button-hole. This adds a lot to the urethral length although it does, of course, require a further operative procedure to release it and to enclose the penis completely in supple skin. The correction of the chordee helps not only with subsequent closure of the bladder but also in later life with sexual intercourse.

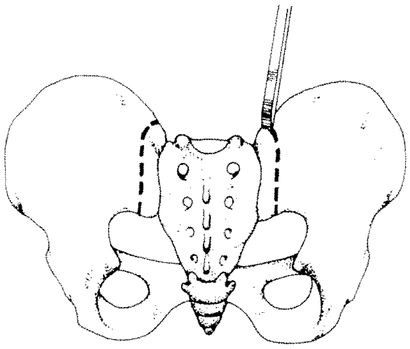

FIG. 2.—Iliac osteotomy. A vertical incision is made a little lateral to the sacro-iliac joint. The muscle is cut and the periosteum is stripped and the bone is cut with an osteotome down to the greater sciatic notch.

The female genital defect is less serious, since the upper vagina, uterus, ovaries, and tubes are almost always normally formed. The vaginal introitus is, however, stenosed and anteriorly displaced. An episiotomy in later childhood or adolescence will usually suffice to make intercourse satisfactory and most of these girls are capable of child-bearing.

The actual closure consists first of bilateral pelvic osteotomy (*Fig.* 2). This was done in 16 of the 19 patients in this series of cases, but it has not been attempted where the child has been past the age of 2 years as it has not been found that sufficient mobility is obtained after this age. Briefly, the child is laid face down with a sandbag supporting the pelvis anteriorly; a vertical incision is made 1–2 cm. lateral to the sacro-iliac joint. The gluteal muscles are incised and the periosteum is stripped from the ileum down to the sacro-iliac notch. A bone lever is inserted into the notch and with an osteotome the ileum is then cut through 1 or 2 cm. lateral to the sacro-iliac joint. When the cut is complete the bone can be hinged inwards by pressure on the femora. The muscle layer is then sutured with catgut and the wound is closed. In many cases the child has then been turned over for immediate reconstruction of the bladder. In others a period of 48 hours has elapsed before the closure operation. After pelvic osteotomy the child has been suspended by the legs in a gallow's splint for 3 weeks.

The reconstructive procedure (*Fig.* 3) is commenced by an incision around the mucocutaneous junction of the bladder and urethra, excising also the umbilical scar superiorly. The incision is deepened so that the retropubic space is opened up on either side and the apex of the bladder is mobilized completely. Towards the base of the bladder the mobilization is carried out against the inner aspect of the pubis so that the fibromuscular fibres joining the bladder to the bone are severed far laterally, thus avoiding the ureters and neurovascular supply of the bladder. After mobilization, the bladder-neck area is narrowed by lateral incisions and the urethral strip is mobilized a little at its edges. Before the bladder is closed a decision must be taken concerning the ureters. Reflux prevention is likely to be required at some stage in the reconstructive programme and if the bladder is large and supple an immediate re-implantation of the ureters by a tunnel technique is practical. If, however, the bladder is small and thick it may be extremely difficult to accomplish a satisfactory reimplant at the same time as bladder closure, and it may be preferable to leave this aspect of the reconstruction until a later date. The bladder and urethra are then closed by two layers of catgut suture in the anterior midline with a suprapubic drain for the bladder and, if necessary, separate drains for the two ureters. The fibromuscular tissue which has been freed from the pubis is wrapped around the front of the bladder-neck area if possible. The rectus sheath is then sutured in the midline with strong catgut or silk. Pressure on the iliac crest during closure of the suture line will enable a simple midline closure to be performed if an osteotomy has preceded this operation; if not, flaps of rectus sheath must be mobilized (*Fig.* 4) and turned inwards to cover the bladder. Similarly, the skin may be closed by simple suture in the midline after osteotomy, while in other cases flaps are required. Postoperatively bladder drainage is continued for 10–14 days and long-term chemotherapy for at least 3 months. In all cases it is usually at least a year before it can be decided whether continence is to be obtained and during this period careful supervision by intravenous pyelography and urinary analysis is vital as infection and upper-tract dilatation are by no means rare complications.

The variants of the closure have been to use isolated segments of ileum or colon in cases where a small bladder needed to be enlarged. In our second series this was only performed once and satisfactory continence was not obtained postoperatively. We have performed bilateral nephrostomies preoperatively in only 2 of the 19 patients and an anti-reflux procedure was done at the time of closure in 4 of the 19 patients.

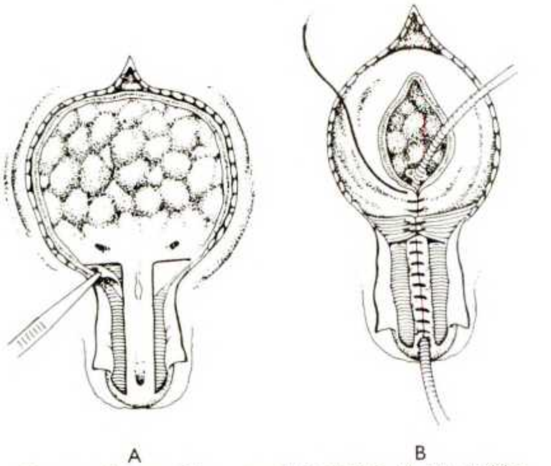

FIG. 3.—Closure of the exstrophied bladder. A, The incision is made along the mucocutaneous junction of the bladder and urethra. Triangles of mucosa are excised from the trigone to create a bladder neck. B, Closure of the bladder and urethra together with the fibromuscular bands across the bladder-neck area.

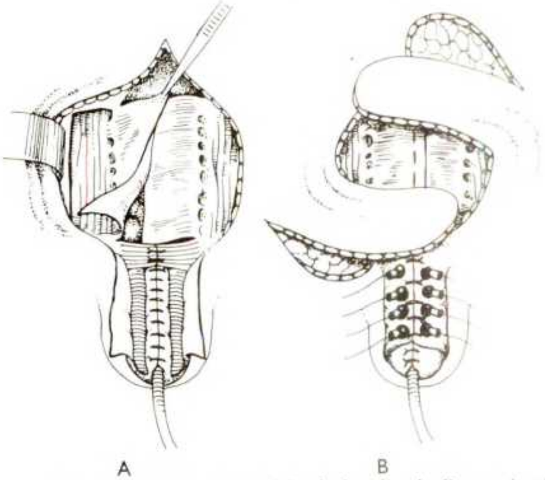

FIG. 4.—Closure of the abdominal wall. A, Rectus-sheath flaps are formed which hinge on the medial border to cover the bladder. B, Skin closure can be obtained by the rotation of broad-based flaps.

RESULTS

The first series of cases from 1949 to 1963 has been reviewed afresh and to a certain extent the results are better than appeared at the time of the original publication (*Table I*). The late follow-up of these 80 cases, of which 51 were reconstructed, shows that acceptable continence was obtained in 5 cases, 3 have rather poor control and are using some sort of external appliance, and 38 have had a secondary diversion. Four patients have died; 1 of these deaths was due to acute poliomyelitis which developed soon after the operation, 1 patient died on the twenty-fifth postoperative day of uncertain cause but possibly related to postoperative sepsis, and 2 have died several years after the reconstructive procedure while under the care of another hospital for a secondary diversion. One case has been lost to follow-up.

Table I.—RESULTS OF RECONSTRUCTION IN THE FIRST SERIES OF CASES FROM 1949 TO 1963

	No. of Cases
Total No. of cases seen	80
Functional reconstruction attempted in	51
Results of reconstruction	
Acceptable continence	5*
Poor control and using appliance	3
Secondary diversion	38
Lost to follow-up	1
Died	4

* Continence: 6·2 per cent of total cases; 9·8 per cent of reconstructed cases.

Examination of the continent patients shows the oldest patient to be 14 years post-reconstruction and the youngest to be 7 years post-reconstruction. Two of these patients have perfect control, no infections, and normal pyelograms. In the other 3 patients infections have occurred but have been cleared satisfactorily. One of these patients had stones in the earlier period but has none at the present time.

The second series of cases was treated between July, 1963, and July, 1969 (*Table II*). During this time a total of 36 cases was referred for treatment and functional reconstruction was attempted in 19. Of these 19 cases, acceptable continence with a normal intravenous pyelogram was obtained in 6. In 3 of these patients the urine is sterile, whereas the other 3 are on maintenance antibiotics for infection. Secondary diversion has been performed in 8 other cases because of failure of continence, and 4 cases are still incontinent and awaiting further treatment. One patient had perfect continence, but hydronephrosis necessitated a urinary diversion. Comparing now the first and second series it will be clear that we have obtained a very satisfactory improvement of continence. In the first series only 6·2 per cent of the total cases and 9·8 per cent of the reconstructed cases were continent, whereas in the second series the figures are 17 and 31 per cent respectively.

Table II.—RESULTS OF RECONSTRUCTION IN THE SECOND SERIES OF CASES FROM 1963 TO 1969

	No. of Cases
Total No. of cases seen	36
Functional reconstruction attempted in	19
Results of reconstruction	
Acceptable continence	6*
Perfect continence but hydronephrosis requiring diversion	1
Secondary diversion	8
Incontinent and awaiting further treatment	4

* Continence: 17 per cent of total cases; 31 per cent of reconstructed cases.

Table III.—COMPLICATIONS OF RECONSTRUCTION IN THE FIRST SERIES OF CASES FROM 1949 TO 1963

Complications	*No. of Cases*		*Percentage Incidence*
Early			
Breakdown		9	
Complete	4		
Partial	5		
Fistula		9	
Stricture		7	
Other		4	
Intestinal obstruction	1

Poliomyelitis	1		
Late			
Persistent pyuria	27 out of 37		73
Pyelographic deterioration	12 out of 35		34
Stone	10 out of 47		21
Reflux	15 out of 18		83

COMPLICATIONS

A depressing feature of the early series was the number of complications (*Table III*). Of the early complications, some breakdown of the wound was common; this usually occurred before osteotomy was undertaken. In the late follow-up the incidence of infection, reflux, pyelonephritis, and stone formation was extremely worrying. In the second series the complications have been less, particularly the late complications (*Table IV*). There have been no stones, infection has not been uncommon but radiological evidence of pyelonephritis has been relatively rare and slight, and it is clear that with better techniques and more careful supervision no serious harm has been done to the upper urinary tract in these children.

Table IV.—COMPLICATIONS OF RECONSTRUCTION IN THE SECOND SERIES OF CASES FROM 1963 TO 1969

Complications	*No. of Cases*		*Percentage Incidence*
Early			
Breakdown		8	
Complete	2		
Partial	6		
Fistula		3	
Stricture		1	
Other		3	
Pulmonary oedema	1		
Intestinal obstruction	1		
Bilateral hydronephrosis (required temporary diversion)	1		
Late			
Persistent pyuria	10 out of 19		53
Pyelographic deterioration	4 out of 19		21
Stone	0 out of 0		0
Reflux	7 out of 9		77

In the second series the 2 complete breakdowns of the wound were in patients whose bladders were closed at a few weeks of life. A reconstruction was attempted at an older age, but both of the patients required later diversion for incontinence. The 6 partial breakdowns were treated conservatively and they healed with time. Suprapubic fistula occurred in 3 cases and again these were treated conservatively and subsequently healed. Stricture occurred much less in the second series and this improvement is possibly explained by the attempt now not to get too tight a closure at the bladder neck and urethra. Again there was the occasional complication as listed in *Table IV*. The intestinal obstruction required an exploratory laparotomy and lysis of adhesions. The bilateral hydronephrosis required temporary nephrostomy tubes.

DISCUSSION

After review of our second series of patients it would seem that we have improved our results and reduced the complications to the point where closure of exstrophied bladders should be attempted in selected cases. The reported figures are certainly sufficiently encouraging for us to believe that functional reconstruction has an important part to play in the treatment of exstrophy, even though the majority of cases will still require diversion. We have attempted to review the various features of the reconstructive procedure to determine what has been useful and what has not.

The penile-lengthening procedure has certainly an important part to play in the achievement of normal erections and genital function, but it has not had any very obvious influence on the attainment of urinary continence. Pelvic osteotomy has made wound closure much more satisfactory and in the long run the abdominal wall has remained sound after this procedure. However, radiographs have shown in all cases that the pubes have sprung apart and there has been no contribution at all towards the achievement of continence. The significance of the results is a little hard to assess since osteotomy was not performed in the older children and it is well known that these children have a better chance of obtaining control.

However, in both the first and second series continence after osteotomy was very poor and we have decided not to perform this manœuvre unless the gap in the pubes is very wide.

The part played by the tightness of the bladder-neck closure has been very hard to assess since we have no accurate measurement of this factor. The general impression has been that the best results have been obtained where the muscle tissue in the region of the bladder neck is well formed and where extreme narrowness of the neck has not been aimed at. In the earlier series it was shown that a bladder of very small capacity did not obtain continence and in the second series such cases were excluded from the reconstructed group. Only 52 per cent of the total cases seen were reconstructed in the second series as opposed to 63 per cent in the first series. Attempts were made in a few cases to enlarge the bladder capacity by colocystoplasty or ileocystoplasty. In none of these was continence obtained.

It is clear that reflux has been a serious factor in some of the postoperative cases and has accounted for early upper-tract dilatation in some. In 1 case there was an extremely satisfactory return to pyelographic normality after a secondary reflux-preventing operation in a patient who was almost completely continent. The choice of larger capacity bladders, reflux prevention, and the more careful control of infection by chemotherapy appear to have been responsible for the absence of stones and only very slight evidence of pyelonephritis in the second series.

Our results compare favourably with the recently reported results of Smith and Lattimer (1966), Fisher and Retik (1969), Ezell and Carlson (1970), Marshall and Muecke (1970), and Jeffs (1971). The approaches of these authors are somewhat similar to ours though Fisher and Retik (1969) have been keen to postpone the primary reconstruction of the bladder neck until adolescence. Marshall and Muecke (1970) perform preliminary bilateral nephrostomies and bilateral reimplantations at the time of the initial closure with fascial covering of the abdominal wall and no osteotomies.

Our conclusion in relation to reconstruction of exstrophy is that about one-half of the number of classic exstrophy cases will be suitable for reconstruction. In the present series only one-third of that group were successfully treated, but one would certainly hope to raise the success rate with improved techniques so that perhaps ultimately one-third of the total number might be successfully treated in this way. Two-thirds of the cases will still need to be diverted.

Our policy for the future will be first to undertake in males penile-lengthening procedures which will avoid any interference with the area of the verumontanum. Secondly, in those patients in whom it can be postponed we will close the bladder later than previously, possibly waiting until the second or third year of life. We will be prepared to do a closure operation which will not, in the first instance, aim at complete bladder-neck correction or reflux prevention and to follow it with a second operation some years later. Thirdly, in the definitive reconstruction we shall not undertake pelvic osteotomy unless the symphysial gap is enormous, but will aim to get abdominal wall closure by large rectus-sheath flaps. We shall aim at a very long posterior urethra constructed out of the bladder base with reimplantation of the ureters at a higher level and with a reflux-preventing submucosal course. This procedure demands a potentially large bladder capacity and if such is not available at the initial closure, then the two-stage procedure of covering over and awaiting events seems the right line of action. One must conclude that however an exstrophy is treated, by reconstruction or diversion, we must accept the child as a patient for the rest of our professional careers, as follow-up will be essential no matter what course we take.

AN ANALYSIS OF 59 CASES OF TRACHEAL STENOSIS FOLLOWING TRACHEOSTOMY WITH CUFFED TUBE AND ASSISTED VENTILATION, WITH SPECIAL REFERENCE TO DIAGNOSIS AND TREATMENT

By M. J. ANDREWS
DEPARTMENT OF SURGERY, UNIVERSITY OF TORONTO

AND F. G. PEARSON
DEPARTMENT OF SURGERY, UNIVERSITY OF TORONTO, AND DIVISION OF THORACIC SURGERY, TORONTO GENERAL HOSPITAL

SUMMARY

An analysis of 59 cases of tracheal stenosis after tracheostomy with cuffed tube and assisted ventilation is reported. Special emphasis is placed upon diagnosis and treatment. The detection of severe strictures is usually easily achieved, but mild to moderate degrees of stenosis may present difficulties in diagnosis and may remain undetected for some time.

Management of the strictures included dilatation (14 cases), segmental tracheal resection with primary end-to-end anastomosis (34 cases), staged plastic reconstruction (2 cases), and permanent tracheostomy (4 cases). No treatment was given in 5 cases.

Dilatation achieved a good result in 6 cases and a satisfactory one in 8. Of 34 strictures treated by segmental resection, a good result was obtained in 29 cases, although 7 required a second operation for restenosis. Three cases had an unsatisfactory result and there were 2 operative deaths. Postoperative complications are discussed.

Mild strictures may be satisfactorily managed by dilatation, but some mild strictures and all severe strictures are best treated by segmental resection with primary end-to-end anastomosis. Segmental defects ranging from 0·5 to 5·5 cm. in length can be satisfactorily resected.

TRACHEOSTOMY with cuffed tube and assisted ventilation has been used with increasing frequency in the management of respiratory insufficiency over the past 15 years, and tracheal stenosis has become a well-recognized complication of this type of therapy (Deverall, 1967; Gibson, 1967; Pearson, Goldberg, and da Silva, 1968; Grillo, 1970; Andrews, 1971; Andrews and Pearson, 1971). The present paper is an analysis of 59 symptomatic tracheal strictures treated at Toronto General Hospital between 1963 and 1970, and the diagnosis and treatment of these strictures are discussed. Thirty-two of the strictures were seen during a 3-year period of a prospective study which was designed to determine the true incidence of this complication, and to clarify the pathogenesis of tracheal injury in those patients requiring tracheostomy and assisted ventilation. The results of this prospective study have been previously reported (Andrews, 1971; Andrews and Pearson, 1971).

MATERIAL

Fifty-nine symptomatic tracheal strictures were treated by the Thoracic Surgical Service at Toronto General Hospital during the 8-year period 1963–70. Thirty-five strictures occurred at the site of the original tracheostomy, and 24 occurred at the level of the inflatable cuff of the tracheostomy tube.

Tables I and *II* summarize some pertinent data relating to the 59 tracheal strictures.

Table I.—DETAILS OF THE 59 PATIENTS WITH TRACHEAL STRICTURES IN THE PRESENT SERIES

	STOMAL STRICTURES (35 cases)	CUFF STRICTURES (24 cases)
Sex		
Male	22	9
Female	13	15
Age		
Range	17–76	15–83
Mean	52·0	45·5
Size of tracheostomy tube		
Male		
Range	11–14	11–14
Mean	12·6	12·0
Female		
Range	9–13	9–13
Mean	10·9	11·0
Duration of intubation (d.)		
Range	4–330	7–42
Mean	30	18

The prospective study mentioned previously (Andrews, 1971; Andrews and Pearson, 1971) indicated the following conclusions:—

1. Tracheostomy tubes of large diameter were associated with an increased incidence of strictures at the level of the original tracheostome.
2. The presence of airway infection predisposes to stomal, and probably to cuff, stenosis formation.
3. Females had a significantly higher incidence of strictures at the level of the inflatable cuff of the tracheostomy tube.
4. Older patients and those with pre-existing lung disease might be more likely to develop stomal stenosis.
5. The duration of cuffed-tube tracheostomy with assisted ventilation did not appear to be important in the development of tracheal stenosis.

The data recorded in *Tables I* and *II* show similarities to those obtained from the prospective study. The sex ratio, mean age of patient, mean size of tracheostomy tube used, and percentage of patients with pre-existing lung disease in both the stomal and cuff stenosis groups are similar to those found in the prospective study.

Table II.—Conditions requiring Tracheostomy and Assisted Ventilation and the Presence of Pre-existing Lung Disease in 59 Patients with Tracheal Strictures in the Present Series

	Stomal Strictures (35 cases)		Cuff Strictures (24 cases)	
	No	Per cent	No	Per cent

Acute and chronic lung diseases	9	25 7	4	16 7
Miscellaneous	3	8 2	4	16 7
Presence of pre-existing lung disease	24	68 6	12	50

DIAGNOSIS OF TRACHEAL STRICTURES

Symptoms and Signs.—Awareness of the complication of tracheal stenosis following tracheostomy and assisted ventilation facilitates diagnosis. However, detection of severe degrees of stenosis should not be difficult since these patients have stridor at rest, usually predominant during inspiration, but this only occurs when the tracheal lumen is reduced to a diameter of 5 mm. or less.

The mild or moderate degrees of tracheal stenosis are more difficult to diagnose. Stridor at rest is usually absent and may become apparent only on exertion or on rapid, deep breathing. However, dyspnoea on exertion is almost an invariable complaint with these milder degrees of stenosis but may be overlooked in patients with chronic respiratory disease (36 out of 59 strictures in the present series), who may have had this symptom prior to tracheostomy. Patients with chronic chest diseases often have a chronic cough with sputum and may find difficulty in raising their secretions if they develop a tracheal stricture. A characteristic brassy cough is also common in patients with functionally significant tracheal narrowing.

Most of the 59 strictures in this series were recognized by the presence of the symptoms and signs detailed above. In fact, 40 patients had stridor at rest, and a further 9 had stridor elicited on rapid, deep breathing. Fifty patients had dyspnoea on exertion, and 31 had difficulty in raising their secretions. The presence of the characteristic brassy cough was recorded in only 5 patients. Forty-five of the 59 strictures (76·5 per cent) were diagnosed clinically, 4 (6·8 per cent) were diagnosed by bronchoscopy, and 10 strictures (17 per cent) were recognized on routine radiography.

One of the 4 cases diagnosed bronchoscopically was recognized at routine bronchoscopy performed on all the patients in the prospective study (Andrews, 1971; Andrews and Pearson, 1971) at the time of the final removal of the cuffed tracheostomy tube.

Nine of the 10 strictures diagnosed radiologically were recognized by the use of routine radiography in the prospective study, and the tenth stricture was recognized on routine chest radiography.

The length of time between extubation and the recognition of stenosis varied between 1 day and 2 years. Details are summarized in *Table III*. It is apparent that about half of the strictures were recognized within 1 month of the final removal of the cuffed tracheostomy tube, and that the majority of the strictures were recognized within 3 months of extubation (49 strictures; 83 per cent).

Table III.—Length of Time between Extubation and Recognition of Stenosis in 59 Patients

Time after Extubation	No. of Strictures recognized	Time after Extubation	No. of Strictures recognized
0–1 wk	6		
1–2 wk	5	0–2 wk	11
2–4 wk	17	0–1 mth.	28
1–2 mth.	17	0–2 mth.	45
2–3 mth.	4	0–3 mth	49
3–6 mth	4	0–6 mth	53
6–12 mth	3	0–12 mth	56
1–2 yr.	3	0–2 yr	59

Precise Diagnosis.—The definitive diagnosis of tracheal stenosis was established at bronchoscopy (usually performed under local anaesthesia) or by the use of tracheal tomograms or cine-tracheograms.

Bronchoscopy allowed assessment of the state of the stricture, special attention being directed to the pliability or rigidity of the stricture, to the presence or absence of coexistent inflammation or ulceration, and to whether the stricture was epithelialized or mature. Often bronchoscopic assessment allowed determination of the level of the stricture (i.e., at the site of the original tracheostome or at the level of the inflatable cuff of the tracheostomy tube). However, accurate perception of the depth or length of a stricture through a bronchoscope is difficult, and the exact position and length are best defined by either tracheal tomograms or, better still, by cine-tracheograms.

Bronchoscopy was used in the precise diagnosis of 30 of the 59 strictures (51 per cent), tomograms in 18 of the strictures (30·5 per cent), and cine-tracheograms in 11 cases (18·5 per cent).

The lengths of the strictures recorded by this precise diagnosis varied from 0·5 to 5·5 cm. (*Fig.* 1), and the diameter of the tracheal lumen was reduced to 5 mm. or less in 40 strictures (68 per cent), whilst the remaining 19 strictures (32 per cent) all had their airway diameter reduced by 50 per cent or more.

THE MANAGEMENT OF TRACHEAL STRICTURES

The management of each of the 59 symptomatic tracheal strictures fell into one of the categories outlined in *Table IV*.

The severity of the stricture is the major factor in deciding which method of treatment to use. Severe strictures (characterized by stridor) in which the diameter of the tracheal lumen is reduced to 5 mm. or less tend to be treated surgically (segmental resection or plastic reconstruction) since there is no evidence that they can be managed nearly as effectively by dilatation (Grillo, 1970), although dilatation is usually used to maintain a satisfactory airway while awaiting the optimum time for surgical intervention. Mild or moderate degrees of stenosis (characterized by an absence of stridor but having exertional dyspnoea and difficulty in raising sputum) in which the tracheal luminal diameter is greater than 5 mm. but less than 50 per cent of normal are usually treated by dilatation.

Table IV.—MANAGEMENT OF 59 CASES OF TRACHEAL STRICTURE

	No of Cases
1 Dilatation	
Endoscopic	11
Long tracheostomy tube	1
Laryngeal stent	2
2. Segmental resection (often preceded by dilatation)	
Circumferential	32
Wedge	2
3. Staged plastic reconstruction	2
	1 (plus 1 after failed segmental resection)
4. Tracheostomy	
Awaiting resection	8
Permanent	4
5 No treatment	5

Table V.—TREATMENT OF 14 TRACHEAL STRICTURES BY DILATATION

Type of Dilatation	*No. of Cases*
Endoscopy	8 stomal strictures 3 cuff strictures
Long tracheostomy tube	1 cuff stricture
Laryngeal stent	2 stomal strictures

Results. Good 6; satisfactory 8.

1. **Dilatation.**—Dilatation was used as the initial step in the treatment in almost all of the 59 cases of tracheal stricture. It was usually achieved by oral bronchoscopy using the bronchoscope as a dilator. The number of dilatations required, and the frequency with which they were performed, varied from case to case and was determined by the progress achieved.

Three patients with strictures at the level of the cuff of the tracheostomy tube had their tracheostomy re-established through the original cervical stoma and a metal tube of large diameter and appropriate length was passed through the stenosis as a method of achieving dilatation. A 5-month period of this type of dilatation was successful in 1 patient; the other 2 patients ultimately required segmental resection of the stricture after 4 months of attempted dilatation.

Re-establishment of the tracheostomy was required in 2 further patients so that a laryngotracheal stent could be used to achieve dilatation.

Table V summarizes the management of 14 tracheal strictures treated solely by dilatation. In general, management by dilatation alone was successful in the patients with mild to moderate degrees of stenosis, and in fact only 1 of the 14 cases had a tracheal luminal diameter of less than 5 mm. Restoration of a satisfactory airway was achieved in all 14 cases, and 8 of these had no clinical evidence of a reduced airway diameter.

2. **Segmental Resection of the Trachea with Primary End-to-end Anastomosis.**—In 34 of the 59 strictures (57·5 per cent) (16 strictures at the level of the original tracheostome, 18 at the level of the inflatable cuff) adequate treatment of the stricture ultimately required a local segmental resection of the tracheal stricture with reconstruction by primary end-to-end anastomosis. Operative details have been reported in a previous publication (Pearson and Andrews, 1971) and are similar to those used by others (Flavell, 1959; Mathey, Bines, Galey, Evrard Lemoine, and Denis, 1966; Gibson, 1967; Grillo 1970). The majority of the 34 cases had strictures classified as severe (diameter of the tracheal lumen reduced to 5 mm. or less), and only 3 of the strictures requiring resection had a tracheal luminal diameter greater than 5 mm.

Most of the 34 cases had initial treatment by some form of dilatation but without adequate improvement. The length of time over which dilatation was attempted prior to segmental resection varied from 1 week to 1 year (*Table VI*). The number of dilatations used in each patient was between one and ten, although 4 patients had multiple dilatations prior to resection. Two patients were dilated by a long tracheostomy tube prior to segmental resection and 6 other patients required tracheostomy.

Segmental resection of the stricture was the treatment of choice in most of the 34 strictures and was not used simply because dilatation had failed to restore a satisfactory airway. In the majority of severe strictures dilatation cannot achieve a satisfactory result, but repeated bronchoscopic dilatation can maintain an adequate airway until such time as segmental resection can be performed under favourable conditions.

Table VI.—LENGTH OF TIME OF ATTEMPTED DILATATION PRIOR TO SEGMENTAL RESECTION IN 34 CASES

Time of Dilatation (mth.)	*No of Cases*
0–1	14
1–2	10
2–6	8
6–12	2

Segmental resection and tracheal anastomoses are best performed through healthy rather than through softened, inflamed, and infected tissues so that the complication of restenosis is avoided. Endoscopic dilatation was used to maintain an adequate airway until the gross inflammatory changes found above and below the stricture had subsided and re-epithelization of the trachea had occurred. The stricture itself did not always epithelialize but segmental resection was delayed if possible until inflammation appeared minimal.

Operative Exposure.—Details of the operative technique used have been described in a previous publication (Pearson and Andrews, 1971). A cervical (collar) incision allows adequate exposure of the trachea to the mid-mediastinal level and was the most commonly used incision (28 out of 34 cases). During the early part of the series median sternotomy was used with the collar incision (3 cases) since it allows access to the entire trachea. It has since been found to be unnecessary, since with correct techniques a sufficient length of the mediastinal trachea is exposed with the collar incision. In 3 cases in which exposure of the distal 5 cm. of the mediastinal trachea was required, median sternotomy (1 case), right posterolateral thoracotomy (1 case), and median sternotomy with right posterolateral thoracotomy (1 case) were used for operative exposure.

Length of Trachea resected.—Circumferential segments of strictured trachea were resected in 32 cases nd 2 lesions were managed by anterolateral wedge esection with preservation of the normal posterior membranous trachea. The length of trachea esected varied between 0·5 and 5·5 cm. There was ood correlation between the length resected at operation and the length of the trachea shown to be nvolved in the stricture measurements of the radiographs (tracheal tomograms and cine-tracheograms), s may be seen from *Fig.* 1.

Pathology.—Of the 34 strictures resected (16 at he level of the tracheostome, 18 at the level of the nflatable cuff), 28 (12 at the stomal level, 16 at the uff level) were fibrous strictures (i.e. of a rigid and ibrous nature) and 6 (4 at the stoma, 2 at the cuff) were collapsing or malacic, the tracheal wall remaining soft and pliable at the level of the defect owing to oss of cartilaginous support of a short segment of the tracheal wall.

At operation a sufficient length of trachea was esected on either side of the stricture to allow rimary end-to-end anastomosis through healthy pithelialized trachea rather than through softened, nflamed, and infected tissue. The cut ends of the rachea were examined and categorized as inflamed, ot epithelialized, or healthy and epithelialized.

Twenty-five strictures (11 stomal, 14 cuff) were esected at the optimum time, the anastomosis being erformed through healthy epithelialized tissue, preoperative dilatations having been continued until the tricture was mature and inflammation in and round the stricture had subsided. Five patients (2 tomal, 3 cuff strictures) had anastomoses performed hrough inflamed tissue, 2 patients (both cuff trictures) had anastomoses performed through nepithelialized trachea, and in 2 cases (both cuff trictures) the state of the cut ends was not recorded.

The Results of Segmental Resection with Primary End-to-end Anastomosis.—*Table VII* summarizes the esults of segmental resection of 34 tracheal strictures

Table VII.—Results of Segmental Resection of 34 Strictures

Result	16 Stomal Strictures	18 Cuff Strictures
Good	13 (including 3 reoperations)	16 (including 2 reoperations)
Unsatisfactory	2	1 (after reoperation)
Deaths	1	1 (after reoperation)
Reoperation	3	4

with primary end-to-end anastomosis. There were 9 good results and these patients had complete bsence of symptoms or signs of airway obstruction no stridor, dyspnoea on exertion, or retention of racheobronchial secretions) following operation, and ad an airway diameter greater than 50 per cent of normal in all radii at the site of the end-to-end nastomosis. None of these patients was lost to ollow-up, which consisted of clinical assessment and racheograms obtained at least 6 months after operation.

There were 3 unsatisfactory results. One of these ollowed a wedge resection of a stomal stricture; a moderate degree of restenosis occurred at the site of anastomosis and was being treated by endoscopic dilatation at the time of the patient's suicide. A second unsatisfactory result followed a circumferential wedge resection of a 3-cm. length of cuff stricture. The anastomosis was performed through inflamed trachea on each side of the anastomosis and an early postoperative anastomotic dehiscence occurred with extensive loss of trachea on both sides of the anastomosis. The resulting long defect required reconstruction, which was performed by Dr. H. C. Grillo in Boston using his own technique of staged replacement with bipedicled skin-flaps (Grillo, 1970). The third unsatisfactory result followed a severe degree of infection in the anastomotic site during the immediate postoperative period with a resultant moderate degree of symptomatic restenosis in a debilitated patient. A second operation was not recommended.

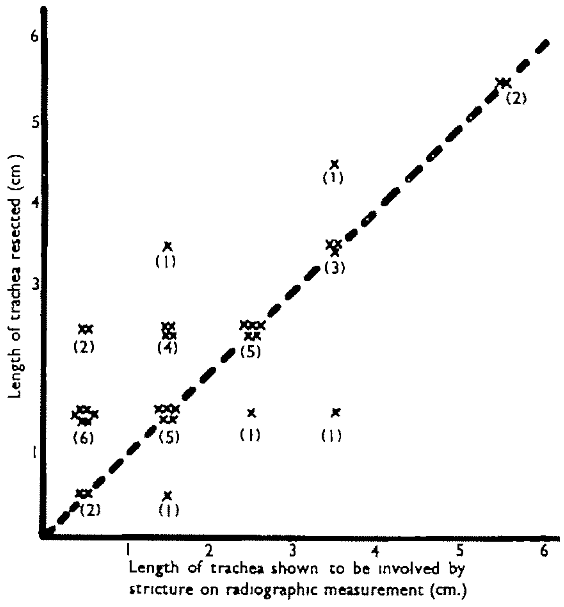

Fig. 1.—The correlation between the length of trachea resected at operation and the length of trachea shown to be involved by stricture on radiographic measurement.

One of the 2 operative deaths should have been avoided, the patient having an hypoxic cardiac arrest following the development of unrecognized laryngeal oedema and airway obstruction due to a haematoma in the neck wound in the immediate postoperative period. The other operative death was caused by erosion of the adjacent innominate artery 12 days after a second resection for restenosis of the mediastinal trachea.

Second Operation for Restenosis.—Seven of the 34 patients managed by segmental resection and primary anastomosis developed significant restenosis at the anastomosis (3 stomal strictures, 4 cuff strictures). Restenosis probably results from performing the anastomosis through an inflamed and infected trachea (4 cases). On the other hand, 3 patients having an anastomosis performed through unhealthy trachea tissue did not develop restenosis. Extensive mobilization may impair the circulation of the trachea, resulting in restenosis (3 cases).

Of the 7 patients requiring reoperation, 5 had a good result following the further segmental resection, 1 required staged reconstruction (as previously mentioned), and 1 died from erosion of the adjacent innominate artery 12 days after operation.

Postoperative Complications of Segmental Resection with Primary End-to-end Anastomosis.—

Dehiscence of the Anastomosis: Partial or total dehiscence of the primary end-to-end anastomosis may occur in the postoperative period (usually because the anastomosis was performed through unhealthy tracheal tissue) and results in restenosis. Seven of the 34 cases treated by segmental resection developed a partial dehiscence (3 had inflamed tissue included in the anastomosis and in 1 the tracheal wall used for anastomosis was not epithelialized). In 5 of these subsequent restenosis was severe enough to warrant reoperation, and in 2 the subsequent stenosis was satisfactorily treated by endoscopic dilatation.

Ischaemia of the anastomosis: Local ischaemia of the anastomotic site may have resulted from the extensive mobilization of the trachea, with subsequent impairment of the blood-supply, that is required in the resection of longer strictures. The local ischaemia caused restenosis either as a direct consequence (3 cases) or by bringing about partial dehiscence of the anastomosis (2 cases). In 3 cases of restenosis caused by ischaemia further operation was required and 2 other cases accounted for 2 of the unsatisfactory results of segmental resection already cited.

Infection of the anastomosis: In 1 case gross infection of the anastomosis was added to local ischaemia and resulted in a degree of restenosis which accounted for the third unsatisfactory result of segmental resection.

Haematoma formation: Two patients had a haematoma develop in the operative wound in the immediate postoperative period. In 1 of the patients it was unrecognized and resulted in obstruction of the airway which was followed by a fatal hypoxic cardiac arrest. The formation of a haematoma was recognized in the second patient. Evacuation and ligation of a small bleeding artery were performed.

Erosion of the adjacent innominate artery: In 1 case requiring further surgery for restenosis in the mediastinal trachea death occurred on the twelfth postoperative day following erosion of the adjacent innominate artery at the site of tracheal anastomosis. Infection was presumably the precipitating factor.

3. **Staged Plastic Reconstructions.**—A staged plastic reconstruction using pedicled flaps of cervical skin was used in 2 patients. Both strictures were in the subglottic area and extended above the lo border of the thyroid cartilage. Lesions at this le are not amenable to segmental resection and very difficult to manage effectively. One patient ha good result following this type of procedure and now asymptomatic. The other patient is m improved but has some clinical evidence of air obstruction. A third patient was treated by Dr. H. Grillo using a staged replacement with bipedic skin-flaps to deal with a restenosis after an early po operative anastomotic dehiscence following segmen resection with primary end-to-end anastomosis.

Details of the operative management of th patients will be reported subsequently. This type staged plastic reconstruction has been repor previously by McComb (1967) and Grillo (1969)

4. **Tracheostomy.**—Eight patients requi tracheostomy to relieve their airway obstruction u inflammation in and around their strictures subsided and segmental resection could be satisf torily performed. In these cases endoscopic dilatati could not maintain a satisfactory airway. This particularly true with collapsing or malacic strictu

Four further patients were so debilitated tha permanent tracheostomy was considered to be only feasible treatment. All 4 have since died of th primary disease.

5. **No Treatment.**—There were 5 patients had no treatment for their strictures. Two of th refused treatment for their severe stomal strictu and later died from airway obstruction due to acute episode of retained tracheobronchial secreti blocking an already compromised tracheal lum Another patient also refused treatment and still dyspnoea on exertion and difficulty in raising sputum. Two other patients have died of th primary condition since diagnosis of their stricture

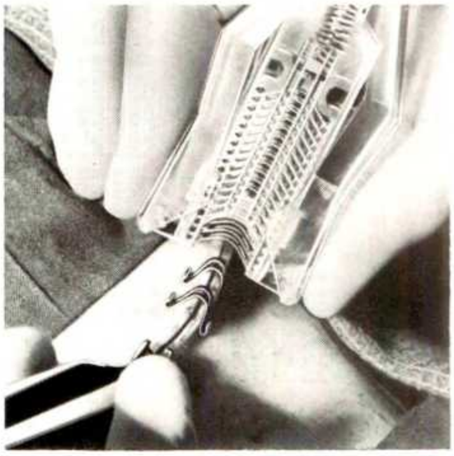
ICI introduces the

AVLOX 18

Trade Mark

SYSTEM



The AVLOX 18 System from ICI provides a new and simple method of wound closure.

Simply hold the wound edges together with forceps and apply clips along the length of the wound.

Obviously this technique offers advantages. It is fast, easy to use and convenient. It reduces the risk of permanent marks because the clips hold and do not generally penetrate the skin.

The AVLOX REMOVER (also illustrated) has been specially designed to minimise discomfort during clip removal.

Both the AVLOX 18 and the AVLOX REMOVER are supplied sterile and ready for use.

K

Kabikinase®
Streptokinase

Streptokinase
Kabikinase®

Surgical clearance of thromboembolism is often hazardous and troublesome. Clearance with Kabikinase can be a simpler matter, and it often yields superior results: probably because the logic of Kabikinase, highly purified streptokinase, is to potentiate the body's own *natural* ability to dissolve clots.

Kabikinase® (pure streptokinase for intravascular infusion) is manufactured by AB Kabi, Stockholm, Sweden and is available only from:

KABI

Kabi Pharmaceuticals Ltd,
Bilton House, Uxbridge Road,
Ealing, London W5 2TH

A handbook of information about thrombolytic therapy with Kabikinase will be sent on request.

ACALCULOUS GALL-BLADDER DISEASE

By A. GUNN, N. C. KEDDIE, and H. FOX
MANCHESTER ROYAL INFIRMARY, AND THE DEPARTMENT OF PATHOLOGY, UNIVERSITY OF MANCHESTER

SUMMARY

A prospective study of 130 consecutive unselected patients submitted to cholecystectomy for biliary disease has been made. Nineteen patients (14·6 per cent) were found to have acalculous gall-bladder disease. The clinical history of these patients did not differ significantly from those with calculous disease, whilst the radiological and histopathological findings in this group were variable.

Eleven of these 19 patients were completely relieved of their symptoms by surgery and it appeared that cholecystectomy was most successful in the patients with a history of either severe pain or previous acute cholecystitis. It is concluded that chronic gall-bladder disease may be acalculous and that, despite the lack of a homogeneous pathological background, surgery is of considerable value in a high proportion of such cases.

THE association between chronic gall-bladder disease and gall-stones, though not fully understood, is well recognized, and few would dispute that patients with biliary symptoms and demonstrable calculi are best treated by cholecystectomy. The condition of acalculous biliary disease is, however, less widely accepted. Several series of patients with acalculous gall-bladder disease have been reported (Mackey, 1934; Glenn and Mannix, 1956; Hoerr and Hazard, 1966; Munster and Brown, 1967), but these have all suffered from being retrospective and the reports have tended to leave in doubt the true proportion of cases in which stones were definitely absent. It is thus not surprising that the existence of acalculous biliary disease has been doubted by many who would maintain that such a diagnosis reflects either an error in investigation or a failure to recognize associated conditions responsible for the symptoms (Clark, 1968); proponents of this view maintain that the results of cholecystectomy are uniformly bad in patients in whom gall-stones are not demonstrable and it is, therefore, understandable that many surgeons are reluctant to operate on such cases (Glenn and Mannix, 1956).

Between December, 1968, and April, 1970, a prospective study of all the patients undergoing biliary surgery (excluding those operated on for malignant disease) in one surgical unit at the Manchester Royal Infirmary was undertaken. A full preoperative examination of each patient was made by one of us (A. G.), and detailed findings at operation, including those noted on operative cholangiography, were recorded; these were later correlated with the radiological and histopathological data. All the patients were followed up for a period of between 12 and 20 months after operation with a mean follow-up time of 15 months.

A surprisingly high proportion of these patients were found to have chronic acalculous biliary disease. The absolute number of such cases was small, but because of the doubts that surround this clinical entity we thought it worth while to record and analyse our experience of this group of patients.

FINDINGS

Incidence.—During the period of study 130 patients were submitted to cholecystectomy and in 19 cases (14·6 per cent) no stones were present in the biliary system. In a further 4 patients stones were present in the common bile-duct but not in the gall-bladder; such cases were not included in this series.

Clinical Features.—All the patients with acalculous biliary disease were Caucasian. There were 15 women and 4 men and the age-range was from 27 to 64 years (median age 47 years; mean age 46·8 years).

The duration of symptoms before surgery ranged from 1 month to 17 years with a mean duration of just over 3 years. All the patients had suffered pain, and in 11 patients this was described as severe; in 3 patients the pain was of moderate intensity, whilst in 5 the pain was described as mild or as an ache. The pain was in the upper abdomen except in 1 patient who had retrosternal pain, and in 10 patients the pain radiated through to the scapular regions. In 12 patients the pain was associated with vomiting; 3 patients seen during an attack of pain had clinical signs of acute cholecystitis.

Biochemical Findings.—Three patients had a raised serum bilirubin at some stage of their illness (levels of 1·3, 2·9, and 5 mg. per cent respectively), with an obstructive cause suggested by the serum-transaminase and alkaline-phosphatase readings. A further 7 patients had a raised serum alkaline phosphatase ranging from 16·5 to 20 K.A. units.

Radiology.—A preoperative cholecystogram or intravenous cholangiogram was performed on all but 1 of the patients. In 5 cases the gall-bladder was reported as non-functioning or as showing only minimal opacification. In 3 cases a polyp was visualized on cholecystography and in a further 2 cases the presence of a polyp was queried but could not be confirmed because of poor opacification of the gall-bladder. In 2 patients it was thought that stones were visible in the gall-bladder on cholecystography but in 1 of these opacification was poor and the evidence for the presence of a stone was unconvincing; in the other patient, however, several small stones did appear to be visible. In 3 patients septa were seen in the gall-bladder but in only 1 of these did the appearances suggest adenomyosis. In 3 patients the cholecystogram showed an apparently normal gall-bladder.

Histopathology.—Six of the removed gall-bladders were histologically normal whilst 4 showed an active chronic inflammation; mucosal hyperplasia was present in 7 gall-bladders whilst cholesterolosis was found in 3, in 2 cases this being coexistent with a mucosal hyperplasia.

Results of Surgery.—Eleven of the 19 patients were completely relieved of their symptoms by cholecystectomy whilst 5 showed no improvement. One patient was symptom-free for 20 months after her operation but then suffered a return of her symptoms. One further patient gained only slight relief of her symptoms from surgical intervention, whilst 1 patient died in the immediate postoperative period from a cerebral haemorrhage.

* Patient died postoperatively from cerebral haemorrhage.

Correlation of Clinical Features and Results of Surgery.—An attempt was made to correlate the results obtained by cholecystectomy in acalculous biliary disease with the clinical history, the radiological investigations, and the histopathology of the removed gall-bladder. The results are shown in *Tables I* and *II*.

DISCUSSION

The results in this series suggest that stones are absent from the biliary tract of a relatively high proportion of patients with symptoms suggestive of chronic biliary disease and that such patients often benefit considerably from cholecystectomy. It is emphasized that each gall-bladder in this series was opened immediately after removal and the presence or absence of stones was noted at that time. We believe that retrospective examination of case notes does not clearly show which gall-bladder contained stones and that most retrospective series probably underestimate the true incidence of gall-stones.

A surgeon is, therefore, going to be faced with patients in whom a history strongly suggestive of gall-bladder disease is apparently belied by an absence of demonstrable calculi. It is recognized, of course, that it is not possible in every case to come to a firm conclusion about the absence or presence of stones preoperatively; it is well known, for example, that a normal cholecystogram may be found in patients with a stone in the cystic duct (Large, 1968), whilst faulty opacification of the gall-bladder may leave the issue in doubt. Nevertheless, the operative results reported here indicate that, if careful investigation fails to reveal disease elsewhere, cholecystectomy is a worth-while procedure in acalculous cases. Eleven of the 18 surviving patients in this series were completely relieved of their symptoms by surgery, a result which, whilst not as good as that achieved by operating on calculous gall-bladders, is nevertheless in opposition to the view that cholecystectomy is rarely of value in acalculous patients.

It is, therefore, unfortunate that these patients do not form a homogeneous group and that relatively few factors emerge from this study which could indicate to the surgeon those patients in whom there is a likelihood of success resulting from operative intervention. The symptoms of acalculous gall-bladder disease do not differ in any significant way from those of calculous disease (LeQuesne and Ranger, 1957; Munster and Brown, 1967), but quite a high proportion of patients with acalculous disease complain of severe pain and it is these who benefit most from cholecystectomy; thus, whilst 10 out of 11 patients with severe pain obtained complete symptomatic relief from surgery this was true for only 1 out of 7 patients with mild pain. A further point that may indicate a successful outcome from surgery is a history of acute cholecystitis; all the patients in this series who suffered a clinical attack of acute cholecystitis became completely symptom-free after operative treatment.

The radiological findings in this series were varied. Patients with normal cholecystograms do not usually benefit from cholecystectomy (Glenn and Mannix, 1956; Cronin and Middleton, 1963), and indeed only 1 out of 3 such patients in our series improved following operation. This is not to say that a normal cholecystogram indicates a normal gall-bladder (Large, 1968), and it is worth adding that gall-bladders containing cholesterol polyps or even small stones may look and feel normal at operation (Lahey, 1927). Patients with a non-visualized gall-bladder on cholecystography usually benefit from surgery if they have severe biliary symptoms and if there is no reason to suspect failure of absorption or excretion of the contrast medium. In clinically doubtful cases, however, an intravenous cholangiogram or a repeat cholecystogram after an interval of 2–3 months may be rewarding. Presumably, acalculous gall-bladders fail to visualize on cholecystography because of a diseased mucosa, for in 4 out of our 5 cases there was histological evidence of active chronic inflammation.

These were 3 patients with convincing evidence of polyps of the gall-bladder, all of whom had severe symptoms and all of whom improved after cholecystectomy. Two further patients had questionable radiological evidence of polyps, 1 of whom had severe symptoms which were relieved by surgery. Thus, cholecystectomy can be recommended for patients with severe pain and a polyp visible on the cholecystogram. When symptoms are minimal the decision is not so easy. Tabah and McNeer (1953) have indicated the risk of carcinoma developing in papillomas of the gall-bladder, and the problem is made more difficult by the inability to differentiate radiologically between inflammatory, adenomatous, and cholesterol polyps of the gall-bladder (Ochsner, 1962). Most polyps, however, are cholesterol, and Eelkema, Hodgson, and Stauffer (1962) traced 113 out of 226 patients with radiological polyps and found no cases of carcinoma of the gall-bladder after 15 years. Procrastination in these patients would, therefore, seem reasonable although follow-up cholecystography may be wise. LeQuesne and Ranger (1957) advise operation for acalculous cases of adenomyomatosis, and more recently Heald (1970) has emphasized both the need for an awareness of this condition and the good results obtained by cholecystectomy if the patient has severe symptoms. The radiological criteria for the diagnosis of adenomyomatosis have been summarized by Colquhoun (1961). Diverticulae of the gall-bladder are easily seen if looked for, but the significance of a septum is not so easily defined and Jutras (1960) believes many of these to be 'segmented manifestations of hyperkinesis'. Thus, in our series septa up to 3 mm. in width appeared only as a slight narrowing or a waist in the opened gall-bladder.

The histopathological findings in this series were also variable and there was no clear-cut relationship between the histological findings and the results obtained by cholecystectomy. Six of the removed gall-bladders were histologically normal and this incidence of normality is somewhat greater than that found in gall-bladders removed for calculous disease; however, 3 of these patients, all of whom had suffered severe pain, were completely freed of their symptoms by cholecystectomy. The incidence of gall-bladders showing active inflammation was approximately the same as that in calculous gall-bladders seen at this hospital, but 1 of the 3 surviving patients with an actively inflamed gall-bladder failed to improve after surgery. Perhaps the most striking histological feature in this series was the relatively high incidence of mucosal hyperplasia. Mucosal hyperplasia can occur in calculous biliary disease, but the incidence of this histological abnormality in this acalculous series was much higher than that seen in gall-bladders with stones. Primary acalculous mucosal hyperplasia is well recognized and has been claimed by some workers to be a potent cause of biliary symptoms (Jutras, 1960; Elfving, Lehtonen, and Teir, 1967); nevertheless, in the present series there was no clear relationship between mucosal hyperplasia and benefit from cholecystectomy, 4 patients becoming symptom-free after surgery and 3 failing to improve.

It would appear, therefore, that acalculous biliary disease does exist as a clinical entity but that its pathological basis is variable. The surgeon faced with such cases can expect cholecystectomy to produce symptomatic relief in a considerable proportion of patients, this being especially so for those with a history of severe pain or of acute cholecystitis.

THE INFLUENCE OF THE VAGUS NERVES ON THE BILIAR

By D. S. HOPTON*
SINGLETON HOSPITAL, SWANSEA

VAGOTOMY has become accepted as a standard operation for the treatment of peptic ulcer during the past 15 years. Although used to treat a specific lesion in the stomach or duodenum, vagus division can have a much wider effect on the digestive system, but little attention has been paid by most surgeons to the effects of the vagus on other organs and it is timely to review the influence of the vagus nerves on the biliary system.

In 1887 Ruggero Oddi suggested that the sphincter which is named after him was partly controlled by a nervous reflex. Since then many anatomists, physiologists, and clinicians have investigated the effects of the vagus nerves on the biliary system. The anatomical distribution of the vagus nerve and its hepatic and coeliac branches has been more thoroughly worked out than have their physiological effects.

ANATOMY

Mitchell (1963) described 'two to four hepatic branches of the anterior vagal trunk or the greater anterior gastric nerve.... It is often possible to trace filaments to the common and cystic ducts and to the gall-bladder.' The posterior vagal trunk gives a large branch to the coeliac plexus. 'Owing to the multiple intricate inter-connections in the coeliac plexus it is impossible to trace the ultimate distribution of individual bundles but the coeliac branch must contain most of the para-sympathetic vagal fibres for abdominal viscera.'

It has been confirmed that in the dog fibres from the left vagus pass by the hepatic branch of the nerve to the gall-bladder, but the destination of fibres in the coeliac branch of the right vagus is still in doubt (Staveney, Kato, Griffiths, Nyhus, and Harkins, 1963).

The common bile-duct and hepatic duct are surrounded by numerous nerve-fibres which extend from the coeliac plexus up to the gall-bladder and down to the region where the bile-duct enters the duodenum (Kirk, 1944; Burnett, Gairns, and Bacsich, 1964; Libman, 1964; Libman and Sutherland, 1966). Kirk (1944) described a constant, well-defined nerve running down the common bile-duct and he thought that it originated in the dorsal vagus nerve.

PHYSIOLOGY

The evidence for neurological control of the gall-bladder and sphincter of Oddi is mainly circumstantial and has been derived from animal experiments and clinical studies.

Oddi (1887) observed that sphincter resistance was increased after irritating the duodenal mucosa and postulated the existence of a nervous reflex through the spinal cord.

Mitchell and Steifel (1916) considered that the sphincter response to vagal stimulation was equivocal, but Westphal (1923), after experimen
pigs, concluded that vagal stimulat

suggesting that the vagi act to maintain both sphincter and gall-bladder tone. This was supported by the observation that intravenous pilocarpine causes a rise in pressure in the dog after vagotomy. (Pilocarpine is a parasympathetic drug.) It is, however, pertinent to note that Lueth in 1931 showed that the intraduodenal pressure rose after administering pilocarpine, and it was possibly this rise in duodenal pressure which stopped the bile-flow in the experiments of Schein and others (1969). In contradiction to those results Williams and Huang (1969) recorded the gall-bladder pressure of fasting dogs before and after bilateral vagotomy and found a significant rise in pressure and a concomitant increase in gall-bladder volume. They concluded that these changes were due to increased sphincter resistance, suggesting that the vagi had an inhibiting influence on the tone of the sphincter of Oddi.

It is evident from these apparently contradictory results that the various investigators have been conducting experiments which were insufficiently controlled or else not comparable in the terms of their results. Several sources of error or confusion are definable in most of the experiments.

Stimulation of the vagal trunks, which are mixed nerves with a wide distribution, produces responses which are not confined to the biliary tract. Gastric secretions entering the duodenum could cause changes in the common bile-duct pressure, and studies under anaesthesia, though initially easier to carry out, may produce abnormal results.

In order to eliminate some of these sources of possible error and confusion Hopton and White (1971) prepared dogs with electrodes affixed to the hepatic and coeliac branches of the vagus nerves. A cannula was placed in the common bile-duct through the cystic duct stump and the gall-bladder was removed. A Thomas fistula (gastric-antral fistula; Thomas, 1941) was fashioned and the animals were allowed to recover for 2 weeks.

In 200 electrical stimulations of the hepatic and coeliac nerves using various currents and frequencies no change in the common bile-duct pressure which was attributable to the stimulation was recorded. The dogs were fully conscious throughout these studies and duodenal stimulation from gastric secretions was eliminated by drainage through the Thomas fistula. This study suggests that the vagal branches do not have a direct effect on the tone of the sphincter of Oddi.

CLINICAL EVIDENCE

The clinical interest in this apparently esoteric topic arises because of the well-documented evidence that the gall-bladder dilates after gastrectomy or vagotomy (Johnson and Boyden, 1952; Cox, Doherty, and Kerr, 1958; Griffith, 1962; Burge, 1964; Ruddick and Hutchinson, 1964). (During a gastrectomy the left gastric artery is ligated and thus damage or interruption of the hepatic branch of the left vagus nerve and of the coeliac branch of the posterior vagal nerve is usually present.)

FIG. 1.—Probable effects of vagotomy on the biliary system.

Griffith (1962) and Burge (1964) have also suggested that any effect on the gall-bladder would be abolished if only a selective vagotomy were carried out, so preserving the hepatic branch of the anterior vagus nerve and possibly also the coeliac branch of the posterior vagus nerve. This has been discredited by the work of Tinker and Cox (1969), who showed that gall-bladder emptying in response to insulin-induced hypoglycaemia and cholinergic and hormonal stimulation with carbachol and cholecystokinin was the same in patients after truncal or selective vagotomy.

Evidence of increased disease of the biliary tract after gastric surgery has been described in several papers but this is more difficult to substantiate than the radiological demonstration of gall-bladder dilatation. Krause (1963) found an incidence of biliary disease of 25 per cent occurring after Billroth-I gastrectomy, compared with an incidence of 12–13 per cent after conservative treatment of comparable patients. A smaller increase in biliary disease following Billroth-II gastrectomy was reported by Lundman, Orinius, and Thorsen (1964) and Schrieber and Luchman (1965). Nobles (1966) recorded an 18·2 per cent incidence of biliary disease in patients 12 years after vagotomy and gastro-enterostomy. Possibly more significant than the overall percentage is the apparent change in the sex ratio of gall-stone formation. In control subjects the female-to-male ratio was

5·8 : 1, but after Billroth-I gastrectomy the ratio was 1 : 2 (Majoor and Suren, 1947).

In order to interpret the clinical consequences of vagal section it is necessary to look further than the localized mechanical effects of changes in muscle tone. The hepatic branch of the vagus supplies the liver parenchyma and might, therefore, be expected to influence the rate of bile secretion and the composition of bile; the effects of the vagus on the stomach and small bowel must also be considered.

CHEMICAL CHANGES IN THE BILE

Recent publications indicate that there are changes in the bile composition as a consequence of vagotomy. Schein and others (1969) described an increased viscosity of canine gall-bladder bile after vagotomy. They also noted that particulate matter was visible in this bile and that after vagotomy canine gall-bladder bile was no longer able to dissolve human cholesterol gall-stones. Some of the dogs with human gall-stones in their gall-bladders developed a syndrome similar to that of acute cholecystitis (also noted by Hilbun and Barnett, 1965).

Fletcher and Clarke (1969) measured the flow-rate and composition of common bile-duct bile before and after vagotomy in dogs. They found that vagotomy markedly reduced the bile volume secreted in response to a fatty meal and that there was a fall in the bile-salt content. The concentration of phospholipids and cholesterol in the bile was not affected by vagotomy and therefore the net result was a fall in the ratio of bile-salt and cholesterol concentrations.

A decrease in the bile-salt : cholesterol ratio endangers the solubility of the cholesterol in the micelles formed by the phospholipids and bile-salts (Small, 1968). Thus, the experimental results of Fletcher and Clarke (1969) in dogs are significant in indicating that vagotomy causes changes in the hepatic bile which increase the possibility of cholesterol precipitation which could in turn increase the risk of gall-stone formation.

VAGAL INFLUENCES THROUGH OTHER ORGANS

To consider the biliary system in isolation in its relation to the vagus nerves would omit possibly important factors mediated through the stomach and small bowel. Vagotomy, by reducing gastric acidity and possibly modifying the rate of gastric emptying, could decrease the rate and amount of secretion of cholecystokinin by the duodenum. This in turn would reduce gall-bladder contraction. Denervation of the small bowel may interfere with the reabsorption of cholate and thus affect the bile-salt enterohepatic circulation and possibly cause a shift in the cholate : cholesterol ratio. Such changes are, however, still conjectural and await experimental demonstration.

CONCLUSIONS

1. The anterior vagus nerve maintains gall-bladder muscle tone through its hepatic branch.
2. The tone of the sphincter of Oddi may be influenced through the coeliac branch of the posterior vagus nerve. This has not been either demonstrated or disproved conclusively.
3. There is a nervous reflex between the gall-bladder and sphincter of Oddi which can be abolished by dividing the common bile-duct and its surrounding nerve plexus.
4. The hepatic branch influences the hepatic bile composition to maintain the bile-salt : cholesterol ratio.
5. Division of the vagus nerves increases the risk of gall-stone formation. *Fig.* 1 shows the probable effects of vagotomy on the biliary system.

COELIAC AND HEPATIC NERVE FUNCTION FOLLOWING SELECTIVE VAGOTOMY*

S. T. D. McKELVEY,† D. TONER, A. M. CONNELL,‡ AND T. L. KENNEDY
DEPARTMENT OF SURGERY, QUEEN'S UNIVERSITY OF BELFAST

SUMMARY

1. In the intact patient insulin hypoglycaemia increases the output of amylase and bile-acids despite the exclusion of acid from the duodenum.

2. This effect is abolished by truncal vagotomy.

3. After selective vagotomy a partial response from the pancreas occurs consistent with preservation of a direct route in the coeliac nerve and the loss of vagally released pancreatic secretagogues. A similar effect in the biliary system could not be demonstrated.

SELECTIVE vagotomy for duodenal ulcer has been advocated because it may reduce the incidence of episodic diarrhoea compared with truncal vagotomy (Kennedy and Connell, 1970). Selective vagotomy involves preservation of the coeliac and hepatic branches supplying the biliary system, the pancreas, and the midgut, but the relation of these nerves to the local reflexes and humoral mechanisms is not known.

Pancreatic secretion in man increases in response to the sight or smell of food (Sarles, Dani, Prezelin, Souville, and Figarella, 1968). The pancreas also secretes in response to hypoglycaemia provided that the vagus nerves are intact (Dreiling, Druckerman, and Hollander, 1952). Hypoglycaemia similarly stimulates the exocrine functions of the biliary system until vagotomy is performed (Baldwin, Heer, Albo, Peloso, Ruby, and Wilen, 1966; Tinker and Cox, 1969). The pathways involved may be direct, through the coeliac and hepatic nerves, or indirect, through the vagal release of antral hormones (Lenninger, Magee, and White, 1965; Nahrwold, Cooke, and Grossman, 1967).

Clinical assessment of selective vagotomy is handicapped by uncertainty regarding the integrity of function in the preserved branches. A study was planned to examine the effect of hypoglycaemia as a central stimulant of these extragastric branches of the vagus nerves in order to determine whether selective vagotomy preserves parasympathetic influence on the pancreas and biliary system.

MATERIALS AND METHODS

Fifteen patients with Hollander-negative selective vagotomy and pyloroplasty were studied more than 1 year after operation for duodenal ulcer. Control studies were performed on 12 patients with Hollander-negative truncal vagotomy and pyloroplasty and also 14 patients with uncomplicated duodenal ulcer who had never had gastric surgery.

Following an overnight fast, a double-lumen tube (Dreiling) was positioned under fluoroscopic control so that the proximal limb drained the body and antrum of the stomach and the distal limb drained the second, third, and fourth parts of the duodenum. Basal secretion was aspirated continuously for 1 hour into a container at 0° C. Following the intravenous injection of 20 U. of soluble insulin, the stimulated secretion was collected similarly for 2 hours in eight fractions. The blood-sugar was measured before and at 30 and 45 minutes after the injection of insulin. In all the patients a hypoglycaemia of less than 50 mg. per 100 ml. was achieved.

Using phenol red as an indicator, the acid concentration of the gastric juice was measured by titration against 0·1 N NaOH. The collection of gastric juice provided information on the completeness of the gastric denervation and also prevented acid from entering the duodenum.

The duodenal samples were analysed for content of amylase and total bile-acids.

Amylase was measured by an automated procedure using the Technicon Auto Analyzer, in which prediluted aliquots of duodenal juice were introduced into a diluent stream of modified starch substrate and incubated at 37° C. for 3 minutes (Strumeyer, 1967). The reducing sugar formed was then dialysed into a recipient stream of alkaline potassium ferricyanide solution. The resultant reduction of the ferricyanide was measured colorimetrically at 420 nm. Pure glucose solutions were used as standards and the results determined as mg. of glucose liberated from the substrate in 3 minutes per 100 ml. of duodenal juice. The total amylase secreted in each collecting period was calculated.

Total bile-acids were measured by a method in which diluted aliquots of duodenal juice in saturated sodium chloride solution were acidified and then extracted with a diethylether/ethanol mixture (3 parts diethylether to 1 part ethanol; Sjovall, 1959). A portion of each extract was then evaporated to dryness in a water-bath at 37° C., and then 50 per cent sulphuric acid was added to the dried residue. The resultant colour reaction with the sulphuric acid was measured in a spectrophotometer at 340 nm. after allowing the colour to stabilize for 1 hour at room temperature in the dark. Test samples were read against cholic acid standards which had been carried through the extraction process along with the test solutions. The results were determined as mg. of bile-acid per 100 ml. of duodenal juice. The total bile-acid secreted in each collecting period was then calculated.

† Present address: Department of Surgery, University of Newcastle upon Tyne.

‡ Present address: Mark Brown Professor of Medicine, University of Cincinnati.

RESULTS

The results for both pancreatic and biliary secretion were expressed in a logarithmic form because of wide variation in the level of secretion between the individuals in each group. The basal secretion of each group was compared with the secretion in the maximal hour after stimulation. In addition, the magnitude of the responses in the postoperative groups was compared with the response of the preoperative patients.

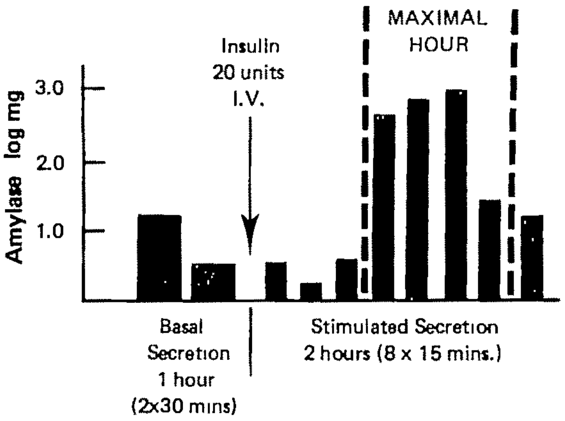

FIG. 1.—Pattern of amylase secretion in a preoperative patient.

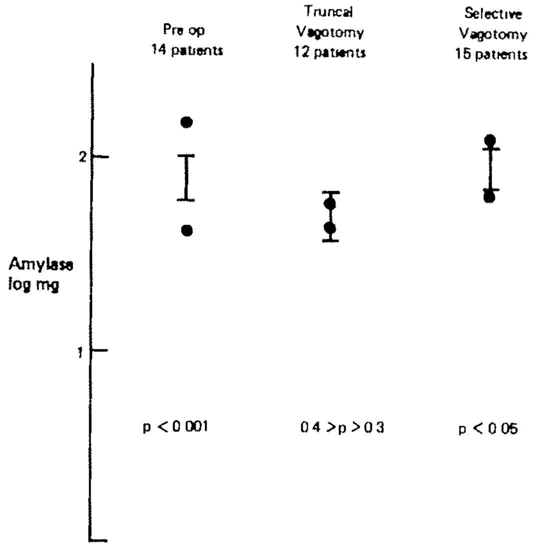

FIG. 3.—Pancreatic response to hypoglycaemia in pre- and postoperative patients. In each group the mean secretion in the basal hour and the mean secretion in the maximal hour are shown, together with 2 S.E. of the difference between the means.

In the preoperative patients the secretion of amylase in the maximal hour after stimulation was 3·6 times that of the basal secretion ($P < 0\cdot001$) (*Figs.* 1, 3). Simultaneously the output of bile-acids rose 3·1 times ($P < 0\cdot05$) (*Figs.* 2, 4).

In the patients with Hollander-negative truncal vagotomy, secretion of amylase in the maximal hour after hypoglycaemia was not different from that in the basal hour (*Fig.* 3). The response was significantly less than that observed in preoperative patients ($P < 0\cdot05$). The output of bile-acids also failed to increase (*Fig.* 4) and differed from the response observed in the preoperative patients ($P < 0\cdot05$).

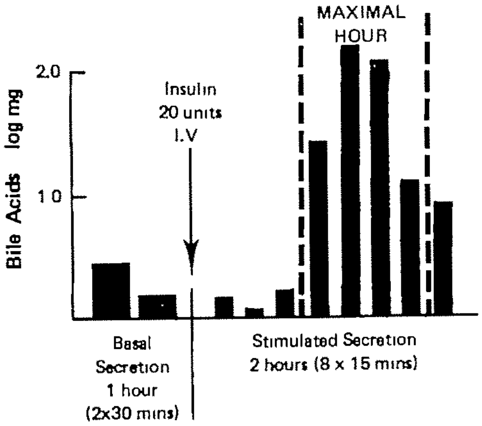

FIG. 2.—Pattern of bile-acid secretion in a preoperative patient.

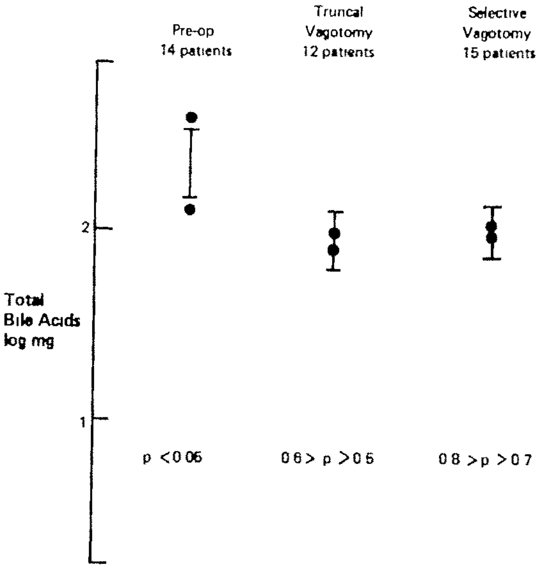

FIG. 4.—Biliary response to hypoglycaemia in pre- and postoperative patients. In each group the mean secretion in the basal hour and the secretion in the maximal hour are shown, together with 2 S.E. of the difference between the means.

In the patients with Hollander-negative selective vagotomy the output of amylase in the maximal hour after stimulation was 1·8 times that in the basal hour ($P < 0\cdot05$) (*Fig.* 3). This increment did not differ significantly from that found in preoperative patients ($0\cdot1 > P > 0\cdot05$). However, a response was not observed from the biliary system (*Fig.* 4) and this was significantly different from that observed in the preoperative patients ($P < 0\cdot05$).

DISCUSSION

In the preoperative patients amylase secretion could be readily increased by inducing hypoglycaemia.

This occurred despite the exclusion of acid from the duodenum and is consistent with the findings of Dreiling and others (1952). Similarly the output of total bile-acids into the duodenal lumen was increased. Evidence that the formation of bile-acids is influenced by the activity of the vagus or vagally released hormones has not been recorded. The biliary response may therefore be due to emptying of the gall-bladder, as reported by Tinker and Cox (1969).

Truncal vagotomy abolished the pancreatic and biliary responses to hypoglycaemia. This finding is consistent with complete interruption of all the vagal pathways to the pancreas and biliary system.

The performance of the patients with selective vagotomy is more difficult to interpret. No evidence was found that this operation preserves vagal influence on the biliary system in response to hypoglycaemia. Similar observations have been reported by Tinker and Cox (1969) using cholecystography to measure the response to hypoglycaemia. On the other hand, a pancreatic response was observed which was statistically significant ($P < 0{\cdot}05$).

Selective vagotomy may preserve the direct innervation of the pancreas through the coeliac nerve while abolishing indirect stimulation through the vagal release of antral hormones. This would account for the diminished, though significant, response. This interpretation is compatible with evidence that vagal stimulation of the antrum augments pancreatic secretion (Preshaw, Cooke, and Grossman, 1966). Alternatively, the diminished response may be due to operative failure to preserve the extragastric nerves in some cases. Such operative failures would obviously make the results of clinical trials of selective vagotomy difficult to interpret. It is possible that the technique used in this study could be adapted to the recognition of patients in whom the operation of selective vagotomy was a technical failure.

The lower incidence of diarrhoea which has been reported after selective vagotomy is difficult to attribute to preservation of pancreatic function. The episodic pattern of this complaint is not consistent with denervation. Malabsorption is not a specific feature of patients with episodic postvagotomy diarrhoea.

Uncontrolled gastric emptying occurs after vagotomy and drainage and is an aetiological factor in postvagotomy diarrhoea (McKelvey, 1970). Patients without diarrhoea after vagotomy can tolerate uncontrolled emptying into the small bowel better than those with diarrhoea. It is possible that preservation of the nerve-supply of the midgut enhances this tolerance. This would be consistent with the observation of Alvarez, Hosoi, Overgard, and Ascanio (1929) that the vagotomized gut is irritable, and of Gutierrez, Kocak, and Cox (1971) that it is supersensitive when subjected to physical and chemical stimuli.

THE KIRSCHNER OPERATION—A FORGOTTEN PROCEDURE

BY G. B. ONG

DEPARTMENT OF SURGERY, UNIVERSITY OF HONG KONG, QUEEN MARY HOSPITAL, HONG KONG

SUMMARY

Kirschner, in 1920, described an operation for benign stricture of the oesophagus. This entails division of the cervical oesophagus, closing the distal portion, bringing the stomach to the neck, and anastomosing the fundus to the proximal divided portion of the oesophagus. This operation has not been performed since, because of the tedious anastomosis between the divided abdominal oesophagus and the jejunum. However, it may be applied in the treatment of malignant oesophagobronchial fistula when it is desirable to isolate the fistula from the upper alimentary tract. This paper describes the operation as carried out in the treatment of 18 cases of advanced oesophageal carcinoma, 6 of whom had a oesophagobronchial fistula. When the operation was successful the patients could eat a normal diet without spasms of cough.

IN 1920 Kirschner described an operation in which, after mobilizing the stomach, he brought it subcutaneously to the neck and there anastomosed it to the divided cervical oesophagus. In his first case he had difficulty in bringing the fundus of the stomach sufficiently high to make a direct anastomosis between it and the cervical oesophagus. However, he managed to restore the oesophagogastric continuity by interposing skin. Subsequently, he succeeded in making a direct anastomosis between the stomach and the oesophagus. At the lower divided end of the oesophagus he performed a Roux-en-Y anastomosis. No report of this operation has been made since, and in 1944 Yudin condemned it as dangerous because of the added anastomosis between the lower end of the oesophagus and the jejunum.

Ong and Kwong (1970) advocated isolating a malignant oesophagobronchial fistula from the rest of the upper alimentary tract by performing a double by-pass with jejunum. The Kirschner operation, however, may be an alternative method of achieving the same end. During the period from March, 1970, to June, 1971, 18 such operations have been performed at the Queen Mary Hospital, Hong Kong.

MATERIALS AND METHODS

All the cases were in an advanced stage of malignant disease in which resection was not possible. Of the total 18 cases, there were 14 males and 4 females. The age-range was from 42 to 81 years, with an average of 59 years.

Clinical Features.—All the patients complained of dysphagia, ranging from 1 week to as long as 18 months in duration. All but 1 of the patients had received no previous treatment. The history was typical of carcinoma of the oesophagus with dysphagia, there being difficulty in swallowing first solids, then semiliquids, and finally fluids. In addition, 6 cases coughed out food on swallowing, indicating the possibility of an oesophagobronchial fistula.

There was marked loss of weight, ranging from 3·6 to as much as 11 kg., with an average of 9 kg. over the period of illness.

Blood-streaked sputum was encountered in 5 of the patients. The sputum itself varied in amount; in some cases as much as 140 ml. of sputum were coughed out during 24 hours, and it was usually purulent with a lot of froth but occasionally the fluid component was excessive.

Examination.—The general health was good only in 1 case; 3 patients were so ill that they could not even sit up in bed. The remaining 14 patients also had poor health. Detailed examination showed evidence of marked loss of weight, and at bronchoscopy invasion of the carcinoma into the trachea or the right or left bronchus was found in all the cases. In addition, an oesophagobronchial or tracheal fistula was demonstrated in 6 patients.

Oesophagoscopy.—The growths were all found to be fixed; in 3 cases the tumour was situated in the upper thoracic part of the oesophagus, while in the other 15 cases the growth was in the mid-thoracic section. In 2 cases chest radiographs showed extensive tuberculosis; in 1 of these a pneumonectomy had been performed in 1968 for a destroyed right lung. The oesophagobronchial fistula was demonstrated in the left bronchus. In another case there was collapse of the right lower lobe of the lung in addition to extensive pneumonitis. Of the 18 cases, the lung was free from infection in only 1 case.

Preoperative Preparation.—Intravenous feeding is usually necessary for the patients who have total dysphagia and in most of these cases a gastrostomy should be performed soon afterwards. In the majorit of cases some weight-gain is apparent after a shor period of feeding.

Tracheostomy for toilet is necessary in cases wher there is profuse sputum, especially in the patients wh have difficulty in expectorating their sputum.

Operation.—As soon as the patient is thought t be strong enough, operation is performed. Before th induction of anaesthesia, bronchial toilet is carrie out through either a bronchoscope or, in those case with a tracheostomy, by suction with a catheter Oesophagoscopy is also done, so that the accumulate secretion proximal to the point of obstruction can b sucked out.

A midline incision extending from the xiphisternum to approximately 2 cm. below the umbilicus is made A generous incision facilitates the subsequen abdominal part of the operation.

Exploration of the abdomen is carried out first afte opening the peritoneum, and if there are metastase in the liver then it would be wise to abandon th operation. If there are no metastases in the abdomina cavity the stomach is mobilized. This is done b dividing the gastrocolic omentum, preserving th arterial arcade on the greater curvature, and dividin the vasa brevia from the lieno-renal ligament. In th process of dividing the uppermost vas brevis (whic is sometimes very short) the spleen is occasionall damaged, necessitating its removal. The lesser curvature of the stomach is then freed. This is done easil by cutting through the lesser omentum and coagulating the few small vessels running over it. As soon a the greater and lesser curvatures are completel free an extensive Kocher manœuvre to expose th aorta and the inferior vena cava is carried out. Th junction between the second and the third parts o the duodenum with the reflection of the transvers mesocolon is freed, so that the duodenum now lie almost in a straight line.

Examination of the biliary tract is important becaus occasionally symptomless gall-stones may be present When the stomach is brought up into the thorax o neck the common bile-duct comes to lie transversel across the abdomen. This change of position of th common bile-duct could cause stagnation of bile i the gall-bladder and stones might become impacte in the cystic duct. This could give rise to empyema o the gall-bladder in the immediate postoperative period

Pyloromyotomy is then performed. There may b some difficulty at this stage as the duodenal mucos may be opened accidentally. Part of the pylori sphincter should be excised and the transverse circula muscle can then be dissected out and a segment of i removed.

After the pyloromyotomy has been completed transection of the stomach is done. The junctio between the oesophagus and the cardiac portion of th stomach is divided; in order to facilitate anastomosi a small portion of the cardia should be left wit the divided oesophagus. The divided cardiac portio of the stomach is then closed with two layers o atraumatic catgut and the stomach is laid aside. A loop of jejunum about 15 cm. from the duodenojejuna junction is prepared. Only one main branch of th jejunal vessel needs to be divided. This should giv sufficient length for the divided distal loop to b brought up to the lower end of the oesophagu without tension. After dividing the jejunum, the vertical limb is brought to the lesser sac through the transverse mesocolon in which a window has been made, usually to the left of the middle colic artery. This loop is then anastomosed to the lower end of the divided abdominal oesophagus with two layers of atraumatic catgut.

Continuity of the jejunum is restored by making a one-layer end-to-side anastomosis between the divided proximal jejunum and the vertical limb. This anastomosis should be at least 45 cm. from the oesophagojejunal anastomosis.

Anastomosis between the Stomach and Divided Cervical Oesophagus.—Having completed the abdominal anastomosis, the stomach is brought up to the neck through a subcutaneous tunnel made with a pair of long scissors of the Albee type. By opening the blades of the scissors a tunnel is created which is sufficiently large to allow the stomach to pass through. There is some danger of damaging the perforating branches of the internal mammary artery in making the tunnel. Should this happen, the skin should be slit open and the bleeding controlled. If bleeding were to take place undetected, the blood might track down into the abdominal cavity, causing hypovolaemic shock and possibly death.

After the subcutaneous tunnel has been completed, a transverse incision is made in the neck. The incision is enlarged and a skin-flap raised so that the anterior border of the left sternomastoid muscle is exposed. This muscle is divided at its attachment to the clavicle and the sternum. By dissecting into the carotid sheath the internal carotid artery and internal jugular vein are exposed.

The middle thyroid and the superior thyroid veins occasionally need to be divided. The inferior thyroid artery is then dissected out behind the carotid sheath and this is ligated and divided. The oesophagus then comes into view. By dissecting close to the oesophagus and gently retracting the trachea, the oesophagus is freed with exposure of the recurrent laryngeal nerves. Care has to be taken not to damage these nerves. The oesophagus, after having been freed completely from its bed, is retracted. It is divided as low as possible but allowing good clearance of the tumour. The lower end of the cervical oesophagus is closed with two layers of atraumatic catgut after the contents have been sucked out. The proximal divided end is brought out after it has been freed so that it can lie subcutaneously without tension. The divided sternomastoid muscle is fixed to the prevertebral muscle and fascia with stout stitches, so that a space is created in which the stomach can be comfortably lodged.

A disk of the fundus of the stomach, usually at the level of the second or the third vas brevis, is removed. This should not be larger than the circumference of the oesophagus to which it is to be anastomosed. After the vessels supplying the fundus of the stomach have been stitched, the anastomosis is made with one layer of interrupted silk sutures. The posterior layer of the anastomosis is made first, and just before the anterior layer is started a nasogastric tube is inserted into the stomach. The proximal end of the tube is threaded into the pharynx and brought out through the nose by the anaesthetist. The anterior anastomosis is then completed. The neck wound is closed with a drain, and the abdomen is finally closed.

Just before the patient is returned to the ward, bronchial toilet is performed again as sputum may have accumulated during the operation, especially in patients with an oesophagobronchial fistula.

Postoperative Care.—Occasionally, the general condition of the patient is so poor that respiratory aid is needed. Blood-gas estimation is done immediately on the patient's return to the ward. If the Po_2 is low a respirator should be used until the patient is able to breathe on his own. Metabolic acidosis might have to be corrected if the pH is low. Blood-gas estimation is repeated every 6 hours for the next 24 hours and then daily for about a week or so.

Intravenous Feeding.—Blood usually has to be given because either the patients are anaemic or their general condition is very poor. Intravenous feeding might have to be continued for the next 4 or 5 days until the stomach has sufficiently recovered its tone and healing has taken place.

Care of the Tracheostomy.—When a tracheostomy has been carried out frequent suction of the tracheostomy must be performed, especially in patients with a malignant oesophagobronchial fistula. This prevents accumulation of sputum and enables the pneumonitis to subside.

Antibiotics.—Antibiotics should be given postoperatively. The benefit of these is most obvious in patients with a malignant oesophagobronchial fistula when the amount of sputum is large. Culture of the sputum and a sensitivity test of the organisms should be carried out, and Terramycin or one of the broad-spectrum antibiotics used in controlling pulmonary infections.

Gastric Aspiration.—Decompression of the stomach is important as accumulation of gastric secretion might occur. If this is not aspirated through the nasogastric tube the accumulation of gastric contents might be regurgitated and then aspirated into the bronchus, which would further aggravate the pulmonary infection. The tube should not be removed until the patient is able to swallow and radiographic examination reveals no leakage at the site of the anastomosis. Once the tube has been removed it is difficult to replace it.

Oral Alimentation.—A Gastrografin swallow should be done on the sixth postoperative day. If no leakage is demonstrated and the patient is comfortable, fluids may be given. A normal diet is started within 7–10 days. At this stage intravenous feeding is discontinued and the patient is allowed to get out of bed.

RESULTS

Of the 18 cases operated on, 4 died in the immediate postoperative period—9, 15, 17, and 14 days after operation respectively. Of these 4 cases, 2 had pulmonary tuberculosis and had been treated for this condition. Three patients died of respiratory insufficiency, while the remaining case had a leak in the jejunojejunal anastomosis. The chest was in a poor state before operation in each case.

Complications.—

Pulmonary Infection.—This was by far the most common complication. All the 6 cases with an oesophagobronchial fistula had severe infection before operation. Eleven cases had pneumonitis befor operation, and in only 1 case were the lungs clear of infection. However, after the operation all the cases with infection had aggravation of their condition and required extensive physiotherapy for its control.

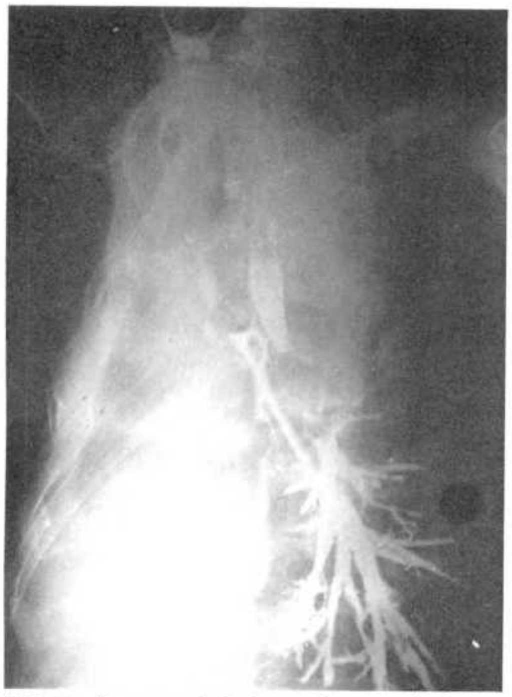

FIG. 1.—*Case* 15. A barium-swallow examination was accidentally carried out in this patient and demonstrated an oesophagobronchial fistula.

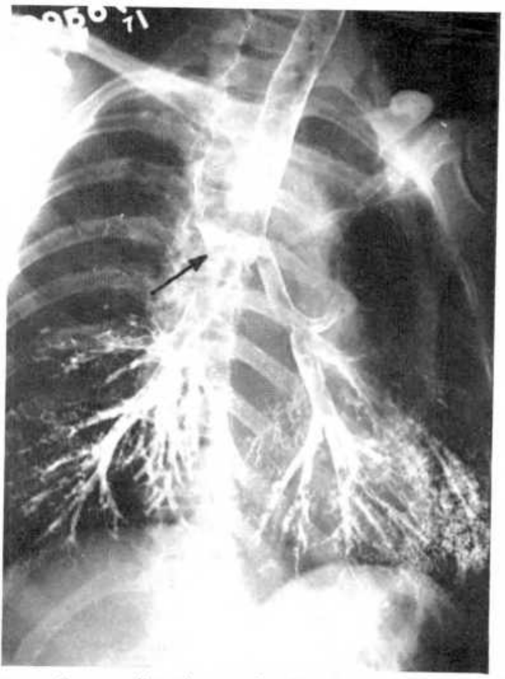

FIG. 3.—*Case* 10. Bronchogram showing an oesophagobronchial fistula (arrow).

CASE REPORT.—

Case 15.—W. H. S., a 65-year-old male, presented complaining of dysphagia for a period of 2 months and weight-loss. He was known to have had pulmonary tuberculosis for a long time, and in 1968 a right pneumonectomy had been done. There was a considerable amount of sputum, an average of 84 ml. being expectorated each day. Before admission on the present occasion the patient had received irradiation to a carcinoma of the oesophagus and had developed an oesophagobronchial fistula which was demonstrated radiographically. The left lung showed pneumonitis (*Figs.* 1, 2). Oesophagoscopic examination confirmed the diagnosis of carcinoma of the oesophagus which even after an irradiation of 3420 rad still gave positive results. Bronchoscopy revealed a fistula between the left main bronchus and the oesophagus. A gastrostomy was performed at the time of bronchoscopy. Operation was carried out on 21 Dec., 1970. After the operation the patient was able to breathe very well without any respiratory aid. Although the sputum lessened initially it began to reaccumulate, and a radiograph of the chest showed that there was extensive infection of the remaining lung. Tracheostomy was performed and bronchial toilet was carried out repeatedly. The patient died on the fifteenth day after operation, and post-mortem examination revealed acute infection of the remaining lung. There was a small leak at the site of the anastomosis. This could have healed spontaneously. The cause of death was respiratory infection.

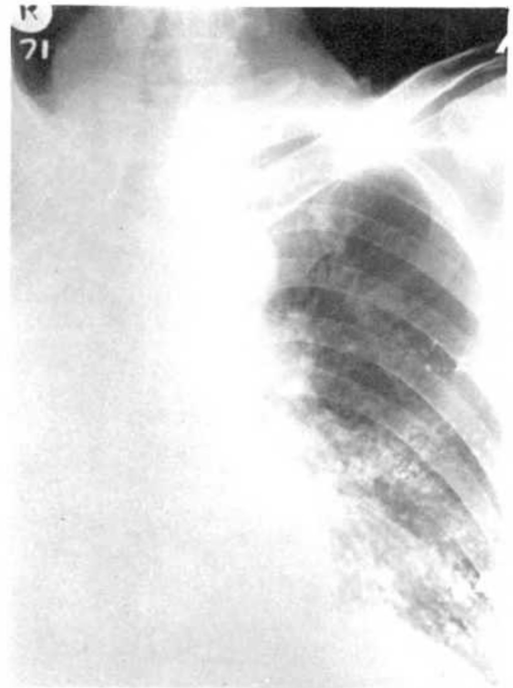

FIG. 2.—*Case* 15. Plain radiograph of the chest showing pneumonitis in the lung with residual barium.

Leakage at the Site of the Neck Anastomosis.—Of the 18 cases, only 5 had primary healing at the site of the anastomosis. The remaining 13 had a varying amount of leakage, usually of the outer anastomosis. However, of these 13 cases, only 2 required a secondary repair. The others healed spontaneously except in 1 case who died 2 weeks after operation. The other patients were able to eat soon after the operation, but in 2 oral feeding was delayed for 2 or 3 weeks.

In 1 case the anastomosis healed by primary intention and the patient was able to eat normally.

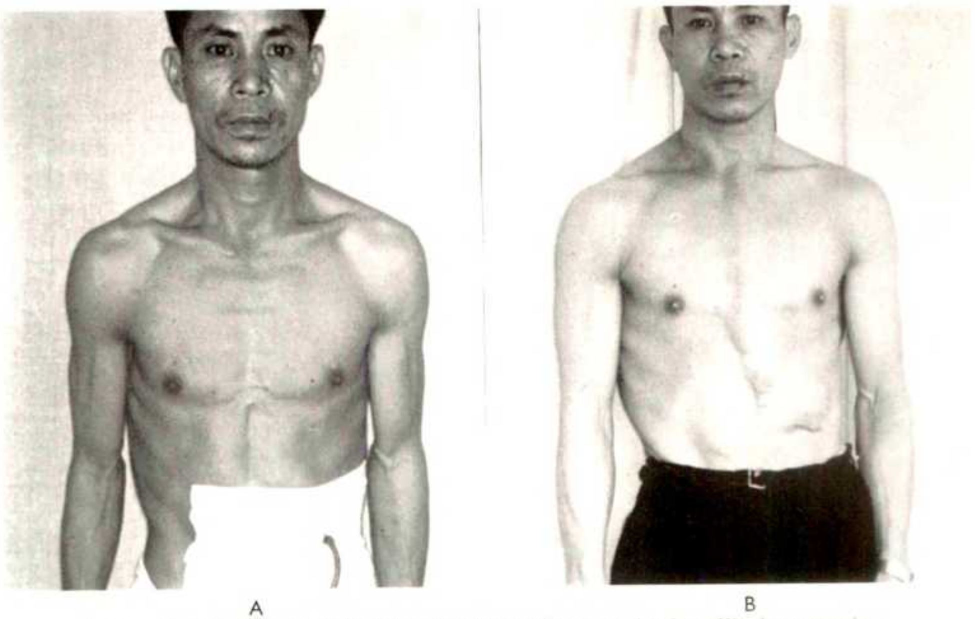

FIG. 4.—*Case* 10. The patient (A) before operation and (B) 14 months after a Kirschner operation.

Table I.—DETAILS OF 18 PATIENTS WHO UNDERWENT A KIRSCHNER OPERATION FOR CARCINOMA OF THE OESOPHAGUS

CASE	AGE AND SEX	STATE OF DISEASE	LENGTH OF SURVIVAL	ABILITY TO SWALLOW
1. A. T. T.	54 M.	Penetration of left bronchus	3 mth.	Normal diet
2. C. K.	74 M.	Penetration of left bronchus	2 mth.	Fluids
3. K. M.	58 M.	Penetration of left bronchus and lungs	3 mth.	Normal diet
4. K. C. S.	53 M.	Penetration of right bronchus	9 d.	—
5. L. C. Y.	68 F.	Penetration of trachea	Discharged: lost to follow-up	Normal diet at time of discharge
6. L. M. S.	50 M.	Oesophagobronchial fistula	8 mth.	Normal diet
7. L. T.	51 M.	Fistula at trachea	1 mth.	Fluids
8. L. K. C.	81 M.	Penetration of trachea	1½ mth.	Fluids
9. L. K.	47 M.	Penetration of trachea	2 mth.	Normal diet
10. L. F.	42 M.	Oesophagobronchial fistula	14 mth.	Normal diet
11. L. S.	75 M.	Penetration of trachea	9 mth.	Normal diet
12. L. Y. C.	79 F.	Oesophagotracheal fistula	2 wk.	—
13. P. H. S.	47 F.	Penetration of left bronchus	3 mth.	Normal diet
14. T. M. F.	50 F.	Oesophagotracheal fistula	2 mth.	Fluids
15. W. H. S.	65 M.	Oesophagobronchial fistula	15 d	—
16. Y. K. S.	64 M.	Penetration of trachea	17 d.	—
17. W. L. S.	50 M.	Penetration of trachea	1½ mth.	Normal diet
18. W. C.	55 M.	Penetration of trachea	1 mth.	Fluids

Two months later, the wound broke down completely and revealed the presence of a large fistula. Under local anaesthesia an attempt was made to repair this fistula. However, on exploration it was found that the site of the fistula was not at the anastomosis but near the point where the stomach was anchored to the prevertebral fascia. The stomach wall had completely thinned out and the fistula was the result of tissue breakdown in a dying patient.

One patient survived for 16 months and was able to swallow a normal diet despite the fact that he continued to have an oesophagobronchial fistula.

CASE REPORT.—

Case 10.—L. F., a 42-year-old male, had a mid-oesophageal lesion which at bronchoscopy was found to have developed a fistula at the left main bronchus. He had lost 9 kg. in weight and had been coughing up 84 ml. of sputum daily. He also had difficulty in swallowing—an act which was usually followed by spasms of cough.

A gastrostomy was done and after 9 days the patient was deemed to be fit for a major operation. He was operated upon on 27 April, 1970. There were no complications, he was able to eat soon after operation, and he was discharged from hospital 30 days after his admission.

Postoperatively he had a course of radiotherapy of 4560 rad. This enlarged the fistula (*Fig.* 3). He was quite well for 14 months and gained over 9 kg. in weight (*Fig.* 4). He was readmitted 14 months after the operation because of haemoptysis. Examination showed that there was a large fistula and recurrence of the carcinoma, which was confirmed by a biopsy taken during oesophagoscopy. A second course of irradiation of 3040 rad was given and the patient was discharged. Despite the large fistula he was able to eat normally. He lived for another 2 months after his discharge and died suddenly at home. No post-mortem examination was carried out.

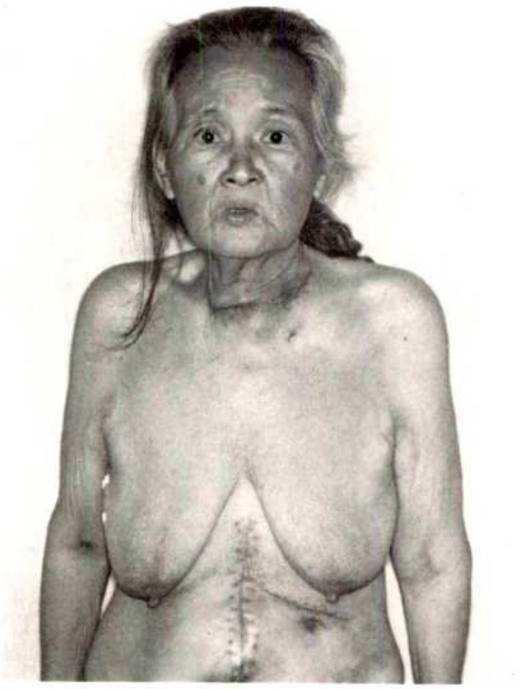

FIG. 5.—*Case* 5. The patient after operation in which the stomach was placed behind the sternum.

Leakage of the Abdominal Anastomosis.—In 1 case there was a leak at the jejunojejunostomy. This was in a patient in whom the anastomosis was made in one layer. The anterior anastomosis was defective and as a result it leaked. It was not detected early so that subsequently the condition deteriorated and breakdown of the anastomosis occurred. The patient died of peritonitis after repair of the anastomosis.

The results of the operation in 18 cases are shown in *Table I*.

DISCUSSION

The Kirschner Operation.—The Kirschner operation is certainly not the best operation for benign stricture of the oesophagus because when the fundus of the stomach is brought up to the neck for anastomosis to the cervical oesophagus the lower end of the oesophagus has to be divided. This necessitates an extra anastomosis, which, according to Yudin (1944), is dangerous. However, by using either the colon or the jejunum one can achieve a by-pass of the stricture without an extra oesophageal anastomosis. When applied to advanced malignant disease such as oesophagobronchial fistula where it is not possible to resect the oesophagus, this procedure allows a complete isolation of the fistula from the upper alimentary tract.

The use of a loop of jejunum to perform a double by-pass also isolates the oesophagobronchial fistula from the upper gastro-intestinal tract so that the patient can eat without spasms of cough. The Kirschner operation fulfils this requirement but instead of using the jejunum the stomach is used for the anastomosis. In effect using the stomach gives the same result. There is no difficulty in stretching the stomach to the neck for anastomosis to the cervical oesophagus, and also the blood-supply of the stomach from the right gastric and right gastro-epiploic vessels is more than adequate. It is a much simpler operation and is less time-consuming. These considerations should be taken into account as in an already moribund patient the operative risk is high.

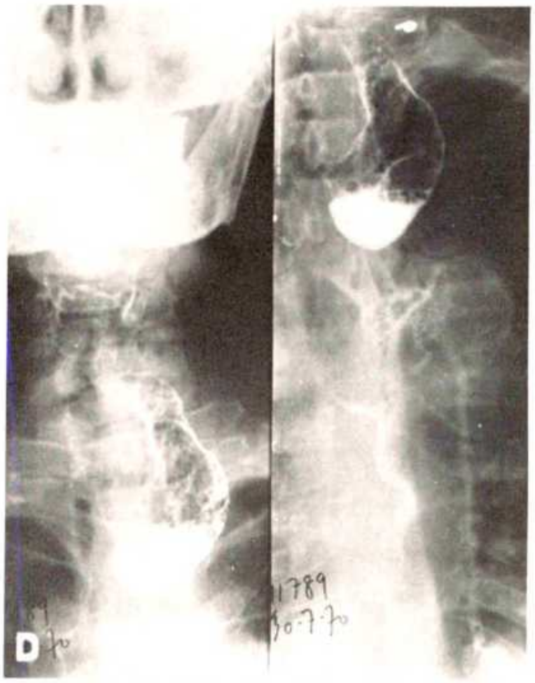

FIG. 6.—*Case* 5. Postoperative barium-swallow film, showing a slight hold-up at the level of the clavicle but the contrast medium cleared satisfactorily.

The route through which the stomach is delivered into the neck may be either subcutaneous or retrosternal. A subcutaneous route has the advantage of being safer and, if leakage should develop, it would be less likely to cause death. However, there is a greater distance to traverse before reaching the neck and tension is more likely to develop at the site of the anastomosis.

The unsightly presence of the stomach lying underneath the skin does not matter much among patients with an oesophagobronchial fistula, but female patients may find it undesirable. In such patients the retrosternal route can be used.

CASE REPORT.—

Case 5.—L. C. Y., a 69-year-old female, was admitted to hospital on 23 May, 1970, because of dysphagia. On examination a carcinoma of the upper oesophagus was found. Bronchoscopy revealed that the growth had penetrated the trachea. A Kirschner operation was carried out on 13 July. The stomach was placed behind the sternum and brought up to the neck. The patient's postoperative course was uneventful and she was discharged after having received a course of irradiation of 4560 rad (*Fig.* 5). Barium-swallow examination showed a slight hold-up at the level of the clavicle but the contrast medium cleared well (*Fig.* 6).

High Incidence of Leakage.—There seems to be a higher incidence of leakage at the site of the anastomosis in the neck when the stomach rather than the jejunum is used. Breakdown of the anastomosis usually occurs in the outer wall. It is possible that it is caused by the stomach, which after a few days gains its tone, producing tension at the suture line. This is supported by the fact that the breakdown in the anastomosis occurs where it is not anchored by sutures, as is the case of the inner part of the anastomosis.

CLOSED LIVER INJURY: AN ASSESSMENT OF PROGNOSTIC FACTORS

BY I. B. FARIS[*] AND H. A. F. DUDLEY[†]

DEPARTMENT OF SURGERY, MONASH UNIVERSITY, ALFRED HOSPITAL, MELBOURNE

SUMMARY

The records of 65 patients with closed liver injuries were studied in order to determine which of 19 variables might be important in predicting the outcome. The statistical technique of multiple regression analysis was used. The presence of hypotension and of head injury were the most important prognostic factors; on the other hand, the number of associated injuries was not a significant factor. The major problem was the patient with the isolated severe liver injury.

PROGRESS in the management of any condition depends upon, first, our understanding of its usual course, secondly, the delineation of suitable discriminant prognostic factors (i.e., symptoms, signs, or special investigations) which can give information about the course the condition is likely to pursue in an individual instance, and, thirdly, having effective therapy available. Often in clinical practice the last has been forthcoming before the first two; debate then tends to centre around the deployment of therapy and may wax strong when the factors determining the clinical course are unknown. The problem is compounded by the multifactorial nature of so many clinical situations in which it is difficult to identify those factors which are of significance in determining what the clinician should do next. Although in the initial stages of the study of an heterogeneous clinical problem, detection of a small number of strong factors may be sufficient to permit radical modifications to natural history, once such situations have been exploited and exhausted further advance can only be predicated upon a rigorous analysis of *all* the factors acting on the individual patient and the assignment of the appropriate weights to those which are most practically significant.

Conventional analysis, as in most published series of medical data, has usually depended upon the determination of mortality for each subgroup specified by an individual criterion such as age, sex, or the number of associated injuries. Although useful, this method ignores the fact that all the subgroup criteria and other factors not so chosen may act concurrently. Multiple-regression analysis, now widely used in other fields, is one way of arriving at a better estimate of predicting factors in the clinical course.

We believe that the stage has been reached in closed liver injury where such a detailed analysis is necessary. The mortality of this injury in civilian life has probably fallen in recent years as therapy in general has improved, but it is well known that certain forms of trauma to the liver are highly lethal and the overall case mortality for closed injuries is about 30 per cent (Walt, 1969; Amerson and Stone, 1970). Furthermore, it is known that treatment of lesions of this type can be effective. What it is now important to determine are the factors which indicate an individual with a potentially treatable injury, which will be lethal unless early and effective treatment is deployed. The current study attempts such a multifactorial evaluation with the aim of the detection at a more remediable early stage of those patients whose subsequent course will be downhill to death or to serious, time-consuming, and anxiety-provoking complications. This method has recently been used to study the factors influencing the occurrence of wound infection (Bruun, 1970; Davidson, Clark, and Smith, 1971) and its application to other situations can be readily envisaged.

MATERIALS AND METHODS

The 65 patients with closed liver injuries admitted to Alfred Hospital, Melbourne, during the 11 years from 1959 to 1969 inclusive were studied. Four additional patients with iatrogenic but minor lacerations sustained during attempted resuscitation for post-infarction cardiac arrest have been excluded from this analysis. During the study period methods of assessment and therapy changed so that some procedures were applied only occasionally or with an uneven distribution in time. However, for the purpose of a multivariate analysis it was possible to identify 19 factors (*Table I*) which occurred sufficiently frequently for them to be useful in predicting outcome. The mortality—19 deaths among 65 patients—was sufficient to provide a predicted variable. The method of classification of the injury (*Table II*) was derived from that of Perry, Root, Hauser, and Keizer (1967). A fracture is defined as a single laceration greater than 10 cm. long or 3 cm. deep. A bursting injury is one in which there are stellate lacerations or severe disruption of the parenchyma.

Table I.—THE 19 FACTORS USED TO PREDICT THE OUTCOME OF INJURY

1. Age
2. Sex
3. Severity of injury
4. Lobe injured (related to falciform ligament)
5. Blood-pressure on admission
6. Presence of abdominal rigidity
7. Number of associated injuries
8. Presence of chest injury
    - Grade 1: Fractured ribs
    - Grade 2: Pneumothorax ± haemothorax
    - Grade 3: flail chest, pericardial tamponade
9. Presence of gastro-intestinal tract injury
10. Presence of urogenital tract injury
11. Presence of splenic rupture
12. Presence of head injury
    - Grade 1: Unconscious on admission
    - Grade 2: Unconscious for longer than 24 hours; subdural haematoma
13. Number of major fractures, excluding ribs, hands, and feet
14. Number of units of blood transfused
15. Time between admission and operation
16. Use of non-absorbable pack
17. Type of operation
    - Grade 1: Exploration ± drainage
    - Grade 2: Suture ± absorbable haemostatics ± drainage
    - Grade 3: Resection
18. Use of prophylactic antibiotics
19. Occurrence of secondary haemorrhage

Table II.—TYPE OF INJURY IN 65 PATIENTS WITH CLOSED LIVER INJURY

Type of Injury	*No. of Injuries*
Subcapsular haematoma	4
Laceration(s)	30
Fracture	19
Burst	11
Avulsed porta hepatis	1

The information was coded for storage on magnetic tape. Correlation coefficients were calculated for each pair of variables and multiple-regression analysis was performed using a programme modified from that of Cooley and Lohnes (1962), with survival of the patient as the criterion to be predicted. The overall accuracy of prediction of the criterion is measured by the multiple-correlation coefficient. The square of this value gives the proportion of criterion variance which can be predicted from all the available predictors.

In addition to this analysis, the therapy and its relation to cause of death were non-statistically analysed in more detail.

RESULTS

Prediction of Death.—The correlation coefficients between the predictors and the survival of the patient are shown in *Table III*. Each of the factors listed makes a significant contribution to the outcome. For the remaining 10 factors (*Table I*) the correlations were not significant. Sixty-nine per cent of the variations in survival of the patients can be predicted by the factors studied; this is a highly significant proportion. The level of the blood-pressure on admission (*Table IV*) stands out as the most important determinant of severity of injury and ultimate death. This fact is of added importance in that, both in the present series and subsequently, patients whose fall in blood-pressure was profound but transient and initially responsive to quite a modest infusion of electrolyte or albumin solutions were subsequently found to have a severe or lethal injury.

Table III.—SIGNIFICANT PREDICTORS OF SURVIVAL

FACTOR	CORRELATION COEFFICIENT	SIGNIFICANCE
Admission blood-pressure (5)	0·4759	$P < 0·001$
Use of antibiotics (18)	0·4653	$P < 0·001$
Head injury (12)	−0·4560	$P < 0·001$
Presence of rigidity (6)	0·4419	$P < 0·001$
Severity of injury (3)	−0·4141	$P < 0·001$
Presence of urogenital tract injury (10)	−0·2769	$0·05 > P > 0·01$
Secondary haemorrhage (19)	−0·2625	$0·05 > P > 0·01$

The numbers in brackets refer to those of the list of factors in *Table I*. A negative correlation coefficient indicates that the presence of this predictor was associated with the death of the patient.

Also, as would be expected, a coexistent head injury often represents a lethal combination. In the current series the reasons for this association were: (i) the head injury itself may be lethal; (ii) the diagnosis of liver injury may be delayed in the presence of a head injury; (iii) the shock as a result of the liver injury may adversely affect the head injury.

Table IV.—SYSTOLIC BLOOD-PRESSURE ON ADMISSION TO HOSPITAL COMPARED WITH THE MORTALITY

Systolic blood-pressure	*No. of Patients*	*No. of Deaths*
Less than 50 mm. Hg	6	5
50–100 mm. Hg	38	13
Greater than 100 mm. Hg	21	1

Also self-evident was the predictive value of the grade of severity of the injury (*Table II*); in 8 deaths a massive solitary injury in a young person posed insoluble therapeutic problems. In addition to these major indicators of lethality, the presence of renal and liver rupture in the same patient was significant, as in the series of Walt (1969). Furthermore, secondary haemorrhage was a significant predictor of death. If this complication is prevented, e.g., by adequate excision of the wound, then a contribution to the survival of the patient has probably been made.

Prediction of Survival.—Somewhat surprisingly the presence of abdominal rigidity was a favourable sign. It was the only clinical feature included in the analysis as it was thought likely that it would have a smaller observer variation than tenderness or rebound tenderness. The explanation is not clear but may be a compound of three factors: (i) the elicitation of abdominal rigidity leads to early definitive treatment; (ii) patients with head injury did not display it; (iii) the very ill patient may also not have this sign. The administration of antibiotics is also favourably correlated with survival. However, it is probable that this association is spurious in that patients who died on the operating table did not get to the stage when prophylactic antibiotics would normally be administered.

Less Significant Factors in predicting Death or Survival.—One of the more valuable aspects of this analysis has been to show that several factors which are generally regarded as being important in determining the outcome of the injury are less significant than they have been thought to be. The most important of these is the number of associated injuries (*Table V*), which was not found to be a significant factor in predicting the death of the patient in the present series. This is in marked contrast to the published results of other authors who have almost universally found that the mortality rises with the number of associated injuries (Crosthwait, Allen, Murga, Beall, and De Bakey 1962; Amerson and Stone, 1970), while the predominant lethal factor in the present series was the technical problem posed by a severe, isolated liver injury in which the bleeding was unable to be controlled. The reports of Mikesky, Howard, and De Bakey (1956) and Kindling, Wilson, and Walt (1969) suggest also that the combination of liver and spleen injury is lethal. However, splenic rupture in this series did not have a significant effect on the mortality, agreeing with the finding of Little and Williams (1969). There was also no significant relation between the presence of gastro-intestinal injury and the death of the patient, and this conclusion is in accord with other authors' published results. Although the morbidity, especially septic complications, may be increased by the presence of bowel injuries there was no significant effect on the mortality. Pancreatic injuries, which by themselves carry a high mortality, were not influenced by and did not influence the outcome of a coexisting liver injury.

Table V.—NUMBER OF ASSOCIATED INJURIES COMPARED WITH THE MORTALITY

No. of Associated Injuries	*No. of Patients*	*No. of Deaths*
0	16	5
1	18	3
2	13	4
3	11	4
4	5	2
5	2	1

Although very commonly associated with liver rupture, injuries of the chest, at least in this series, did not have a significant effect on the outcome, which probably reflects the improvements in the care of patients with chest injuries, and particularly the use of intermittent positive-pressure respiration. The number of fractures present significantly increased ($P<0{\cdot}05$) the time between admission and operation, thus suggesting either difficulty in making the diagnosis in such instances or the possibility that mobilization of the appropriate team took longer when multi-system trauma was present.

As with secondary haemorrhage, the amount of blood transfused has been used as a retrospective index of outcome (Little and Williams, 1969; Amerson and Stone, 1970). In our series a significant influence was not observed, but this may represent inadequate recording when very massive transfusions were given in desperate circumstances usually associated with subsequent death.

Cause and Course to Death.—It would appear from the multivariate analysis that greater attention focused upon the patient who is initially hypotensive on admission and suspected of a large solitary liver lesion would reduce the mortality. The cause of death in the 19 fatal injuries confirms this view, for 10 patients died on the operating table and 2 within 6 hours of operation. Admittedly, 3 of these patients were apparently moribund on admission and 1 patient was found at operation to have total avulsion of all the structures in the porta. However, in 3 patients therapeutic delay which could have been avoided took place, and in 4 patients bleeding could not be controlled. It is conceivable that in some or all of these patients better preparedness could have been achieved through the knowledge that has been gained in recent years.

In addition to the ordinary clinical indications the availability of the gamma camera now permits the easy delineation of areas of tissue damage in the liver and spleen. Although scintiscanning was used only three times—each with positive results—between 1959 and 1969 it has been employed increasingly during the past 3 years (Dugdale, Rosengarten, and Dudley, 1973). It adds considerably to the more conventional techniques, although careful scrutiny of plain radiographs both for rib fractures and soft-tissue shadows may be helpful in about one-third of the patients (Little and Williams, 1969). In the later stages of management scanning may also have a place in detecting residual areas of necrosis which may presage the development of an abscess or post-traumatic haemobilia.

Operative techniques have changed as surgeons have gained increasing competence and confidence. Although before 1963 unabsorbable packs were used four times with 2 deaths, only 1 patient had such a pack in the ensuing 6 years. Suture was the commonest operation, but a lobectomy was undertaken three times. Two further patients should have had such a procedure, for both died of the consequences of extensive contusion.

Our recent experience since reviewing this series confirms the concept that the liver wound, whether open or closed, should be treated as any other by meticulous excision, haemostasis, and accurate, non-devascularizing, primary suture. In extensive bursting injuries these therapeutic goals can only be achieved by lobectomy. Both excision and lobectomy require good exposure. Often, as in the majority of these patients reviewed, a long abdominal incision is adequate. However, no hesitation should be felt in opening the chest either by lateral extension of an abdominal wound or as a primary procedure.

The problems of liver injury are now, we believe, clearly delineated. Although head injury as part of the damage profile of the civilian at risk will continue to claim some patients, the accurate interpretation of the physical signs and decisive treatment should save all except the most devastatingly injured patient.

Acknowledgements.—We are grateful to Dr. M. W. Johns for help with the statistical analysis and to the surgeons of the Alfred Hospital, Melbourne, who allowed access to their cases.

THE COAGULUM PYELOLITHOTOMY

BY V. J. PATEL

UROLOGICAL CLINIC, STADTKRANKENHAUS, 605 OFFENBACH, WEST GERMANY

SUMMARY

Coagulum pyelolithotomy is mainly indicated in cases of multiple stones, soft and crumbly stone or stones, small, mobile caliceal stones, and as an aid to fixing caliceal stone or stones in the calix prior to partial resection of the kidney or nephrolithotomy. Its main advantages are:—

1. Trauma to the kidney is minimized.
2. All the free stones in the pelvicaliceal system may be removed, thus reducing the incidence of so-called 'recurrent' stones.
3. Fragmentation of the stone during removal is avoided.
4. Surgical mobilization of the kidney is not necessary since it is sufficient to expose the pelvis.

A method of coagulum pyelolithotomy is described in detail and discussed. The operation has been performed in 22 cases with good results. Two cases are described in detail. It is suggested that this method could be utilized for common bile-duct stones.

THE number of cases with recurrent renal stones after pyelolithotomy and nephrolithotomy reported in the world literature is very high. However, it is very questionable whether these are always recurrent stones. In many cases this 'recurrence' is due to incomplete removal of renal stones during the operation. Oppenheimer (1940) reported incomplete removal of renal stones in 41·4 per cent of nephrolithotomies, in 32·4 per cent of pyelonephrolithotomies, and in 10·6 per cent of pyelolithotomies. Barney (1922) stated that there was incomplete removal of stones in 45 per cent of nephrolithotomies, and the author feels certain that the percentage of incomplete removal of stones is even higher, since postoperative radiographic checks fail to reveal all the stones which are left behind after operation. Several factors may be responsible for the impossibility of removing all the stones present at the time of operation:—

1. The shadow of smaller stones could be obscured by that of a bigger one on the radiograph.
2. Radiolucent stones and small radio-opaque stones may not be visible on the radiograph.
3. The interior of the renal pelvis cannot be completely surveyed through a pyelotomy incision, and the fact that a small stone may move from one calix to another in the course of the operation makes it difficult or impossible to locate the calculus.
4. A blood-clot may cover a small stone, which is then difficult to locate.

The technique of overdistending the renal pelvis with an isotonic saline solution with the ureter occluded has served well in washing out elusive stones, but this method leaves much to be desired. The same is true of carrying out routine radiographs on the operating table. Oppenheimer (1940) found that in a series of 63 cases radiographs taken on the operating table showed no evidence of any stones remaining in the kidney, yet a subsequent check revealed stones in 12·7 per cent of these cases.

Table I.—REVIEW OF COAGULUM PYELOLITHOTOMIES REPORTED IN THE WORLD LITERATURE

Author	*No. of Cases*
Dees (1943, 1944, 1946, 1955)	73
Harrison and Trichel (1949)	10
Hoffmann (1950)	1
Moore and Sweetser (1952)	7
Stoll (1959)	6
Singer (1962)	12
Total	109

From the above it is obvious that urologists are and always have been in search of more precise and certain methods for the operative removal of renal calculi. A significant contribution in this direction is contained in the original work of the American urologist, Dees. In 1943 he reported on a method for the removal of renal calculi with the help of a fibrin coagulum. Fibrinogen and thrombin solutions were injected into the renal pelvis. Within several minutes the mixture formed a firm clot which was then removed together with the incorporated stones. To date only 109 coagulum pyelolithotomies have been reported in the world literature (*Table I*).

It is obvious that this method has not gained the popularity that it deserves. There are two main reasons for this. First, no suitable commercial fibrinogen was available during the Second World War and post-war periods. Secondly, the method as described by Dees (1943) was somewhat complicated. Owing to many technical errors at different stages of the procedure, it proved difficult to produce a firm and elastic clot in the renal pelvis which would enmesh all the free stones and could be extracted completely and in one piece. Similar difficulties were experienced with the earlier cases in the present series. However, the method has since been simplified so that a suitable coagulum is now always obtained.

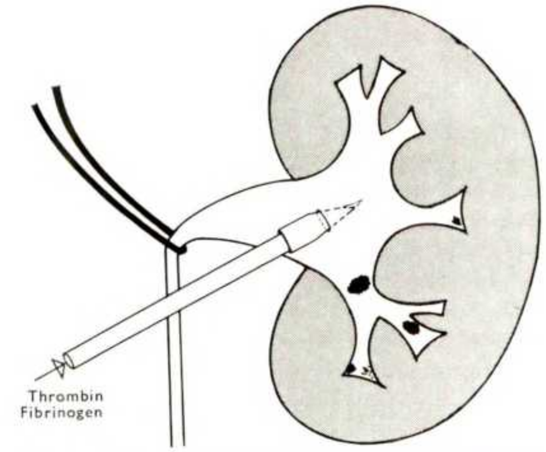

FIG. 1.—Injection of the fibrinogen and thrombin mixture into the renal pelvis with the help of a funnel-shaped catheter.

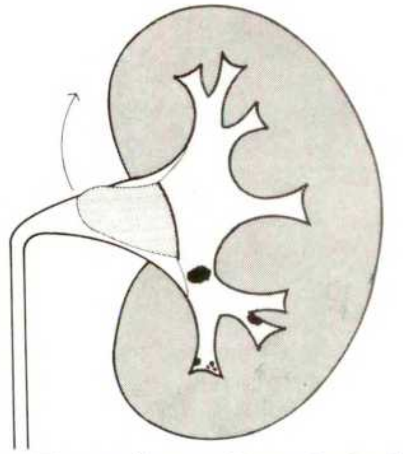

FIG. 2.—The protruding part of the coagulum is pulled with a movement slightly turning it towards the upper pole of the kidney.

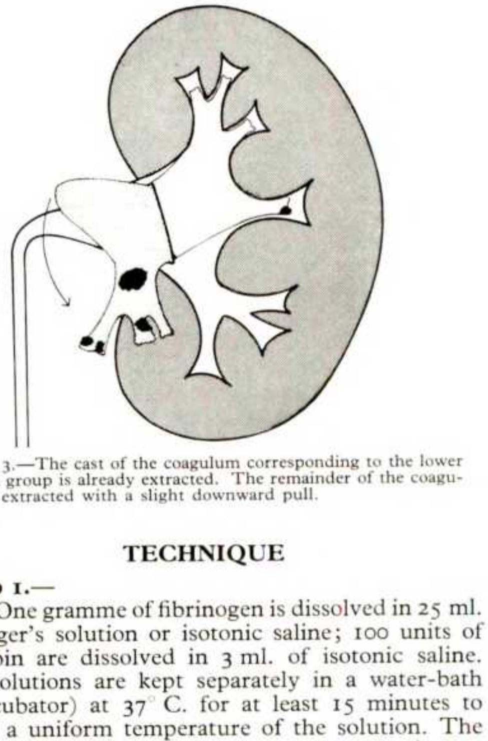

FIG. 3.—The cast of the coagulum corresponding to the lower caliceal group is already extracted. The remainder of the coagulum is extracted with a slight downward pull.

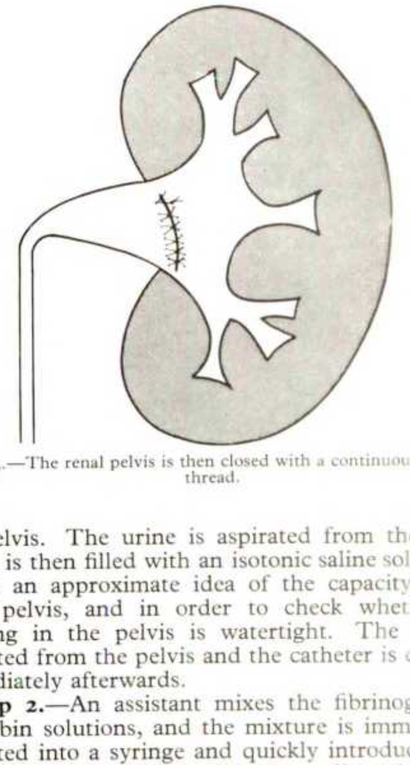

FIG. 4.—The renal pelvis is then closed with a continuous catgut thread.

TECHNIQUE

Step 1.—

a.—One gramme of fibrinogen is dissolved in 25 ml. of Ringer's solution or isotonic saline; 100 units of thrombin are dissolved in 3 ml. of isotonic saline. Both solutions are kept separately in a water-bath (or incubator) at 37° C. for at least 15 minutes to ensure a uniform temperature of the solution. The properties of the solutions are in no way altered, even if they have to be kept at 37° C. for a considerably longer period of time.

b.—In the meantime the renal pelvis is exposed. It is not necessary to mobilize any other part of the kidney. A small transverse incision is made in the pelvis. A catheter which is funnel-shaped at the tip is introduced into the renal pelvis so that it fits snugly into the aperture (*Fig.* 1). There is no need for a purse-string suture to ensure a watertight fit. The ureter has to be occluded with a rubber sling or a suitable soft clamp so as to keep the injected fluid in the pelvis. The urine is aspirated from the pelvis which is then filled with an isotonic saline solution to obtain an approximate idea of the capacity of the renal pelvis, and in order to check whether the opening in the pelvis is watertight. The fluid is aspirated from the pelvis and the catheter is clamped immediately afterwards.

Step 2.—An assistant mixes the fibrinogen and thrombin solutions, and the mixture is immediately aspirated into a syringe and quickly introduced into the renal pelvis until it is slightly overdistended. The catheter is then clamped to prevent any backflow. This entire procedure must be carried out rapidly, since coagulation begins within 30 seconds after the fibrinogen and thrombin solutions have been mixed. Normally the process of mixing the solutions, the aspiration of the mixture into a syringe, and its introduction into the renal pelvis takes less than 10 seconds. This is the most vital point in the entire operation, and it will therefore be described in detail.

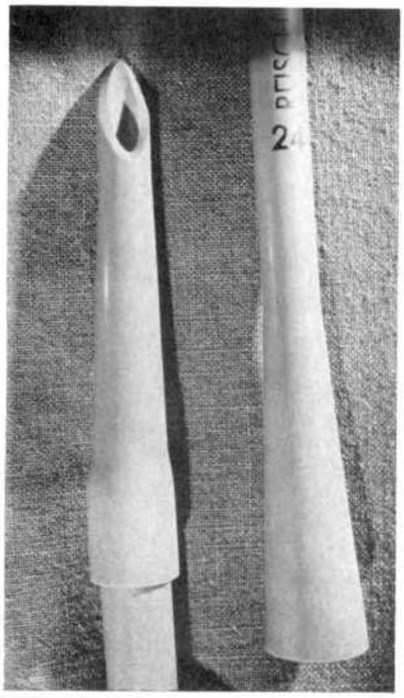

FIG. 5.—The funnel-shaped catheter used to introduce the fibrinogen and thrombin mixture into the renal pelvis.

A second assistant pours the warm solutions simultaneously into a prewarmed crucible on the instrument table. The operating urologist stirs the mixture. Stirring should be even and gentle, since the mixture, which is viscous, otherwise tends to become foamy and the enclosed bubbles subsequently diminish the tensile strength of the coagulum. The assistant then aspirates the mixture into a syringe. There is no need to attach a needle to the syringe; this saves time and prevents the aspiration of air through any leakage between the junction of the needle and the nozzle of the syringe. It is important to aspirate the mixture quickly but without air. If there are air-bubbles inside the syringe it takes many precious seconds before they rise to the surface of the viscous fluid, and it is impossible to wait for all the bubbles to come up since coagulation begins within 30 seconds. Particular care should be taken in handling the last 2 ml. of the mixture, because it is especially then that large quantities of air may very easily be aspirated. Meanwhile the first assistant opens the clamp on the catheter, applies a syringe, aspirates urine which might have gathered in the pelvis, and clamps the catheter to prevent the suction of air into the pelvis. The urologist then applies the syringe containing the coagulum mixture to the catheter with the help of a suitable connecting piece; the first assistant releases the clamp and the solution is quickly injected into the pelvis. The catheter is clamped again by the first assistant.

Step 3.—After 7 minutes the catheter is withdrawn (5 minutes would probably be sufficient to ensure the formation of a firm and elastic clot). The transverse pelvic incision is enlarged. Usually the distal part of the coagulum then pops out of the pelvis.

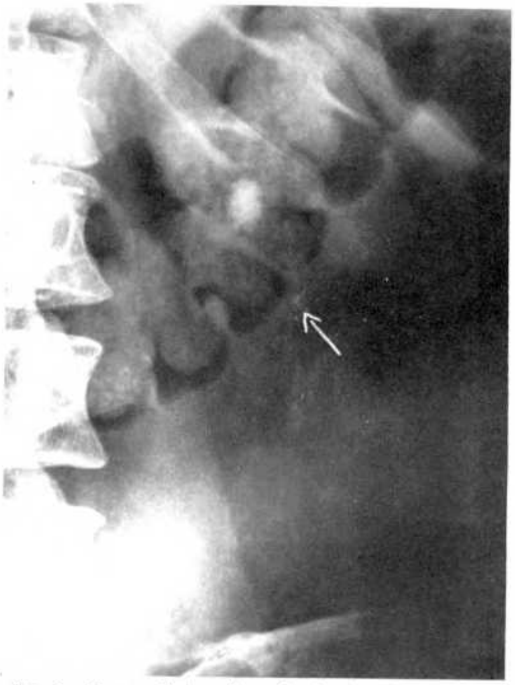

FIG. 6.—*Case* 1. Plain radiograph, showing a large stone in the area of the renal pelvis and a minute stone (indicated by the arrow) in the lower pole of the kidney.

Step 4.—The protruding part of the coagulum is very gently pulled at with a Desjardins's forceps with a movement slightly turning it towards the upper pole of the kidney (*Fig.* 2), so as first to extract that part of the coagulum which corresponds to the pelvis proper and to the lower caliceal group. Subsequently with a slight downward pull the remainder of the coagulum is extracted (*Fig.* 3). The cast which corresponds to the upper caliceal group may, of course, be extracted first, but this is more difficult since the upper caliceal group is usually longer than the lower one.

Step 5.—A ureteric catheter is passed through the incision towards the bladder to ascertain whether the the passage is free, and the pelvis is then closed with a continuous catgut thread to ensure a watertight closure (*Fig.* 4). Some urologists prefer to leave the pelvic incision partly open, but the present author sees no reason to do so. Once the passage to the bladder is free of obstruction it is advisable to close the pelvic incision so as to reduce the danger of urinary phlegmon and infection around the pelvis.

It is the author's practice to take radiographs of the coagulum containing the stones.

The funnel-shaped catheter which is used to apply the fibrinogen and thrombin solution into the renal pelvis is not available commercially. The author constructs one by cutting the funnel-shaped distal end of a Nélaton catheter and fixing it to the proximal end of another catheter which is 2–3 charrières wider (*Fig.* 5).

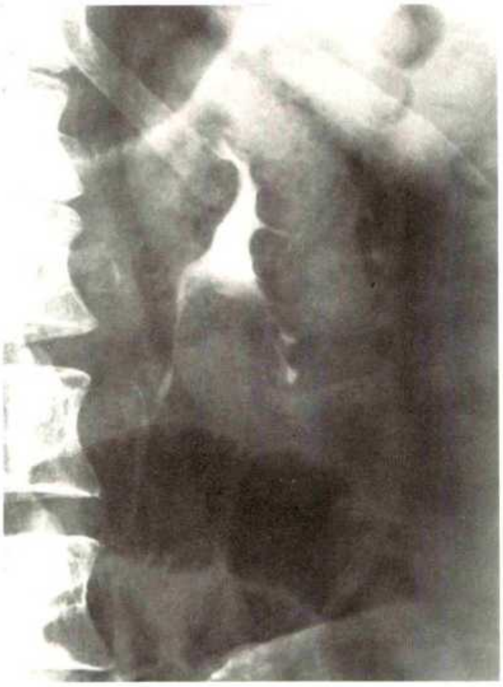

FIG. 7.—*Case* 1. Intravenous pyelogram.

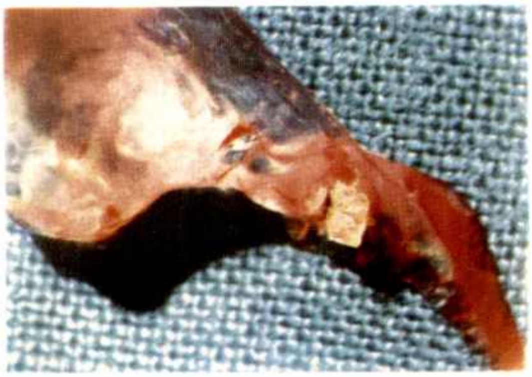

FIG. 9.—*Case* 1. Close-up of the coagulum corresponding to the lower calix, showing the crystalline stone.

PRESENT SERIES

The author has performed coagulum pyelolithotomy in 22 cases. In the first 11 cases Dees's (1943) method was employed and in the remaining cases the method was as described here. In 5 cases of the first group a firm coagulum was not produced owing to technical errors, such as an uneven mixture of the fibrinogen and thrombin solutions or leakage around the catheter. No such failures occurred when the new method was used. With the exception of those cases in which there was a technical breakdown all the free stones were removed. In fact, there were no complete technical breakdowns; in all 5 cases we did achieve a coagulum, although it was deficient in quality, and at least some stones were removed. Subsequently lavage of the renal pelvis failed to remove the remainder of the stones, which might in some cases have even been parenchymal stones.

In 9 of the 22 cases, apart from the stones which had been diagnosed, other stones were removed which had not been shown up during the preoperative radiographic diagnosis.

In 1 case of multiple stones in a parapelvic cyst communicating with the pelvis, the latter was filled with coagulum prior to the mobilization of the kidney. Stones were thus prevented from escaping into the pelvis and subsequently all the stones were removed by nephrotomy. In 1 case coagulum was used prior to lower-pole resection to block the escape route of a lower caliceal stone.

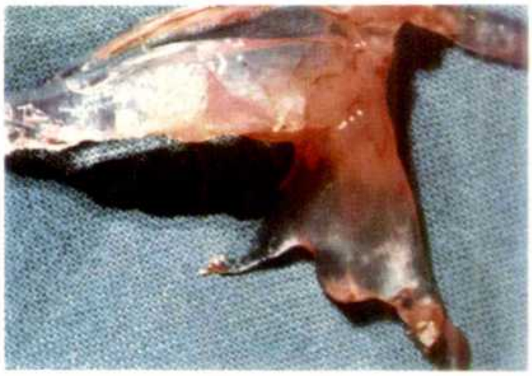

FIG. 8.—*Case* 1. The coagulum, showing the lower caliceal stone in the corresponding part of the coagulum.

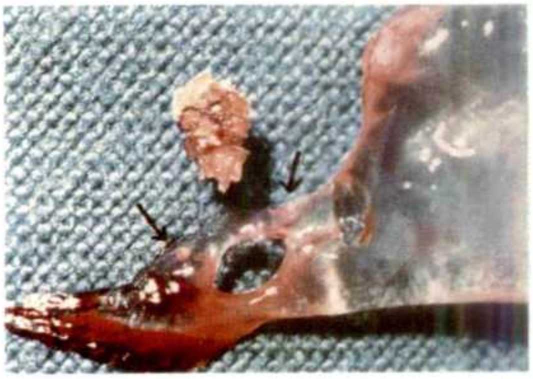

FIG. 10.—*Case* 1. The stone is removed from the coagulum revealing the thin ramifications of the coagulum which held the stone firmly. Two more tiny stones (indicated by arrows) can be recognized, which escaped radiographic detection because of their minute size.

A detailed analysis of the cases will be published at a later date; however, 2 cases are described here in detail to illustrate the effectiveness of coagulum pyelolithotomy.

CASE REPORTS

Case 1.—A 61-year-old patient was admitted to hospital with a diagnosis of a renal pelvic stone. On closer scrutiny the radiograph (*Fig.* 6) showed, apart from the large stone, a minute radio-opaque shadow in the lower caliceal group which might have been caused by a stone (cf. *Fig.* 7, which shows the intravenous pyelogram of the same kidney).

The large stone was removed through a pyelotomy incision with the help of stone forceps. Afterwards a fibrin coagulum was formed in the renal pelvis. The small lower caliceal stone which had been diagnosed on the radiograph was found in the corresponding part of the coagulum after its removal (*Fig.* 8). Close examination of the cast (*Fig.* 9) clearly showed the crystalline nature of the stone. It might well have been adherent to the caliceal wall, especially in the area where the surface of the stone was not covered by the coagulum. *Fig.* 10 shows the coagulum after the stone had been removed from it. Comparison with the size of the stone revealed that the ramifications of the coagulum holding the stone were extremely thin, and yet they were able to hold the stone firmly, thus making extraction possible. The coagulum was sufficiently firm not to tear even though it was very thin. Closer observation of the coagulum showed that in the vicinity of the stone, which itself was very small, there were two more tiny stones. These stones had escaped radiographic diagnosis owing to their minute size.

The operation was concluded in the usual manner. The patient was discharged after an uneventful postoperative period. The postoperative intravenous pyelogram failed to reveal any further stones.

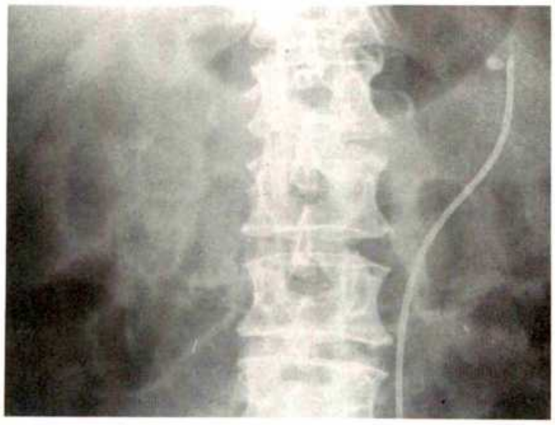

FIG. 11.—*Case* 2. Plain radiograph, showing a renal stone and a ureteric catheter on the left-hand side. No radio-opaque shadows are visible on the right-hand side.

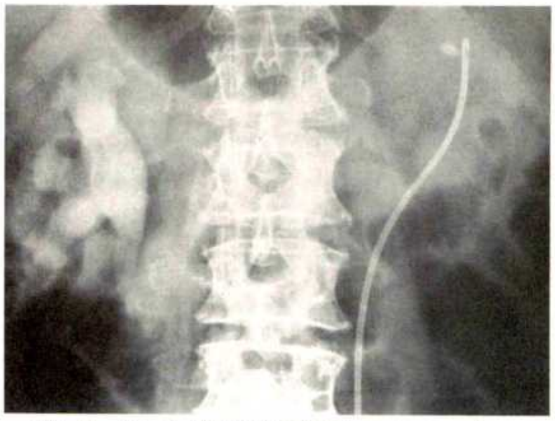

FIG. 12.—*Case* 2. Twenty-four-hour intravenous pyelogram, showing retention and stagnation of the contrast material in the renal pelvis on the right-hand side. Ureteric obstruction at the level of the third lumbar vertebra is also demonstrated.

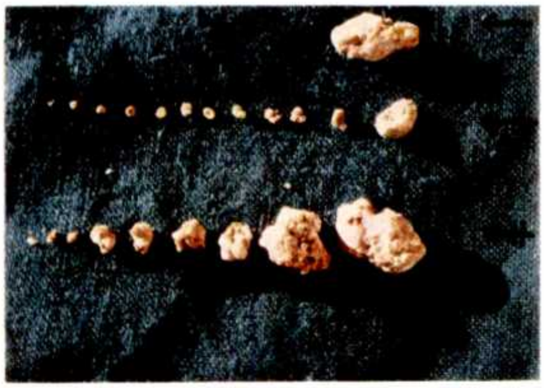

FIG. 13.—*Case* 2. The ureteric stone (←), the stones removed by ureteric lavage (←+), and the stones removed by coagulum pyelolithotomy (←++).

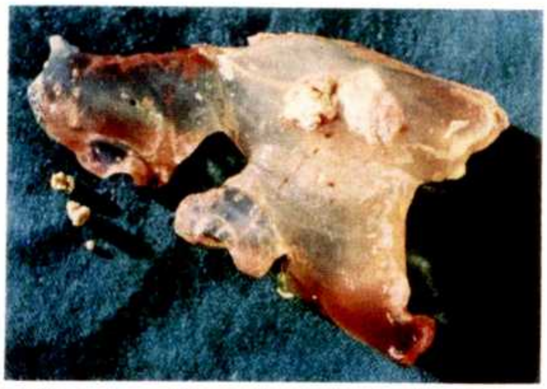

FIG. 14.—*Case* 2. The coagulum, showing the embedded stones.

Case 2.—A 55-year-old female patient was admitted to hospital in a poor general condition. She had not passed urine for about 8 days and her general practitioner had treated her with antispasmodics. On admission the urea-nitrogen was over 150 mg. per cent. The uric acid level in the serum was within the normal range at 5·1 mg. per cent. A plain radiograph showed a radio-opaque shadow near the vertebral column at the level of the second lumbar vertebra on the left-hand side. On the right-hand side no radio-opaque shadow was found which might have been attributed to ureteric calculus. On this side it was not possible to insert a ureteric catheter beyond 20 cm., nor was it possible to pass any contrast material beyond the obstruction. On the left-hand side the stone, which must have occupied the uppermost part of the ureter, was pushed back into the renal pelvis with the help of an 8 charrière ureteric catheter. The catheter was left in situ (*Fig.* 11). Subsequently the patient was treated with infusions, insulin, antibiotics, and strophantin until her general condition improved; her diabetes was regulated and the urea-nitrogen in the serum became normal. The infusion pyelogram obtained at this time on a 24-hour film showed considerable stagnation and indicated obstruction in the right ureter at the level of the third lumbar vertebra (*Fig.* 12).

The patient was operated on from the right-hand side. The radiolucent stone was removed by a ureterolithotomy incision (*Fig.* 13←). Through this incision the renal pelvis was lavaged and a number of small stones emerged with the irrigating fluid (*Fig.* 13⇷). It was then decided to perform a coagulum pyelolithotomy, assuming the presence of more stones in the renal pelvis. A Nélaton catheter was passed through the ureterotomy incision into the renal pelvis, where the coagulum was formed. A number of stones of varying sizes which had also escaped radiographic diagnosis were found in the coagulum after its removal (*Figs.* 13⇺, 14). Chemically they were uric acid stones.

The postoperative period passed without complications. The early postoperative intravenous pyelogram revealed a still slightly enlarged renal pelvis, but the calices showed no sign of stagnation (*Fig.* 15). The patient was discharged and advised to undergo a further operation on the other side after a period of 1 or 2 months.

DISCUSSION

The Solutions.—Dees (1955) suggested the use of a 4 per cent fibrinogen solution for the coagulum pyelolithotomy; the fibrinogen that he used was not available commercially. Stoll (1959) used fibrinogen manufactured by Behringwerke, but found that this product in a 4 per cent solution was not successful. He decided on a 3·84 per cent solution, which proved satisfactory. Klosterhalfen (1969) also had difficulties in obtaining a suitable coagulum and therefore decided to use a mixture of fibrinogen plus fresh blood-plasma with thrombocytes and thrombin plus a $CaCl_2$ solution. This seems to have proved satisfactory. The author has always used the fibrinogen manufactured by Behringwerke in the concentration suggested by Dees (1955) and has found it perfectly satisfactory. The early failures in the present series were due to the method being too complicated; since the simplified method has been used, as described in this paper, there have been no technical failures.

What happens to the Coagulum if it is left in the Kidney?—If part of the coagulum should remain in the kidney no harm is done. Dees (1943) showed that any coagulum kept in human urine at body temperature will dissolve within 6–24 hours, whereas a human blood-clot will have only partially disintegrated after 72 hours. Klosterhalfen (1969) found in a series of experiments involving 78 kidneys of rabbits that fibrin particles dissolved before encrustation could take place even in cases of chronic stone formation with urinary infections, alkaline urine, and hypercalcuria.

Partial Nephrectomy versus Coagulum Pyelolithotomy.—The main argument advanced in favour of partial nephrectomy (or pole resection) is that not only the stone itself but also its site of origin—the defective calix—is removed, thus reducing any possibility of stone recurrence. On closer examination, however, this assumption does not apply to all cases where pole resection is performed. Papathanassiasis and Swinney (1966) reported a series of 50 partial nephrectomies for calculi, of which 88 per cent were lower-pole resections. This is a similar figure to those reported by other authors. However, the frequent occurrence of calculi in the lower pole does not necessarily imply that the stones originated there. The stone nucleus might have developed in any part of the kidney and later have been deposited in the lower caliceal group owing to the effect of gravity. Of course, this explanation does not cover parenchymal stones.

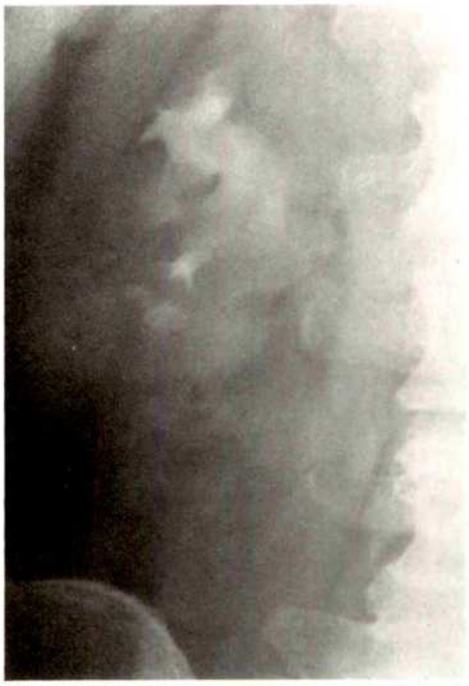

FIG. 15.—*Case* 2. Postoperative intravenous pyelogram.

Where the calix at the site of a stone shows extreme pathological/anatomical changes it is probably advisable to perform pole resection. However, it should be borne in mind that not all calices with gross pathological/anatomical changes necessarily form stones; this has been sufficiently well demonstrated by the many cases of pyelonephritis without nephrolithiasis. Therefore unless there is definite proof that the calix in which the stone has been found is responsible for its formation, coagulum pyelolithotomy rather than pole resection should be performed. Coagulum pyelolithotomy is much less traumatic and at the same time highly efficient, since it ensures complete removal of all the free stones, many of which may not even have previously been diagnosed. In many cases it proves to be technically difficult to remove a caliceal stone without inflicting gross injury to the kidney. In such cases nephrolithotomy or partial nephrectomy is often performed. The author would suggest performing coagulum pyelolithotomy first for the reasons mentioned above. Where the infundibulum of the calix is too narrow and the coagulum tears, leaving the part with the stone enmeshed inside the calix, partial nephrectomy or nephrolithotomy might still be performed. This procedure would have the additional advantage of the stone being fixed inside the calix so that it could not escape into the pelvis or another calix during the operation.

Suggestion for Common-duct Surgery.—The incidence of incomplete removal of stones in common-duct surgery, as reported by Paine and Firme (1957) and Catell (1957), varies from 2 to 28 per cent. Many other authors such as Glenn (1952), Hicken (1954), and Thomson (1956) have reported an incidence of 7–20 per cent. Common-duct stones, débris, and gravel might be removed as follows:—

a. Insert a Fogarty (1968) biliary balloon catheter through a small incision in the common duct in such a way that the balloon passes through the sphincter of Oddi.

b. Inflate the balloon and pull the catheter slightly so as to make the sphincter watertight. The hepatic ducts might be obstructed with the help of a soft clamp or one or two Fogarty catheters.

c. Inject a coagulum in a manner similar to that described for renal stones and extract it together with the enmeshed stones after deflating the balloon.

Intrahepatic calculi could be extracted in a similar fashion.

CONCLUSIONS

The indications for coagulum pyelolithotomy are as follows:—

1. Multiple stones and detritus in the renal pelvis.
2. Soft and crumbly stone.
3. Small mobile caliceal stones.
4. As an aid in fixing caliceal stone or stones prior to partial resection of the kidney or nephrolithotomy.

The advantages of this method are summarized below.

1. Trauma to the kidney is minimized. Every urologist has at one time or another experienced considerable difficulties in searching for an elusive stone. During his search he might injure not only the renal pelvis but also the calices and possibly even the renal parenchyma. Sometimes, owing to excessive bleeding a nephrectomy might have to be performed. Apart from this danger, it must be borne in mind that a traumatized kidney is more liable to form new stones. All of this may be avoided by the almost non-traumatic process of a coagulum pyelolithotomy.

2. Surgical mobilization of the kidney and subsequent nephropexy are not necessary since it is sufficient to expose the renal pelvis.

3. All the free stones within the renal pelvis are removed regardless of size, number, or position. Frequently additional stones are removed which for a variety of reasons had not been diagnosed and therefore not looked for. At a later date such stones would probably have been considered to be 'recurrent' stones. Sometimes it is even possible to remove stones which have been partly adherent to the mucosa. In the case of crystalline stones in particular the tough coagulum encloses that part of the stone which is not adherent to the mucosa so firmly that mucosal adherence constitutes no serious obstacle to extraction. Where the caliceal infundibulum is too narrow it is, of course, impossible to extract any stone. However, the width of the infundibulum as shown in an intravenous pyelogram does not correspond to the actual width. Once the renal pelvis is overdistended by the coagulum the width of the infundibulum increases considerably. This may be confirmed preoperatively with the help of an oxygen retrograde pyelogram, whereby the renal pelvis is distended by oxygen until the patient feels a slight pain in his kidney. Even when it is impossible to remove the coagulum with the stone enmeshed no harm is done, since partial resection may still be performed. In some cases it has been possible to remove stones which could not be dislodged even with extensive lavage of the renal pelvis.

4. In some cases it is advisable to fix a caliceal stone with the help of the coagulum prior to pole resection or nephrolithotomy. In this way the stone cannot get lost during further surgical mobilization and operation. This fixation is especially useful in the case of multiple caliceal stones, where the danger is greater because minute stones may escape unnoticed into the pelvis or into another calix.

5. Fragmentation of the stone during removal is avoided. Stone fragmentation happens more often than is realized. It occurs especially when the stone is soft and crumbly. However, even when the stone is fragmented the residual fragments may easily be removed with the help of the coagulum.

Acknowledgements.—I should like to express my gratitude for their active support to Dr. W. Becker, Head of the Urological Department, Municipal Hospital, Oldenburg, and Professor Dr. (med.) G. Karcher, Head of the Urological Clinic, Municipal Hospital, Offenbach.

'FRUIT-STONE ILEUS'

BY PAUL C. WEAVER AND DAVID H. TRAPNELL
WESTMINSTER HOSPITAL, LONDON

SUMMARY

Three cases of 'fruit-stone ileus' are reported in which ingested plum stones were obstructed in their progress through the bowel by other disease. Over the succeeding months or years the stones enlarged and then began to cause symptoms. Radiological aids to diagnosis are discussed together with the surgical treatment.

'GALL-STONE ileus' is a well-known clinical diagnosis. In fact, it is inaptly named because the process is essentially one of simple mechanical obstruction by the calculus. This name is now so well established that we suggest it is reasonable to call the condition that is described here—intestinal obstruction produced by plum stones—by a similar misnomer, 'fruit-stone ileus'.

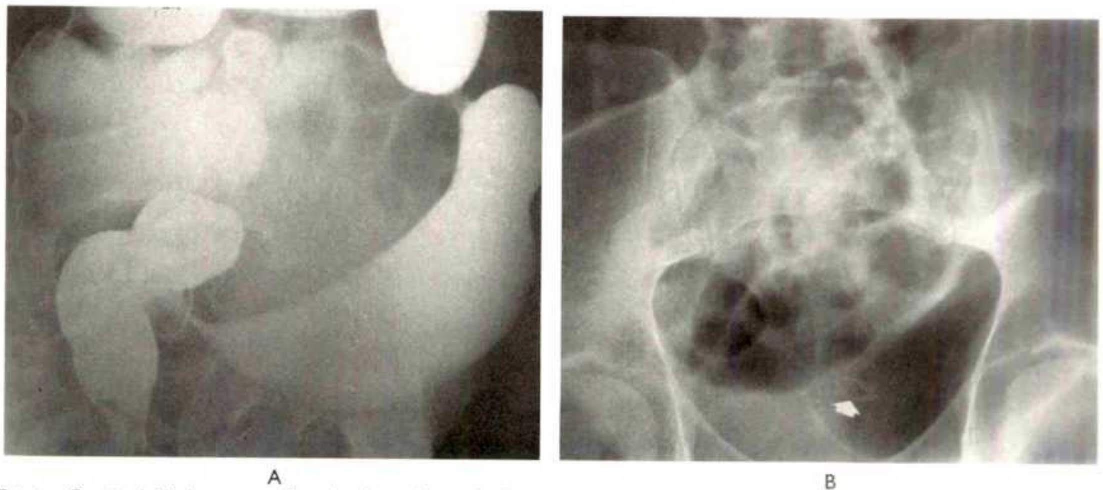

FIG. 1.—*Case* 1. A, Barium-enema film, showing strictures in the sigmoid colon. B, Plain radiograph, showing a calcified plum stone in a segment of gas-distended sigmoid colon.

Three cases are described to illustrate the 'silhouette' sign in the initial radiographic investigation and the presence of some pathological lesion within the intestinal tract which initially impeded progress of the fruit stones. In 2 patients the stones became coated by inorganic and organic material, permitting them to become large enough to produce intestinal obstruction. In the third case obstruction was caused by the plum stone itself when it impacted in a colonic stricture.

CASE REPORTS

Case 1.—Mr. L. L. C., aged 55 years, had a history of recurrent diarrhoea and blood in the faeces for 30 years. This had been diagnosed as chronic ulcerative colitis. Two years before admission to the Westminster Hospital the patient had been admitted to another hospital with an abscess in his right iliac fossa which was drained. A diagnosis of Crohn's disease had been made at that time and had been confirmed by barium studies of the small intestine in the following year. A barium-enema examination had shown multiple strictures in the colon (*Fig.* 1 A).

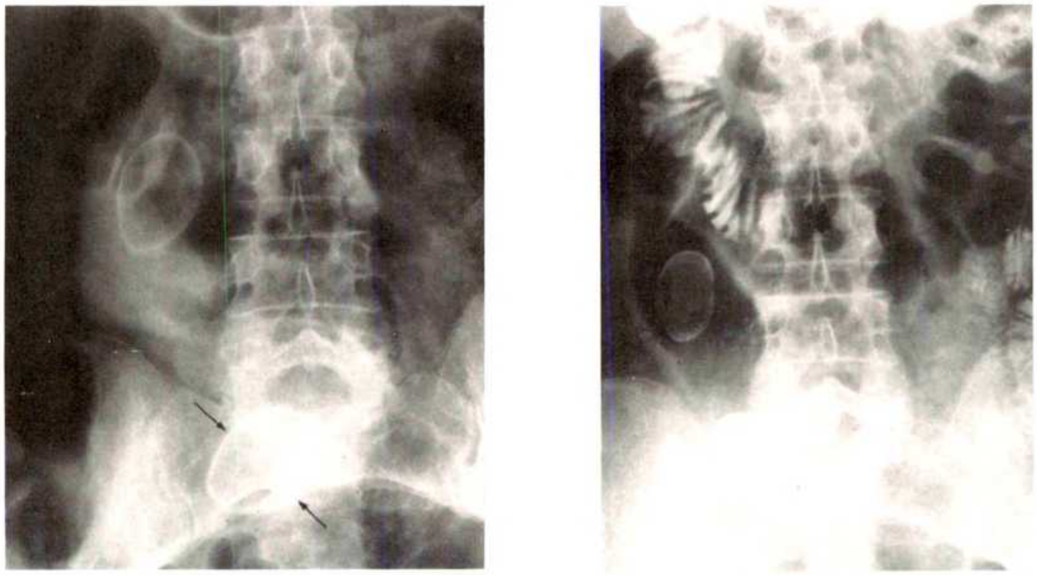
For the next year or so he had suffered from recurrent attacks of abdominal distension with pain, and alternating diarrhoea and constipation. Barium-enema examination again showed colonic strictures. During one of these attacks a plain radiograph of the abdomen revealed what looked like a calcified plum stone in the segment of gas-distended sigmoid colon (*Fig.* 1 B).

The patient said that he had eaten no plums or prunes recently. Later radiographs showed the opacity unchanged. A subsequent operation 5 months later to remove part of the left colon and its strictures proved the presence of a plum stone trapped in a length of sigmoid colon between two strictures. Histological examination of the excised colon showed changes typical of Crohn's disease.

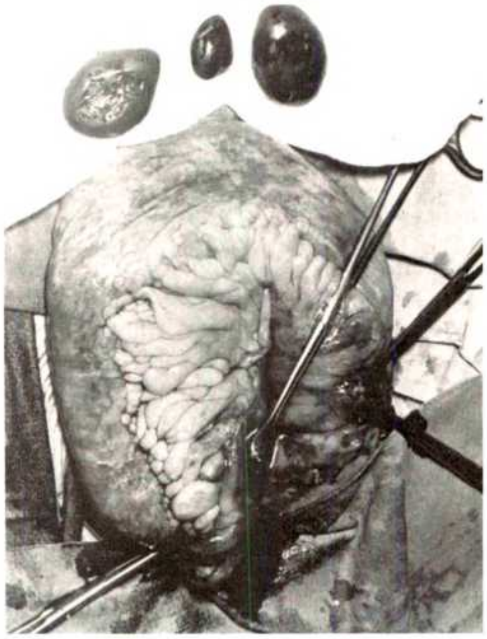
Case 2.—Mrs. F. B., aged 62 years, was investigated for attacks of abdominal pain in 1965 at another hospital in London. She was told that there were two radio-opaque foreign bodies which appeared to be in a loop of dilated small bowel. An operation was offered but was declined. From that time she had minor intermittent attacks of colicky abdominal pain and was subsequently admitted to Queen Mary's Hospital, Roehampton, in August, 1970, as a surgical emergency with severe colicky abdominal pain and vomiting. She had had an appendicectomy at the age of 16, a laparotomy for adhesions at the age of 18, and a hysterectomy at the age of 32 years.

On examination there were three lower abdominal scars. The abdomen was distended. Plain radiographs of the abdomen showed a dilated loop of small bowel and three calcified foreign bodies. The patient's symptoms settled on conservative treatment and she again refused operation.

A Gastrografin meal confirmed that the foreign bodies were in the lumen of the bowel with the help of the 'silhouette' sign (*Fig.* 2 A, B). The films also indicated that the lesions were impacting at a narrowed segment within the ileum. The patient agreed to operation 9 days later when three large black stones were found lying in a distended loop of small intestine. This loop was occluded at its distal end by dense adhesions. There was also a fistula between the two ends of the loop (*Fig.* 2 C). The stones proved to be plum stones with numerous layers of faecal material around them, the outermost parts being calcified. The patient made a satisfactory and uneventful recovery.



A B



C

FIG. 2.—*Case* 2. A, Gastrografin-meal film, showing two foreign bodies within a distended loop of bowel. Gastrografin surrounds them and makes them less distinct. B, Plain radiograph, showing the foreign bodies without surrounding Gastrografin. The upper stone is surrounded by air and is therefore more sharply defined. The lower stone is surrounded by fluid and overlies part of the sacrum making it less distinct. The thick wall of the distended loop of intestine is well shown. C, Operative photograph, showing the obstructed loop of bowel with the three coated plum stones removed. Instruments mark the site of the fistula.

Case 3.—Mrs. A. W., aged 85 years, was admitted as a surgical emergency in March, 1971, to Queen Mary's Hospital, Roehampton, with a history of abdominal pain and vomiting for 2 weeks. Two years earlier she had had an attack of colicky abdominal pain which had settled without treatment. A plain radiograph of the abdomen at that time had shown an oval opacity, which looked like a plum stone, near the left sacro-iliac joint (*Fig.* 3 A). There had been no evidence of intestinal obstruction at that time.

On examination on the present occasion the patient was a frail, elderly woman with a distended abdomen which was tender and quiet. Abdominal radiographs showed the presence of multiple fluid levels in the small intestine and also two laminated foreign bodies (*Fig.* 3 B). Laparotomy was carried out and the terminal ileum was found to be obstructed by two large black smooth stones which could not pass along the lumen because they were held back by a pedunculated polyp (*Fig.* 3 C). The bowel wall over the larger stone had perforated and there was generalized peritonitis. The segment of ileum containing the polyp, stone, and perforation was excised. The patient deteriorated and died from intraperitoneal sepsis and congestive cardiac failure.

The stones were found to have a nucleus of fruit stone around which there were layers of inorganic and faecal material. Histological examination showed that the polyp was a pedunculated angioma.

DISCUSSION

Each of our 3 cases had intermittent attacks of intestinal obstruction caused by radio-opaque foreign bodies within the bowel lumen impacting against a pathological form of mechanical obstruction. When considering such a diagnosis it is obviously important to be certain that the foreign body lies within the lumen of the bowel. The 3 cases described here show how this can be proved radiologically by the 'silhouette' sign, as described by Melhem, Habbal, and Imad (1970), who applied it to the localization of urinary-tract calculi. They point out that when a radio-opaque calculus lies within a hollow viscus it is clearly seen in the radiograph. However, when the viscus is filled with contrast medium the opacity becomes less clearly defined or if the contrast medium is sufficiently opaque it 'disappears' and the whole lumen becomes evenly radio-opaque (*Figs.* 1 A, 2 A, B). On the other hand, if the foreign body is lying outside the viscus containing contrast medium it will remain visible through it and the edges of the opacity produced by the lesion will remain sharply defined.

In the present cases the downward passage of the fruit stone in the gut was blocked by some mechanical obstruction: in the first case by a stricture due to Crohn's disease, in the second case by adhesions following appendicectomy, and in the third case by a polyp. These cases illustrate that fruit stones may be held up by a narrowed segment of bowel where they may become the centre of an enterolith by being coated with layers of organic or inorganic material. When large enough the enterolith may cause obstruction or perforation of the bowel. Where intraluminal foreign bodies are removed it is worth looking carefully for the site of gut narrowing which should also be removed to prevent a recurrence of the problem.

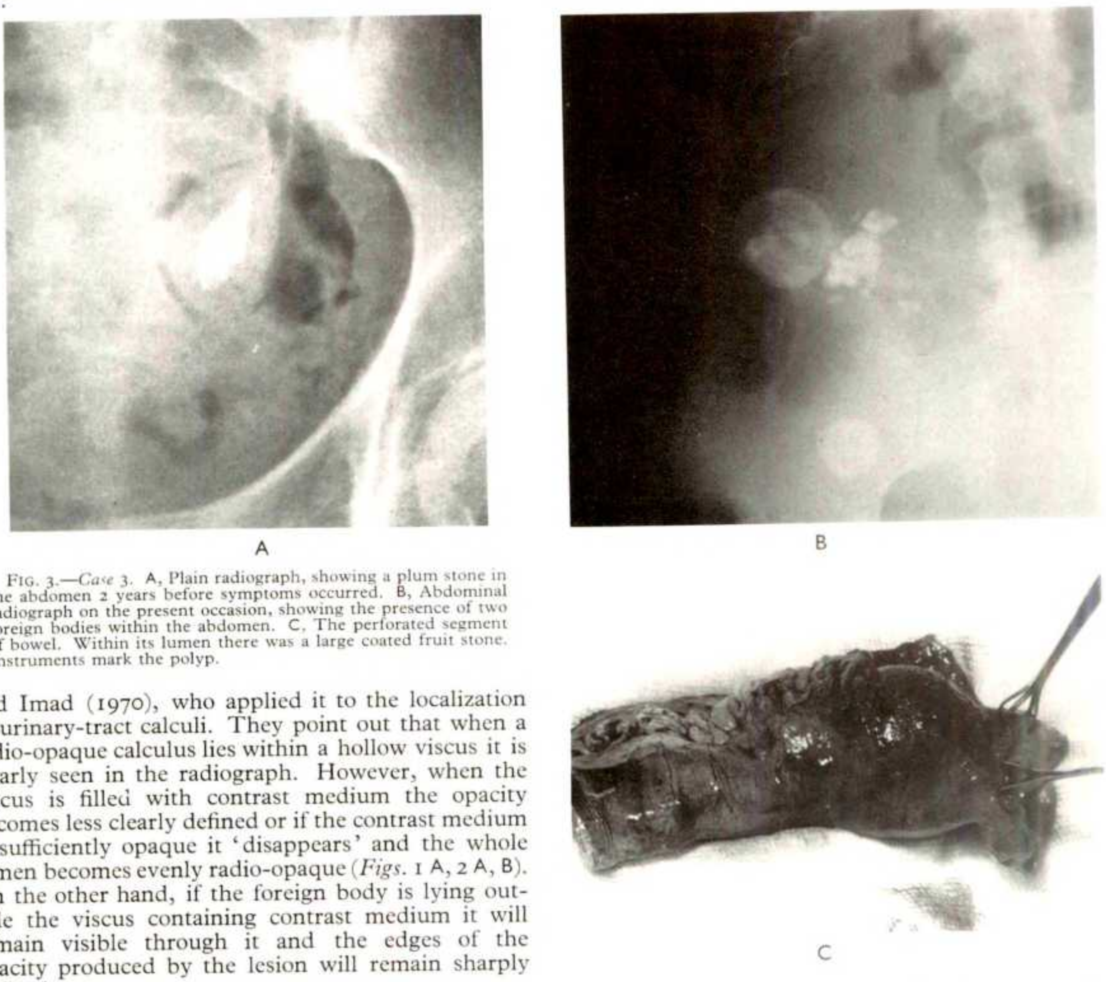


FIG. 3.—*Case* 3. A, Plain radiograph, showing a plum stone in the abdomen 2 years before symptoms occurred. B, Abdominal radiograph on the present occasion, showing the presence of two foreign bodies within the abdomen. C, The perforated segment of bowel. Within its lumen there was a large coated fruit stone. Instruments mark the polyp.

Acknowledgements.—We are indebted to Professor Harold Ellis and Mr. A. G. Rutter, under whose care these patients were admitted, for permission to publish details of these cases, to the Department of Medical Photography, Westminster Hospital, for the preparation of the photographs, and to Miss R. Kitson for typing the manuscript.

SHORT NOTES OF RARE OR OBSCURE CASES

GLOVE-POWDER GRANULOMA OF THE TESTIS AFTER SURGERY

BY J. I. PUGH AND PAUL STRINGER
ST. ALBANS CITY HOSPITAL, ST. ALBANS, HERTFORDSHIRE

SUMMARY

A case of epididymitis and periorchitis due to talc granulomatosis 11 years after operation for hydrocele is reported. The pathology of the lesions caused by the inadvertent contamination of tissues during surgical operations is reviewed with particular reference to the testis.

THE contamination of operation wounds by dusting powder (either *Lycopodium* or magnesium silicate) from the surgeons' gloves with the reaction of tissue granulomata has been the subject of numerous studies both clinically and experimentally. The widespread recognition of talc granulomata, particularly within the peritoneal cavity, prompted the adoption of starch powder, but similar changes have now been described following the use of this agent. These may occur at other sites outside the abdomen, such as the skin, soft tissue, and viscera, and give rise to clinical and histological problems, as the present case illustrates.

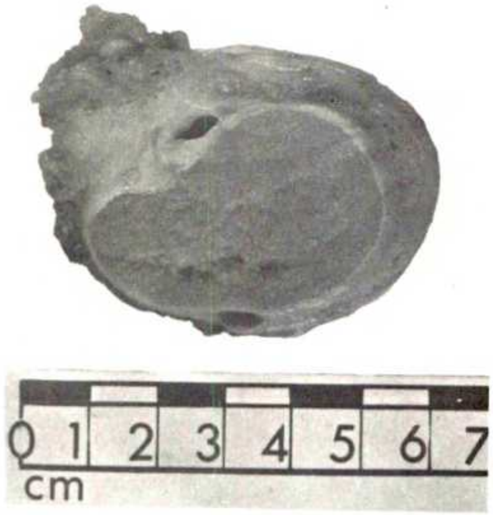

FIG. 1.—Bisected left testis showing periorchitis and a white mass in the head of the epididymis.

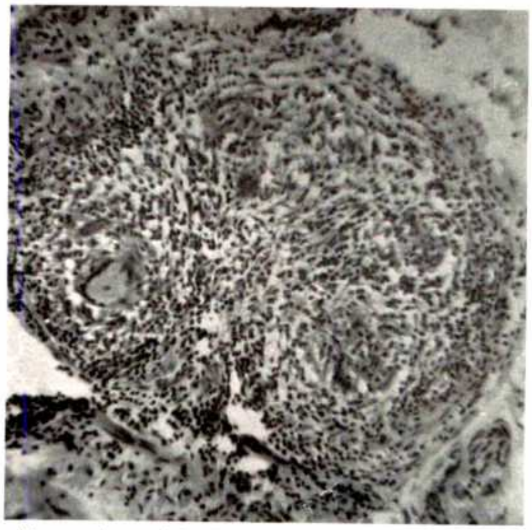

FIG. 2.—A rounded cell nest in the epididymis composed of foreign-body giant cells, epithelioid histiocytes, and lymphocytes. H. and E. (× 54.)

CASE REPORT

F. P., aged 71 years, underwent left orchidectomy for the removal of a craggy testis in October, 1970. He presented with one episode of haematuria when the enlarged testis was noted. As he gave a history of the removal of a left kidney for hypernephroma by Mr. M. R. Williams at the Isle of Thanet Hospital in October, 1969, a preoperative diagnosis of metastatic deposit in the testis was contemplated. It was not until after the specimen had been examined microscopically that the patient admitted on questioning that an operation for radical cure of a left hydrocele had been done in 1958. Also, in May, 1967, a similar operation had been performed for a right hydrocele, and at the same time a herniorrhapy had been carried out. All these operations had been done in Thanet by Mr. Williams who kindly confirmed the patient's story. The patient made an uninterrupted recovery from the present operation. He remained free of trouble until September, 1971, when after a second episode of haematuria a space-occupying lesion was demonstrated in the lower mid-zone of the single remaining kidney by an excretory urogram. Further investigations are now proceeding at another hospital.

PATHOLOGY.—The testis measured 5 × 4 × 4 cm. and weighed 55 g. and had been removed with a stump of spermatic cord. The bisected testis was noted to be normal but there was a thick layer of connective tissue applied to the tunica albuginea. Replacing the head of the epididymis was a hard, white, poorly defined lump, 2 cm. in diameter (*Fig.* 1).

Microscopic examination of haematoxylin-and-eosin-stained paraffin sections showed a dense fibrous reaction within the head of the epididymis, at the base of the spermatic cord, and around the tunica albuginea. Amongst the fibrous tissue were rounded nests of cells, 0·5 mm. in diameter, which were confluent in places. They consisted of foreign-body giant cells with both central and peripheral nuclei surrounded by epithelioid histiocytes and lymphocytes. Only rarely was a small focus of fibrinoid necrosis seen. The seminiferous tubules were normal for a man of 71 years apart from a very occasional granuloma found between superficially placed tubules.

Examination of the same section by polarized light revealed a multitude of needle- or irregularly shaped optically active crystals, up to 20 μ long, lying mainly amongst collagen fibres but also within giant cells (*Figs.* 2, 3). In general it was noted that the fully developed granulomata contained scanty optically active crystals.

At this point a histological diagnosis of glove-powder granuloma was considered and two further sets of examinations were employed to confirm the diagnosis. First, the nature of the optically active material was investigated and, secondly, other forms of granuloma were excluded. For the latter Ziehl-Neelsen preparations were examined for tubercle bacilli, and a search for lipid was made by the use of the periodic acid-Schiff and long Ziehl-Neelsen techniques, as described by Phillips (1961). These investigations proved negative. In order to identify positively the birefringent material a spodagram was used (Wolman, 1970). In this technique the dewaxed unstained paraffin sections were incinerated to about 600° C. and after cooling a cover-slip was placed over the residue. Examination of this preparation by polarized light showed the needle-shaped and amorphous material to be present to the same extent as before, thus establishing their nature as silica or talc. Resistance to exposure to 50 per cent hydrochloric acid for 1 hour was further proof of identification.

CLINICAL APPRAISAL

The appearance of nodules within tissues, particularly the peritoneum, after surgical intervention presents the clinical problem of either recurrent or newly acquired disease, and in respect of malignant neoplasms the possibility of metastasis. The occurrence of granulomata following the use of various glove powders is now well recognized, and the literature concerning these lesions mostly pertains to the peritoneum (Antopol, 1933; German, 1943; McAdams, 1956; Hyden and McClellan, 1959; Myers, Deaver, and Brown, 1960; Blair and Blumenthal, 1964; McNaught, 1964; Bates, 1965; Cox, 1970).

The direct implantation of glove powder into the tunica vaginalis is illustrated in 2 case reports. Antopol (1933) records the case of a 35-year-old Spaniard who developed a mass in the epididymis with a persistent sinus 2 months after operation for traumatic hydrocele. Orchidectomy was performed and microscopic pathology revealed a tuberculous type of lesion due to spores of *Lycopodium*. Cox (1970) also reports the case of a 6-year-old boy whose testis was explored for suspected torsion. Epididymo-orchitis was found and the scrotum was closed. A mass developed during the following month and, assuming a diagnostic error, the testis was excised. The mass was a starch granuloma.

In the case reported here it was reasonable to postulate secondary deposits of a renal adenopapillary carcinoma, spreading by extension or embolism along the left spermatic vein. The apparent enlargement of the testis was not associated with the previous operation for hydrocele, which would necessarily entail the opening of the tunica vaginalis. It is not necessary, however, for the scrotum to be incised to produce testicular foreign-body granulomata. Saxén and Saxén (1965) report an example (*Case* 13) of the transmission of starch powder from the abdominal cavity to the testis after laparotomy for ruptured liver in a boy aged 4 years. Two months later an olive-sized nodule was found in the testis when removed. Microscopic examination showed a starch granuloma within the tunica vaginalis. Presumably, although it is not actually stated, the processus vaginalis was patent. Crystalline talc has also been shown to spread by lymphatics and to give rise to granulomatous lesions in regional lymph-nodes (Shattock, 1917). Starch particles also spread in this manner and cause lymphadenitis (Neely and Davies, 1971). The powder is either a contaminant from the surface of the gloves (Lee and Lehman, 1947) or from punctures, which are often unrecognized (Weed and Groves, 1972). Butterfield (1970), analysing 100 operations, found a total of 190 separate punctures and confirms the findings of Shouldice and Martin (1959) and Russell, Roque, and Miller (1966) that there is at least one defective glove after operations lasting 1 hour. The recognition of this complication and the importance of washing fresh gloves are emphasized (Taft, Lasersohn, and Hill, 1970).

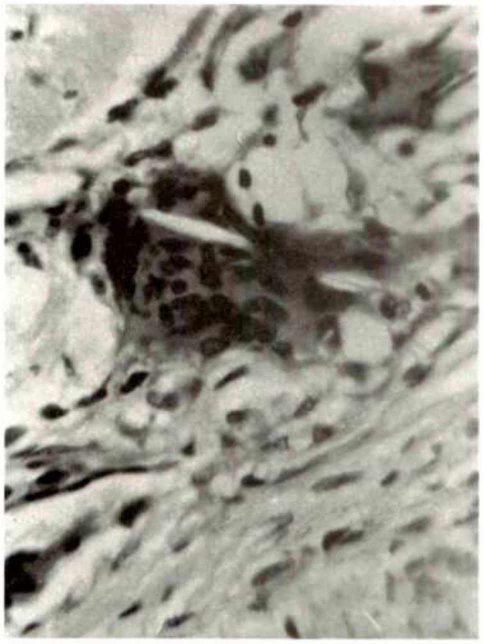

FIG. 3.—A foreign-body giant cell containing birefringent talc crystals in a fibrous tissue reaction. H. and E. (× 240.)

The recognition of glove-powder granulomatosis is primarily for the histologist, but without knowledge of previous operations the microscopical appearances could easily be confused with sarcoidosis, tuberculosis, syphilis, granulomatous orchitis, sperm granuloma, malignant lymphoma, and miscellaneous inflammatory lesions simulating malignancy (Morgan, 1964). This is because the mixture of cellular elements is so variable. The key to microscopic diagnosis is the examination of sections by strong polarized light, for the foreign bodies may be quite inconspicuous by ordinary light microscopy. Foreign bodies that are not in proximity to the cells comprising the granuloma should be ignored, for they may be derived from either the surgeon's or the pathologist's gloves whilst handling the specimen.

Lee, Collins, and Largen (1952) state that no matter how benign the powder may be and no matter how quickly absorbed, it is, for the duration of its presence in tissue, a foreign body. Furthermore, the longer the granules remain unabsorbed the more advanced the foreign-body reaction will be and the less chance there is that it will be reversible. When a complicating factor such as an infection is added to the foreign-body reaction of the tissues the process is exaggerated and the extent of permanent scar tissue is proportionately increased. The amount of the contaminant powder is another factor in the pathogenesis and, as would be expected, the larger the contamination the greater is the lesion. The variation in response is reflected in the clinical manifestation after contamination by starch powder. The time lapse may be between 2 weeks and 4 years (Cox, 1970) but most appear within a few weeks or months (Saxén and Saxén, 1965). Mackey and Gibson (1948) describe florid granulomata developing within 2 weeks of implantation of talc, and Walker (1948) has shown that a siliceous granuloma can produce a firm peritoneal adhesion in 7 weeks. However, talc may also remain dormant in tissues and 45 years may pass before a lesion appears (Roberts, 1947). In the example reported here over 11 years elapsed between the two operations within the scrotum. Neely and Davies (1971) consider that the condition is more common than is usually realized, particularly within the peritoneum. That starch powder is preferable to talc is borne out by Myllarniemi (1967), who found a foreign-body reaction in 61 per cent of patients after abdominal surgery, for which talc was responsible in 31 per cent and starch in 1 per cent of cases. Nevertheless the comparative rarity of starch granulomata despite the wide use of glove powder and the possibilities of contamination suggests that the response is due to hypersensitivity or an allergi reaction. No such response was evident in the presen case and no such experimental confirmation ha been hitherto adduced (MacQuiddy and Tollman 1948; Lee and others, 1952; Bates, 1965).

NEURILEMMOMA PRESENTING AS A LUMP IN THE BREAST

BY RICHARD COLLINS AND GILLIAN GAU
WYCOMBE GENERAL HOSPITAL, HIGH WYCOMBE, BUCKINGHAMSHIRE

As far as is known a neurilemmoma growing in the breast tissue has not previously been reported. Such a case is described here.

CASE REPORT

The patient was a 43-year-old housewife and mother of 4 children. One child had been breast-fed for a month, the second child had not been breast-fed because a breast abscess had developed, and after the births of the other 2 children breast-feeding had been suppressed.

Nine years prior to admission the patient had been on a contraceptive pill for 1½ years. In 1965 she had had a hysterotomy for a termination of pregnancy. She also had curettement of the uterus and dilatation and cauterization of the cervix in 1966 for a cervical erosion. Sh had had a variety of complaints recently including depression and, 6 months prior to admission, a mycoplasm pneumonia.

The patient presented with a lump in the right breas which she had noticed for 1½ weeks whilst she was havin a period. It was not tender and the patient thought tha it might have become larger during the time that she ha waited for an out-patient appointment.

On examination she had a firm lump, 2 × 1 cm., o rubbery consistency and regular outline in the uppe outer quadrant of the right breast. This was mobile an not tender. There were no axillary or supraclavicula nodes palpable, no stigmata of neurofibromatosis, an no other abnormal physical signs. She had not noticed any discharge from the nipple. Clinically, it was considered that the lesion was a fibro-adenoma of the breast and that it should be removed.

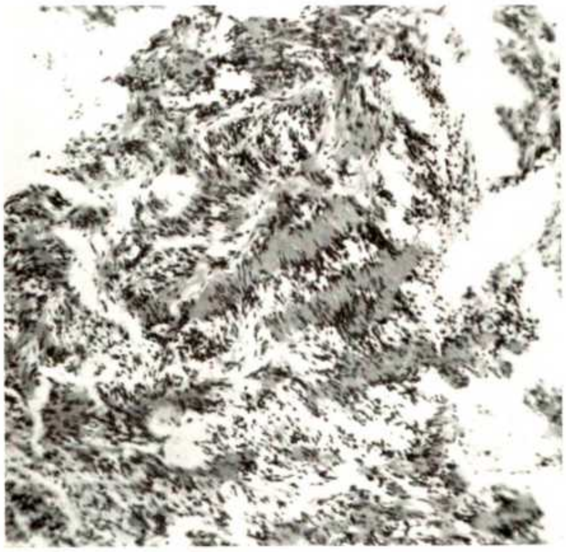

FIG. 1.—Characteristic nuclear palisading in Antoni A areas. H. and E. (× 75.)

OPERATION.—At operation a freely mobile lump was removed from deep in the breast. It did not have the appearances of a fibro-adenoma in that it seemed myxomatous and there was an area of yellow material at one end that looked like hard, dense fat. This was subjected to a frozen section, the report of which was inconclusive. However, it was felt that there were no grounds for advocating a mastectomy until the paraffin section had been seen. The wound was closed with silk sutures and the patient returned to the ward. Subsequently the wound healed satisfactorily and the patient was discharged a few days later. Postoperatively she has remained well.

HISTOLOGY.—Paraffin sections of the tumour showed a typical neurilemmoma. Both the main histological features of Antoni A areas (highly cellular with a dark-staining cytoplasm) and Antoni B areas (pale cells with an irregular outline lying in a watery matrix) were present. Within the Antoni A areas there were groups of cells showing the characteristic palisaded nuclei (*Fig.* 1).

DISCUSSION

Solitary neurilemmomas or Schwannomas may arise from any nerve that has a sheath. They are thought to be tumours of the Schwann cells which comprise the nerve-sheath, although there has been some attempt to cast doubt upon this theory (Penfield, 1932).

Neurilemmomas may be intracranial or peripheral. The commonest form of intracranial neurilemmoma is the acoustic neuroma. Peripherally the commonest sites are on the flexor aspect of the principal nerves of the limbs, in the posterior mediastinum, and in the stomach (Stout, 1935). However, although various sites have been described we can find no evidence of one presenting as a lump in breast. In several series (Willis, 1967) it has been noted that whatever the site females are more frequently affected than males.

The tumour itself is not locally invasive and, depending upon the site, it should be possible to enucleate it completely without damaging the underlying nerve. Local recurrence only occurs if enucleation has not been complete.

Acknowledgements.—Our thanks are due to Mr. Peter Lord and Dr. David Spencer for allowing us to report on this case, to Professor Noel F. Gowing for his second opinion on these sections, and to Mr. Martin Casling for the photography.

HORSESHOE KIDNEY AND ABDOMINAL AORTIC ANEURYSM

BY J. M. SYMES AND D. G. EADIE
THE LONDON HOSPITAL

SUMMARY

A case of horseshoe kidney and an abdominal aortic aneurysm is presented. The 32 previously described cases are reviewed and the diagnosis and management are discussed. The major factors influencing the operative approach to an aortic aneurysm associated with a horseshoe kidney concern the site of origin of the renal arteries, their number, and the portion of the kidney which each supplies.

THE association between a horseshoe kidney and an abdominal aortic aneurysm has previously been reported and 32 cases are documented in the world literature. A further case is described here and the previous 32 cases are reviewed.

CASE REPORT

Mr. J. S., a 65-year-old man, presented with a 4-month history of aching midlumbar backache and abdominal pulsation. On examination he was found to be normotensive and to have a large abdominal aortic aneurysm.

INVESTIGATIONS.—A radiograph of the abdomen confirmed calcification in the abdominal aneurysm. An intravenous pyelogram (*Fig.* 1) showed calcification in the right kidney and malrotation of both sets of calices, suggestive of a horseshoe kidney. The blood-urea was 33 mg. per cent.

OPERATION.—On 17 Sept., 1970, a laparotomy was performed via a long midline incision which confirmed the preoperative diagnosis. The main bulk of the horseshoe kidney with its convexity caudad lay on the left side. The tissue bridging the aorta was 2·5 cm. in thickness and 5 cm. in depth, the right half of the kidney being small. There were three separate renal arteries, renal veins, and ureters (*Fig.* 2). The distribution to the left and right halves of the kidney was essentially normal, with the ureters descending anteriorly to the isthmus. The isthmus was tethered by its vascular supply with the central artery arising from the posterior aspect of the abdominal aorta at its bifurcation and the central vein descending across the aortic bifurcation and entering the right common iliac vein. The central ureter lay behind the right common iliac vein. To gain access to the proximal and normal-looking aorta it was necessary to retract the kidney by dividing the central artery, vein, and ureter (*Fig.* 3).

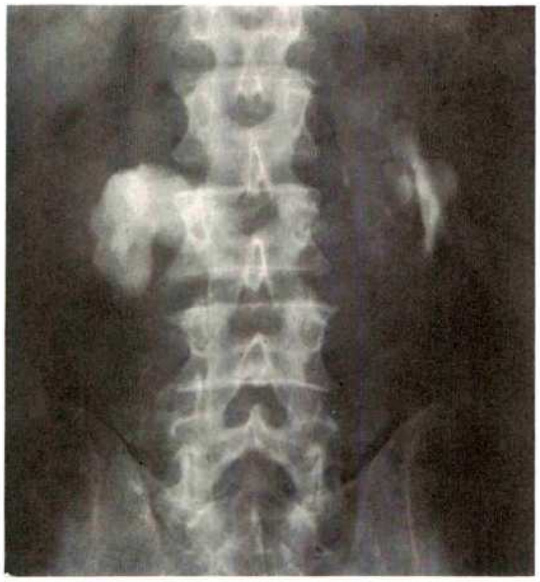

FIG. 1.—The intravenous pyelogram, showing rotation of the pelvis and calcification in the right kidney.

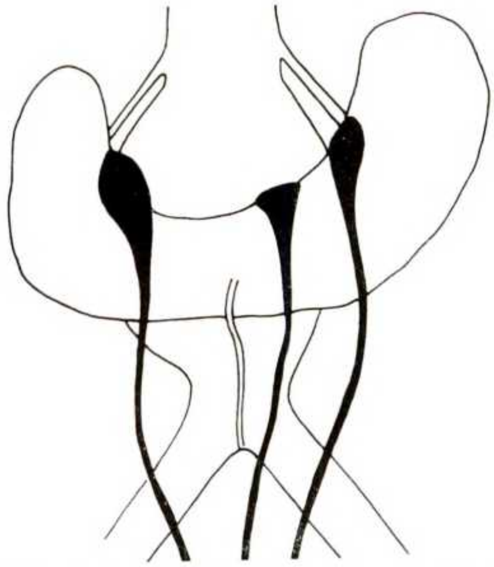

FIG. 2.—Diagrammatic representation of the anatomical configuration in the present case. For the sake of clarity, the veins have been omitted. The ureters are depicted in black.

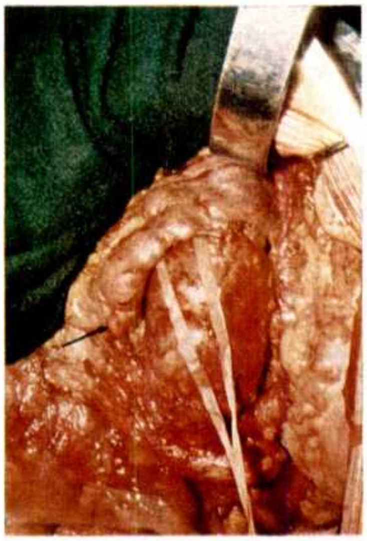

FIG. 3.—Peroperative photograph. The isthmus of the horseshoe kidney is retracted proximally after division of the central artery and ureter. The right ureter is arrowed.

The artery was clamped initially and this produced only a minimal area of cyanosis. The aneurysm lay distal to the main renal arteries and aneurysmectomy was performed with a 16-mm. woven Dacron graft, 2 cm. distal to the renal vessels.

The patient made an uneventful postoperative recovery and was discharged home on the twelfth postoperative day, with a blood-urea of 54 mg. per cent. He remains well 2 years later.

DISCUSSION

The association between horseshoe kidney and abdominal aortic aneurysm was first recorded by Julian in 1956, who found that the aneurysm was non-resectable because it supplied multiple small vessels to the kidney.

A horseshoe kidney is a congenital abnormality that occurs between the 4th and 8th weeks of foetal life, with a frequency ranging from 1 in 400–1000 births. There is an early midline fusion of the metanephric blastema that prevents rotation and migration of the kidneys. The isthmus joining the two renal masses may vary from a thin fibrous band to functioning renal tissue. Ninety per cent of cases have their convexity caudad with the isthmus lying at L.V.3 or 4, but this may vary from L.V.1 to the pelvic brim. In 60 per cent of cases the vasculature is anomalous with the arteries arising at various sites on the aorta in segmental distribution from the iliac vessels to the mesenteric vessels.

It is the anomalous distribution of the blood-vessels that provides the major surgical complication in dealing with the association of abdominal aortic aneurysm and horseshoe kidney. Lacombe, Vaysse, Andreassian, and Desmonts (1970) described four groups of arterial distribution, each requiring a different management:—

Group I: Normal vascular distribution. Twelve cases (37·5 per cent) have been reported. In each case resection was carried out and in 3 cases it was necessary to divide the isthmus.

Group II: One or two main arteries arising from the aneurysm. The management of the 11 cases (34·5 per cent) in this group is shown in *Table I*.

Table I.—THE MANAGEMENT OF ABDOMINAL AORTIC ANEURYSM ASSOCIATED WITH HORSESHOE KIDNEY IN CASES IN WHICH ONE OR TWO MAIN ARTERIES ARISE FROM THE ANEURYSM (GROUP II)

Author	*Management of Aneurysm*
Falor and Rufflo (1964)	(i) Not resected. Right renal artery from aneurysm. (ii) Aneurysm wrapped in Mersiline polyester. One single anterior renal artery from aneurysm.
Lynn and Bruce (1965)	Resection of aneurysm and left heminephrectomy. Left renal artery from aneurysm.
Cohn, Stoney, and Wylie (1969)	Resected. Renal artery reimplanted into graft.
Scott, DeBakey, and Mani (1969)	Resected. Renal artery reimplanted into graft.
Trabattoni, Miele, and Losapio (1969)	Not resected. Both arteries from aneurysm.
Hoofer (1970)	Resected. The left renal artery was reimplanted.
Lacombe, Vaysse, Andreassian, and Desmonts (1970)	(i) Resected with ligation of two smaller vessels to the lower poles. (ii) Resected. There were two normal arteries plus two vessels from the aneurysm that were reimplanted.
Marable and Thomford (1970)	Resected with ligation of two smaller vessels to the lower poles.
Davis, Hardin, Hardy, and Neely (1971)	Resected. Left renal artery was reimplanted.

Since 1969, 5 cases have been recorded where a reimplantation of a major renal artery has been performed successfully. Prior to that the aneurysm has been considered inoperable except on one occasion (Lynn and Bruce, 1965), when a left heminephrectomy was performed.

Group III: One or more arteries supplying the isthmus from the aneurysm. Seven cases (22 per cent) have been recorded, including the present case. In 4 cases it was found necessary to divide the isthmus. One patient died—the only operative death in the series. In each case the artery to the isthmus was divided after prior assessment of its distribution. If after clamping the vessel cyanosis occurred the isthmus was divided. Division of the renal tissue results in an increased risk of infection to the Dacron graft. Whenever this manœuvre is performed, a culture should be taken from the cut surface of the kidney.

Group IV: Vessels from the aneurysm are too numerous to consider resection. Two cases (6 per cent) have been described.

It becomes obvious that the major factors influencing the operative approach to an aortic aneurysm associated with a horseshoe kidney concern the site of origin of the renal arteries, their number, and the portion of the kidney which each supplies.

Preoperative intravenous pyelography is necessary to demonstrate the renal pattern and the distribution of the calices. Prior knowledge of an abnormal renal pelvis is essential if division of a thick isthmus is required, as leakage of urine will compromise the graft.

Preoperative aortography, whether by the high translumbar route (Scott, DeBakey, and Mani, 1969; Press, 1970) or by the left axillary artery (Marable and Thomford, 1970), may delineate the aneurysm and the renal arteries. Minken and Rob (1967) and Cox and Machado (1968) both performed operative aortography. Demonstration radiologically is probably better and the risks of leakage from the aneurysmal wall or disruption of a mural plaque do not arise.

In cases where division of the isthmus or sacrifice of renal vessels may have to be performed the distribution of the arterial supply may be demonstrated preoperatively by selective angiography (Press, 1970) or renal scanning with ^{203}Hg (Allen and Riley, 1963). If this problem presents at operation, as in the case described here, temporary clamping of the involved renal vessel will produce an area of cyanosis related to its distribution.

In the event of reimplantation of a major renal vessel some form of local cooling or perfusion may be required. Szilagyi, Smith, and Whitcomb (1959) commented that if the left renal artery is involved this may be successfully anastomosed to the splenic artery.

In the whole series of 32 cases the resection rate was 82 per cent with a mortality-rate of 4 per cent.

Acknowledgements.—We should like to thank Mr. R. Ruddick for his help in preparing the photographs and Miss I. Love for her secretarial assistance.

SUBMANDIBULAR DUCT LITHIASIS ASSOCIATED WITH A MIXED SALIVARY GLAND TUMOUR

A CASE REPORT

By R. A. HINDER

DEPARTMENT OF SURGERY, JOHANNESBURG HOSPITAL AND UNIVERSITY OF THE WITWATERSRAND

AND N. S. F. PROCTOR

SCHOOL OF PATHOLOGY, SOUTH AFRICAN INSTITUTE FOR MEDICAL RESEARCH AND UNIVERSITY OF THE WITWATERSRAND, JOHANNESBURG, SOUTH AFRICA

SUMMARY

A case of submandibular gland pleomorphic adenoma in association with duct lithiasis is presented. These are probably incidental findings, but it is possible that they may be causally related.

EXAMINATION of the recent English literature has revealed no reported case of pleomorphic adenoma associated with duct lithiasis. Such a case is presented here and the possible aetiological factors are discussed.

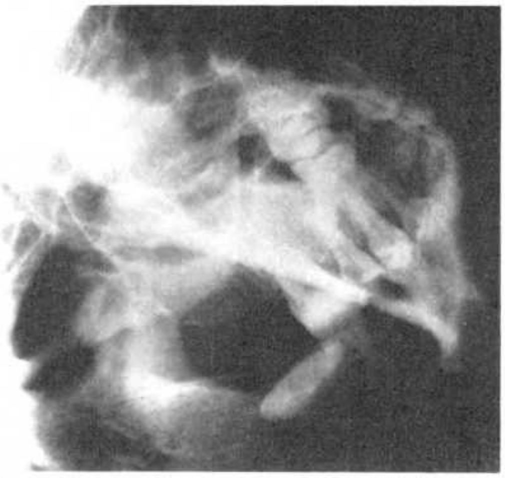

FIG. 1.—Oblique radiograph of the mandible, showing a large radio-opaque calculus in the left submandibular duct.

CASE REPORT

M. M., a Bantu female aged 43 years, was admitted to the General Hospital, Johannesburg, in February, 1971, with a 1-year history of a painful tender swelling in the area of the left submandibular gland. The mass had slowly been increasing in size and was more tender and painful during mastication. There had been a recent weight-loss of about 4 kg. Systematic and past history revealed nothing of significance.

On examination the patient was found to be a fit middle-aged female with a discrete oval swelling measuring 2·5 × 3 cm. in the position of the left submandibular gland. The surface of the mass was slightly lobulated and the gland was mildly tender. No cervical lymphadenopathy was detected. Palpation of the floor of the mouth revealed a 1-cm. calculus in the posterior part of the left submandibular duct. This was confirmed radiographically (*Fig.* 1). The lungs were clinically and radiologically normal.

A diagnosis of sialitis secondary to duct lithiasis was made. Under general anaesthesia and endotracheal intubation a longitudinal mucosal incision was made over the calculus, which was removed. The wound was not sutured. A mild cellulitis at the operative site was treated with antibiotics and it settled after 3 days. The gland remained tender and swollen for 7 days and then diminished slightly in size and became non-tender. The patient was discharged on the fifteenth postoperative day. Over the next 9 weeks the gland remained the same size and without tenderness.

The patient was readmitted in May, 1971, for complete removal of the left submandibular gland. This was

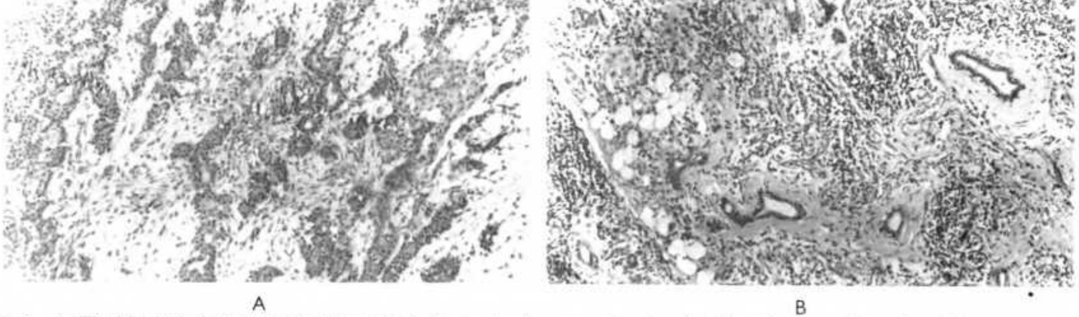

FIG. 2.—A, The histological appearances of the mixed salivary-gland tumour, showing glandular elements and cartilage-like stromal change. B, A representative area showing chronic sialitis. H. and E. (× 42.)

done under general anaesthesia using a submandibular incision.

Pathological examination revealed a gland weighing 24·5 g. A partly encapsulated tumour measuring 3·0 × 3·5 × 2·2 cm. was found in the superficial part of the gland.

On histological section the features of a typical mixed salivary tumour were seen (*Fig.* 2 A). The deep part of the gland showed periductal fibrosis, fatty infiltration, atrophy of the parenchymal tissue, and a chronic inflammatory infiltration, the features being those of a chronic sialitis (*Fig.* 2 B).

The patient made an uneventful postoperative recovery and was discharged from hospital on the seventh postoperative day.

DISCUSSION

Two relatively rare conditions—submandibular gland pleomorphic adenoma and duct lithiasis—have been found to be present simultaneously in one patient. This raises the question whether these could be causally related or whether this association is incidental. Evans and Cruickshank (1970) feel that there is at present no definite correlation between salivary-gland tumours and duct lithiasis, and urge that clinicians should make a deliberate note of conditions and disorders that may be associated with salivary-gland tumours.

The question exists as to whether the tumour is secondary to the stone or the stone is secondary to the tumour. The former proposal seems unlikely, and although the latter is a possibility, it is more likely that they are both incidental findings in this patient.

Formation of a stone in the duct of a gland containing a tumour might arise by desquamation of part of the tumour into the duct to act as a nidus for stone formation. A decreased rate of secretion in the duct owing to the presence of the tumour may result in stasis and stone formation. Stewart (1968) reported the development of a squamous carcinoma in a gland that was chronically infected as a result of the presence of a calculus. Shanon (1965), in a case report, showed the presence of a squamous carcinoma of the submandibular duct in association with a stone.

Phleboliths are commonly seen in soft-tissue cavernous haemangiomata and when these occur in or near a salivary gland they should not be confused with lithiasis (Hopkins, 1969).

Acknowledgements.—Our thanks are due to Mr. C. G. Bremner, under whose care this patient was admitted, to the Superintendent of the Johannesburg Hospital, and to the Director of the South African Institute for Medical Research for permission to publish this report.

PRIMARY ADENOCARCINOMA ARISING IN A VITELLO-INTESTINAL DUCT REMNANT AT THE UMBILICUS

By G. GLAZER*
HILLINGDON HOSPITAL, UXBRIDGE, MIDDLESEX

Summary

A case is presented of a primary adenocarcinoma which arose from a vitello-intestinal duct remnant at the umbilicus in a 46-year-old woman. The incidence, diagnosis, and management of these unusual tumours are reviewed.

A primary adenocarcinoma arising at the umbilicus is very rare. A case is presented of one such tumour which appeared to develop in a vitello-intestinal (omphalomesenteric) duct remnant.

CASE REPORT

Mrs. V. S., a 46-year-old housewife, was referred to the Out-patients' Department of Hillingdon Hospital, Uxbridge, in August, 1967, because of a mucopurulent umbilical discharge of 6 weeks' duration. She had no other symptoms but admitted to some menorrhagia on direct questioning. Micturition was normal. For the previous 10 years she had noticed an occasional slight gelatinous discharge from the umbilicus but this had always cleared up spontaneously after a few days. Examination of the anterior abdominal wall revealed a normal-looking umbilicus which was discharging small amounts of pus. Above the umbilicus there was a round, tender, subcutaneous swelling approximately 6 cm. in diameter; the overlying skin was inflamed but intact. The only other abnormality found on examination was a large fibroid uterus. A diagnosis of an infected umbilical cyst was made and the patient was admitted to hospital. Under general anaesthesia the swelling above the umbilicus was incised and a large amount of mucopurulent discharge was obtained; a bacteriological swab from this showed a growth of anaerobic non-haemolytic streptococci. The inflammation and discharge rapidly settled and the patient was allowed home after a few days.

The possibility of this lesion being a metastatic deposit was considered and a chest radiograph, barium-meal, follow-through, and barium-enema examinations, and sigmoidoscopy were performed at the follow-up clinic but these were all normal.

Eight months later the patient returned with a discharging sinus above the umbilicus, but there was no evidence of an underlying swelling. There was a moderate amount of brown mucoid discharge tinged with blood from both the sinus and umbilicus. The patient only

---

* Present address: Surgical Unit, St. Mary's Hospital, London.

agreed to admission 3 months later (September, 1968) by which time she had developed a fungating tumour 4 cm. above the umbilicus (*Fig.* 1). This was a firm, non-tender, oval mass measuring 4 cm. vertically and 5 cm. horizontally. The surface was heaped up irregularly and was constantly secreting mucus; the mass was not infiltrating locally and there was no surrounding induration or inflammation. Neither the axillary nor the inguinal lymph-nodes were palpable. The umbilicus was again apparently normal to inspection and palpation, with only an occasional slight discharge. Repeated investigations were all normal apart from an iron-deficiency anaemia with a haemoglobin of 8·3 g. Surgery was performed on 9 Oct., 1968, after a preoperative blood transfusion.

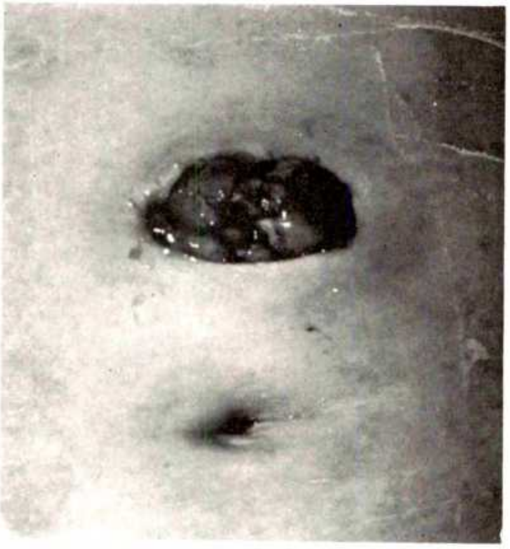

FIG. 1.—Preoperative view of the anterior abdominal wall, showing a supra-umbilical tumour.

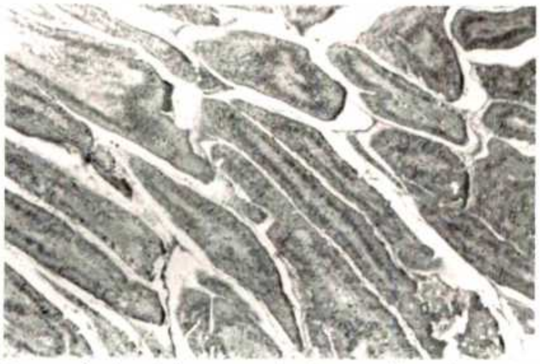

FIG. 2.—Section of the tumour, showing a papillary adenocarcinoma of low-grade malignancy. H. and E. (× 11.)

OPERATIVE PROCEDURES.—Cystoscopy revealed a normal bladder. On pelvic examination the cervix was normal but the uterus was enlarged to the size of a 16-week pregnancy. A cervical smear and then curettage of the uterus were carried out. Laparotomy performed through a lower left paramedian incision revealed no evidence of an intra-abdominal tumour. The presence of a large fibroid uterus was confirmed. The omentum was attached to the parietal peritoneum beneath the umbilicus but there was no evidence of spread of tumour into the abdominal cavity. There was no Meckel's diverticulum or vitello-intestinal duct remnant in the abdomen. The fundus of the bladder felt normal and there was no swelling or tumour along the line of the urachus running up to the umbilicus. All the other viscera were normal and the incision was therefore closed. Excision biopsy of the supra-umbilical lesion was then performed via a transverse elliptical incision. The tumour was surrounded by a well-defined fibrous capsule which ran downwards as a patent, narrow, fibrous duct towards the umbilicus. The umbilicus was not excised at this stage.

The histological reports were as follows: cervical smear, normal; uterine curettings, hypoplastic endometrium showing secretory changes with no evidence of malignancy; abdominal-wall tumour, a columnar-cell, papillary, mucus-producing tumour showing evidence of low-grade malignancy (*Figs.* 2, 3).

The patient's postoperative progress was satisfactory but she declined to have a radical excision of the umbilicus which was advised. Over a period of several weeks she began to have an increasingly heavy discharge of mucus from the umbilicus and finally agreed to further surgery which was performed on 10 Jan., 1969. A wide transverse elliptical incision with a 12-cm. clearance on either side of the umbilicus was made and this block of tissue containing the umbilicus, subcutaneous tissues, muscle, sheath, and peritoneum was excised *en masse*. The peritoneum was closed and a Mayo repair using silk was performed on the rectus sheath. The patient's postoperative course was again satisfactory. The specimen showed a solid core of neoplastic tissue, 3 cm. thick, extending down beneath the umbilicus through the rectus sheath but not spreading through the peritoneum. Histology of the specimen showed identical appearances to the previous biopsy.

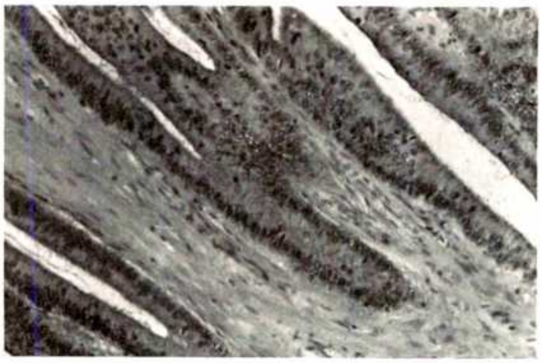

FIG. 3.—Section of the tumour, showing a well-differentiated, columnar-cell adenocarcinoma. H. and E. (× 53.)

In February, 1970, the patient underwent an abdominal hysterectomy for her fibroid uterus. A general examination of the abdomen was again normal at this time. She has remained in good health since her last operation with no evidence of local spread or distant recurrence of her tumour.

DISCUSSION

The embryological remnants found in the region of the umbilicus are derived from the vitello-intestinal (omphalomesenteric) system or the urachus. The anatomy and incidence of these uncommon anomalies have been reviewed by Cullen (1916), Begg (1931), Trimingham and McDonald (1945), and Moore (1956).

An adenocarcinoma occurring at the umbilicus is nearly always a metastasis from an intra-abdominal tumour. In a review of 112 tumours of the umbilicus Steck and Helwig (1965) found 64 benign and 48 malignant lesions; 40 of the malignant lesions were secondary deposits, 36 being adenocarcinomas. There were 7 definite primary tumours of the umbilicus (4 malignant melanomas, 2 basal-cell carcinomas, and 1 myosarcoma), whilst the remaining case, a 37-year-old male, presented with an umbilical discharge and tumour which proved on excision to be an adenocarcinoma resembling an intestinal epithelium. This patient died after 2 months with multiple tumour nodules throughout the abdomen. No other primary tumour was demonstrated and this fact together with the presence of a Meckel's diverticulum suggested that the tumour could have arisen in a cutaneous remnant of the vitello-intestinal duct. Steck and Helwig (1965) also studied 40 patients with cutaneous vitello-intestinal anomalies, 48 with urachal remnants at the umbilicus, and 28 with umbilical endometriosis and failed to detect any tendency to neoplastic change in these uncommon conditions. Thus, they confirmed the findings of Beurey, Rousselot, Vadot, and Barbier (1961), O'Leary and O'Leary (1964), and Willis (1967) that primary adenocarcinoma of the umbilicus is excessively rare.

In the case reported here the 10-year history of umbilical discharge suggests a previous underlying umbilical abnormality. The absence of any other tumour indicates that the lesion is a primary. Furthermore, the long-term survival of the patient is unlike the behaviour of patients with umbilical secondary deposits in whom the average survival time was only 11 months in the series reported by Steck and Helwig (1965).

A primary adenocarcinoma at the umbilicus can only arise from a pre-existing endometrioma or an embryological remnant. A pre-existing endometrioma can be excluded in this patient on clinical grounds since there had been no pain or bleeding from the umbilicus and the discharge was not related to menstruation. The histology (*Figs.* 2, 3) of the tumour showed it to be a columnar-cell, papillary, mucus-producing adenocarcinoma of low-grade malignancy—a picture which is consistent with a vitello-intestinal duct origin. However, since the majority of urachal tumours resemble intestinal tumours histologically (Mostofi, Thomson, and Dean, 1955; Nadjmi, Whitehead, McKiel, Graf, and Callahan, 1968; Grogono and Shepheard, 1969) this does not help in the differentiation of the tissue of origin, which will depend more on the anatomical and clinical features of the case.

The urachus runs downwards in the extraperitoneal space from the umbilicus to the apex of the bladder. Urachal tumours are usually found at the apex of the bladder, 75 per cent occur in males (Nadjmi and others, 1968), and the initial symptom is commonly related to micturition. A suprapubic mass is palpable in 80 per cent of cases at the time of presentation (Grogono and Shepheard, 1969). The tumour spreads in the retropubic space and despite radical surgery the prognosis is poor, with a 5-year survival rate of 8 per cent (Nadjmi and others, 1968). Begg (1931) discussed several urachal tumours found below the umbilicus but admitted that the diagnosis of such a tumour actually situated at the umbilicus is difficult to confirm. Willis (1962) stated that there has been no proved case of a urachal tumour at the umbilicus, but Pettorelli Lalatta (1966) reported a possible case.

Theoretically, urachal tumours might occur at any point up to the umbilicus but not above, as occurred in the present case. The features in this patient thus favour the diagnosis of a primary adenocarcinoma arising in a vitello-intestinal remnant. From the few reports of similar cases (Cullen, 1916; Williams, 1946; Steck and Helwig, 1965; Boscaino and Gambardella, 1968) it is difficult to determine the normal clinical course of such tumours. The present patient had a well-differentiated, slow-growing tumour and she is symptom-free 5½ years after the onset of symptoms (4 years after final surgery). These features are different from those in the possible case reported by Steck and Helwig (1965) in which there was rapid dissemination of the tumour and early death.

The management of an umbilical neoplasm is surgical excision. In the unlikely event that the tumour is a primary lesion, radical local surgery is indicated. If the tumour is a metastatic deposit the prognosis is poor but palliation is achieved. However, since the occasional long-term survivor has been reported in this situation (Steck and Helwig, 1965) an aggressive attitude to both the primary tumour and the umbilical secondary should be adopted.

Acknowledgement.—I would like to thank Mr. C. G. Scorer for permission to report this case and his helpful advice in the preparation of the manuscript.

REVIEWS AND NOTICES OF BOOKS

Hamilton Bailey's Emergency Surgery. Ninth edition. Edited by T. J. McNair, M.D., F.R.C.S. (Edin.), F.R.C.S. (Eng.), Royal Infirmary of Edinburgh. 9¾ × 6½ in. Pp. 998, with 1155 illustrations. 1972. Bristol: John Wright & Sons Ltd. £12 50.

There can be no doubt about the continued popularity of this book, which is specifically designed to help the less experienced surgeon—a category that we all fit into for a time. Since the first edition which appeared in 1930–1 there have been vast changes in surgical practice and in the prevalence of different emergencies; therefore the present edition, like its predecessors, contains important new material. However, the charm of the book does not lie in the fact that it has been brought up to date but in the retention of Hamilton Bailey's style of teaching which by a combination of vivid English and liberal illustrations confers on the reader not only facts but a judgement which reflects the combined experience of the contributors. The language may seem archaic at times, for example, 'Unless Nature is overcoming the obstruction as announced by . . .', but it impresses itself on the mind. The illustrations, sometimes realistic, sometimes diagrammatic, and often a combination of photograph and diagram, are all memorable. 'Strangulated gangrenous small bowel' is not just a phenomenon, it is 'a warning to those who procrastinate'.

The book comprises sections on the treatment of shock, electrolyte imbalance, infection, respiratory failure, cardiac arrest, and injuries to major vessels, nerves, and tendons. This is followed by sections dealing with emergencies on a regional basis: head, neck and spine, ear, nose, and throat, thorax, abdomen, genito-urinary tract, and extremities. There is a final section on emergency conditions peculiar to the tropics. The present edition contains excellent new sections by Professor H. A. F. Dudley on the resuscitation, assessment, and treatment of the severely injured which reflect experience in the Vietnam War. Sections on burns and cardiorespiratory emergencies have been completely rewritten and many other areas have been brought up to date. It may be doubted whether any book is truly indispensable, but certainly those who have to get up at night and operate will do well to be familiar with this book.

The Scientific Fundamentals of Surgery. By J. Gwynne Brockis, Ch.M., F.R.C.S., F.R.A.C.S., University of Western Australia. 8¼ × 5½ in. Pp. 719 + x. Illustrated. 1972. London: The Butterworth Group. £10.

This is a remarkable book in that it contains a tremendous mass of information collected together by one man. With the vast expansion of physiology and biochemistry this is a great achievement. Some of the chapters, such as those on the biology of ageing and on pain, are fascinating essays which are a pleasure to read. Other chapters are composed of masses of data grouped together in a rather uncoordinated fashion. The single authorship has the advantage over multiple-author volumes in that there is no repetition, but it does suffer in this case from some serious omissions. The most noticeable of these concern the spleen and lymphatic system, and there is little about cardiac function and its control—matters which are so important to the surgeon.

In the preface the author states that the book is designed to help surgeons to apply the basic sciences to their surgical thinking; at the same time it sets out to provide extensive bibliographies and reference lists to help those working in surgical laboratories; the needs of doctors taking a training in surgery and facing examinations have also been kept in mind. In these respects the book hardly achieves its aims, for in the subjects which are adequately dealt with it tends to be too detailed for the surgeon in training, while the research worker will still have to refer to the original papers. In spite of these comments the information provided is up to date and there is much in the book which will be of immense value to surgeons who wish to keep in touch with progress in the basic research on which their clinical practice depends, and for this the book is to be recommended.

Scar Tissue—Its Use and Abuse. By J. J. Longacre, M.D., Ph.D., Ohio. 10 × 7 in. Pp. 170 + xv. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $18.50.

This is an important book. It deals with a problem which confronts every surgeon and causes anxiety and disappointment to the surgeon and patient alike, and comes from the pen of an experienced surgeon, who has tenaciously studied the problem of scar tissue for more than 30 years and has involved his colleagues in the laboratory to assist him in interpreting his clinical observations. Histological and chemical research has supported Longacre's clinical concepts; they are novel, and in this book he sets them down and backs them with a wealth of photographic records which are most convincing and cover a follow-up period of more than 20 years.

The role of collagen in wound healing and scar formation is the thesis of the book. The orientation of collagen in the normal dermis is described; it is principally along the crease lines of the skin and secondarily perpendicular to the crease lines. The crease lines are at right-angles to the direction of pull of the main muscle mass exerting tension on the skin. The mechanism of production of collagen from the fibroblast is discussed, including its chemical composition and the factors necessary for its production. The writer then turns to the effect of wounds and wound healing on the production of collagen, concluding that in hypertrophic scars there is excessive production in lines of tension and in the direction of stresses produced by muscle movement as, for example, across a joint. He makes the point that even after a prolonged period of postoperative immobilization these stresses will promote excess collagen formation, leading to hypertrophic scars and contracture as soon as movement commences, and that the greater the effort made the more the scar hypertrophies.

In contrast to the linear arrangement of collagen along the lines of tension in hypertrophic scars, the author asserts that in keloids there is lack of orientation of collagen and overflow of it into the surrounding tissues. He regards this as 'consistent with the disorganization characteristic of that twilight zone approaching neoplasia'.

The surgical application of these findings is to change the lines of stress in a hypertrophic scar by multiple Z-plasties and to apply skin-grafts and skin-flaps whenever possible, with their crease lines corresponding to the crease lines at the recipient site. He recommends that the Z-plasties should be contained within the hypertrophic scar itself; if normal skin is included new tensions set up in it may provoke hypertrophy in just these parts of the operation field. He maintains that hypertrophic scars even 3–4 cm. thick can be transposed safely providing dissection is carried down to the fascia and the vascular supply to the subcutaneous fat is uninjured.

The rapid and permanent improvement in the scar which he notes after this procedure is analysed by the collagen chemist, Professor Helen Berry. She succeeds, in describing her biochemical studies, in making this highly complicated subject relatively easy for the uninitiated. She stresses the normally concurrent processes of collagen synthesis and degradation in healing wounds and the failure of the remodelling process in hypertrophic scars. Most important, she notes the greatly increased urinary excretion of the collagen-degradation products—hydroxyproline and hydroxylysine—after multiple Z-plasties confined within the hypertrophic scar.

The value of directional placement of skin-grafts is equally convincing, as judged by the illustrations. It is a pity that the work has not so far included a study of the possible influence on the cosmetic result of the tension at which grafts are sewn into place to resurface defects. Such a study would seem a natural continuation of the present work.

The book also includes a full chapter on the biophysics and pathology of radiation. One concludes, although the author says so only by implication, that he regards irradiation as useless and potentially harmful in scars, and that its use should be restricted to the treatment of malignancy.

The temptation to excise and suture a hypertrophic scar will always remain, and occasional successes from this simple procedure will continue to encourage, and maybe rightly so, but the weight of evidence which the author has brought to support his new concept of treatment is indisputable and surgeons will do well to heed the advice given in dealing with these difficult problems. Longacre has shown that it works.

Peptide Transport in Bacteria and Mammalian Gut. A Ciba Foundation Symposium. 9 × 6½ in. Pp. 161 + vii. Illustrated. 1972. Amsterdam: Elsevier Excerpta Medica. £2·40.

THIS volume contains the papers read at a Ciba Foundation Symposium held in 1971 (not 1972 as stated in the book), together with verbatim records of the discussion. The central theme was the relatively recent recognition that peptides do not all have to be broken into their amino-acid components before they can be absorbed. The phenomenon of peptide absorption has been observed in bacteria and in mammals. Several of the reports are concerned with the mechanisms by which such direct absorption can occur and with the controversy as to just where—in or on the cell—the subsequent breakdown to amino-acids takes place. One chapter draws from studies of genetic errors of metabolism, such as Hartnup disease, to illustrate the relevance to disease, but the rest are concerned with biochemical and physiological studies.

Physiologie des Kreislaufs, Volume 1. By E. BAUEREISEN, Wurzburg. 9¾ × 6½ in. Pp. 505 + xiv. Illustrated. 1971. Berlin: Springer-Verlag. DM.148.

ONE is aware of a gap existing between clinical medical science and the theoretical basic sciences such as pathology and physiology. In this book, which is volume 1 of a series dealing with the circulation, one is astonished by the exactness with which the velocity of the blood-stream, the resistance in the vessels, and the elasticity modules of the vessel walls can now be measured.

Old laws such as the famous law of Poiseuil are still important but electromagnetic measurements and clearances of radioactive substances must complete the investigations in the physiology laboratory. For the clinician the effect of the autonomous nervous system and pharmacological substances such as vasoconstricting and vasodilatating drugs deserves careful attention; one may gain the impression that many of the drugs produced by industry are not as valuable as the manufacturers suggest. Needless to say, every vascular clinic needs a modern physiologist and a mathematician as advisers.

This book belongs among the best on modern medicine.

The Principles of Transurethral Resection and Haemostasis. By J. P. MITCHELL, T.D., M.S., F.R.C.S., F.R.C.S.E., Bristol. 9¼ × 6⅜ in. Pp. 276, with 124 illustrations. 1972. Bristol: John Wright & Sons Ltd. £6.

THERE can be no doubt that with modern methods of illumination and diathermy equipment the loop resectoscope represents the most versatile instrument in dealing with many varieties of bladder-outflow obstruction and selected bladder tumours. The technique of perurethral resection, however, is sophisticated and any description which aids in its accomplishment is to be welcomed. Hitherto, the British literature has remained sparse in this respect, but during the past year two useful additions have been made. These may essentially be regarded as complementary, and the emphasis laid in the present account on the need for scrupulous haemostasis stems from the author's profound knowledge of the principles of surgical diathermy and his personal modification of the instrument. These attributes are modestly proclaimed and a wealth of useful practical and clinical information is included which greatly enhances the value of the book to the urological trainee. There is also a great deal of practical common sense which may help even the established urologist in the selection of suitable cases and, despite its price, the volume should find a place in the library of every urological department.

Core Textbook of Surgery. Edited by RICHARD H. EGDAHL, M.D., Boston, J. A. MANNICK, M.D., Boston, and LESTER F. WILLIAMS, jun., M.D., Boston. 9¾ × 7 in. Pp. 484 + xii. 1972. New York. Grune & Stratton Inc. Hardback, $13.50; paperback, $8.75.

THIS textbook of surgery has been written by 25 members of the staff of the Boston University School of Medicine. and is for medical students, surgical house-officers, nurses, and 'other allied health personnel'. The aim was to produce a book that contained the essential facts of surgery without the technical operative details that are unnecessary for the undergraduate. It is intended to be used in conjunction with standard reference textbooks and not to supplant them. The editors have integrated the work of the contributors in an exemplary fashion.

There are two parts: 'general' and 'organ systems' (though it is not clear why urology, orthopaedics, and paediatric surgery are included under 'general'). The general section has excellent chapters on pre- and post-operative care, in which principles are discussed and also very practical details are included which house-officers will find useful. There is a good chapter on anaesthesia, which reflects the increasing importance of clinical measurement. The chapter on advanced cancer is clearly set out, and staging, treatment, and care, including the care of the dying patient, are discussed. The chapter on immunology is lucid and relevant.

The organ systems section covers a wide field, including cardiothoracic, vascular, and gynaecological surgery and the subjects are presented clearly and briefly. As might be expected from Dr. Egdahl, the chapter on surgical endocrinology is particularly good, although the pituitary gland is not included.

One pleasing feature is the annotated bibliography of key papers (some of them British) that follows each chapter. There are no diagrams or photographs. The index is adequate.

The soft-cover edition (at $8.75) will be a very useful part of the student's library throughout his surgical course, but the book is too long and detailed for nurses and 'other allied health personnel'.

Embryology for Surgeons. By STEPHEN WOOD GRAY, A.B., M.A., Ph.D., Atlanta, and JOHN ELIAS SKANDALAKIS, M.D., M.S., Ph.D., F.A.C.S., Atlanta. 10 × 7¼ in. Pp. 918+xv. Illustrated. 1972. London: W. B. Saunders Co. Ltd. £15·30.

DEVELOPMENT from the fertilized egg to the newborn baby with its millions of cells and complex tissues and organs is such a remarkable feat of biological programming that it is hardly surprising that so many potential individuals fail to get born. In their excellent introductory chapter the authors demonstrate the striking probability that only some 30 per cent of fertilized human eggs will develop into normal babies; of the remainder, about 69 per cent fail to implant in the uterus or become absorbed or otherwise lost at some stage in pregnancy. This may well be of some comfort to the ecologist and, indeed, one school of thought has suggested that such embryonic mortality is not so much sheer waste as a biologically determined method of population control. The authors, however, are mainly concerned with the small number, perhaps 1 per cent of all fertilized eggs, which gives rise to babies with recognizable congenital defects presenting surgical problems.

The remainder of the book is devoted to a systematic account of congenital anomalies of the various organ systems as they are seen in the foetus or after birth. The incidence, diagnosis, and treatment of the various conditions are described, as well as their morphology and embryogenesis; the inclusion of scholarly historical notes is most welcome. Each section begins with a clear and well-illustrated account of normal development and contains a good bibliography.

The embryologist may regret that this book does not deal with the interesting and relatively common defects of the face and palate, or with abnormalities of the limbs and the organs of special sense; presumably these topics are regarded as falling within the province of the specialist rather than the general surgeon. Within its terms of reference, however, the book is a mine of information on congenital conditions. It should be of great value to surgeons; its lucid style and systematic method of arrangement make it particularly suitable as a work of reference. It will also be much appreciated by those who teach human embryology, and who wish, very properly, to enliven anatomical detail by clinical illustration.

Operative Surgery. Principles and Techniques. Edited by PAUL F. NORA, M.D., Ph.D., Chicago. 11 × 8½ in. Pp. 1106+xvii. Illustrated. 1972. London: Henry Kimpton. £26 10.

THE editor of this book and his 72 eminent contributors have produced a comprehensive one-volume operative surgery textbook. The only contributor not working in the United States is Richard S. Handley, who gives a characteristically lucid account of modified radical mastectomy. The book, though bulky, is very readable, and is clearly set out in two parts, with some references at the end of each chapter. The four largest sections—alimentary and para-alimentary, thoracic, and vascular surgery with principles and fluid dynamics—form two-thirds of the volume. Urology is allotted one-tenth, and there are chapters on the extremities, head and neck, paediatric surgery, and the breast, with small sections on abdominal hysterectomy and burns.

There is perhaps more detailed discussion and description in the text than in some popular British books on operative surgery. The line drawings of the operative techniques are excellent.

This book should find a place in every hospital library, and will be of great value to the isolated surgeon. It is a convenient detailed reference book to operative surgery, and reflects current practice in the United States.

Mammakarzinom Diagnose und Differentialdiagnose. By HANS-KLAUS ZINSER, Koln-Lindenthal. 9 × 6 in. Pp. 134+xviii. Illustrated. 1972. Stuttgart: Georg Thieme Verlag. DM.29.70.

WHILE the frequency of breast carcinoma is not declining a booklet containing a more or less complete inventory of diagnostic resources must be welcomed by everyone who is interested in the subject. Hints are given to the patients on how to detect tumours themselves. Mammography and galactography are valuable diagnostic assets and thermography of the breast might prove to be as important but biopsy is indispensable in most cases.

The size of the tumour is much more important for the prognosis than the localization; the idea that a carcinoma in the medial quadrants of the breast is more unfavourable is outdated. Laboratory chemical tests include enzyme determinations for metastases of the liver, while the sex chromatin in the carcinomatous cells might be of special interest. The differential diagnosis receives adequate attention. One may cherish the hope that this book will contribute to better achievements in the still disappointing results in treatment of breast cancer.

Homoiostase. Wiederherstellung und Aufrechterhaltung. Edited by Professor Dr. R. FREY, Mainz, Dr. F. KERN, St. Gallen, and Professor Dr. O. MAYRHOFER, Wien. 9 × 6 in. Pp. 192+ix. Illustrated. 1972. Berlin: Springer-Verlag. DM.68.

THIS small monograph, No. 60 in the series 'Anaesthesiology and Resuscitation', records the proceedings of a symposium held in October, 1970, at Mainz. It is brightly called 'Maintenance of Homoeostasis', but in fact deals with what von Bauer has named 'thanatogenesis'. By this is meant the complex alterations in homoeostasis caused more by the complications than by the primary disease itself, and having an obstinate tendency to run their own independent but lethal course. The three systems mainly concerned are the circulation, respiration, and acid–base balance, and each is separately analysed and discussed. There is a considerable number of contributions, each covering a few pages. This implies that the subject-matter is given in a very condensed form, while taking a considerable basic knowledge on the part of the reader for granted. Those carrying Wright's *Applied Physiology* in their intellectual baggage will not have too much trouble in following the discourse. They will be helped by the illustrations, consisting exclusively of diagrams, which are very clear and most informative. The book seems best suited for those beginning work in an intensive-care unit. It may serve as a frame around which the required amount of theoretical knowledge can be conveniently built up, and this will be aided by the selected references at the end of each paper.

Post-prostatectomy EPSIKAPRON® is better than post-prostatectomy bleeding*

*This observation has a high degree of clinical significance.

Post-prostatectomy blood loss may be a litre or more[1,2]. Use of EPSIKAPRON can reduce this loss by 80-90%[3,4]. "The control of blood loss has proved to be not only statistically but also clinically significant"[2]. Blood transfusion, which is costly and not without risk, ". . . can be avoided and draining catheters kept patent without difficulty and removed earlier, which makes the post-operative course smoother and shorter"[3].

INJURY

Volume 4/Number 3

The British Journal of Accident Surgery

INJURY provides a focal point of information for all those engaged in the many fields of medicine which accident surgery involves—casualty officers, surgeons concerned with all parts and systems of the body, specialists in orthopaedic and plastic surgery, anaesthetists, nursing staff in accident units, etc. Original articles take up a large section of the journal, and contributions from all over the world are published. Book reviews, abstracts from other publications, and summaries and reports of meetings add to the wide and well-organized coverage which INJURY offers its readers.

Contents

W. H. Rutherford	189	Experience in Accident and Emergency Department, with Royal Victoria Hospital patients from civil disturbances in Belfast 1969–1972, with a review of disasters in the United Kingdom 1951–1971

SCIENTIFIC BASIS OF SURGERY

Edited by W. T. IRVINE

1972 *Second Edition* *680 pages* *173 illustrations*
£9·50

'This is a book for those seeking up-to-date authoritative information on the scientific problems underlying day-to-day surgical practice. It will prove of immense value to postgraduate students, to men about to undertake research projects, and to many practising surgeons, particularly those with teaching responsibilities. Professor Irvine and his collaborators are to be congratulated on this outstanding volume.'—*Lancet*

FUNDAMENTAL TECHNIQUES OF PLASTIC SURGERY AND THEIR SURGICAL APPLICATIONS

IAN A. McGREGOR

1972 *Fifth Edition* *312 pages* *180 illustrations*
£4·00

'Mr. McGregor is to be congratulated upon his breadth of outlook and his industry in producing this edition. We recommend it to all surgeons who have occasion to treat injuries or deformities resulting from ablative surgery. It can hardly be possible to obtain a more concise and reasonably comprehensive introduction to plastic surgery.'—
British Journal of Plastic Surgery

'The author has set out to instruct the surgeon who finds himself faced with problems usually dealt with in a plastic unit. In this he has succeeded, and he has, besides, provided a very useful introductory manual for the trainee in plastic surgery. The style is lucid and direct and the illustrations are plentiful and informative.'—*British Medical Journal*

AN AID TO CLINICAL SURGERY

PETER R. SCOTT

1971 *336 pages* *60 illustrations* **£4·00**

It provides a brief but authoritative statement of the clinical features and the principles of treatment of the more common surgical conditions. Though often didactic, it sets out an easily digested presentation of the fundamental clinical facts. Much of the subject matter is considered in relation to specific symptoms such as haematemesis or post-operative vomiting. Consideration of the specialities of orthopaedics, urology and otorhinolaryngology is limited to matters of general concern.
'This book is highly recommended to those who wish to gain insight into the surgical approach.'—*Zodiac*

Anorectal Surgery

E. S. R. Hughes and A. M. Cuthbertson
Staff surgeons at the Royal Melbourne Hospital
January 1973: 241 × 178mm: 332pp: half-tone and line illus: 85878 008 9: **£4.50**

The purpose of this book is to set out current practice in the field of anorectal surgery. Special emphasis has been placed on common conditions and the authors' own approach to these has been described.

Contents: Surgical Anatomy of the Anal Canal and Rectum; Rectal Continence and Defaecation; The Symptoms of Anorectal Disease; Investigation of Anorectal Disease; Surgical Wounds of the Anal Region; Anaesthesia for Anorectal Surgery; Anorectal Suppuration (Abscess); Anorectal Suppuration (Anal Fistula); Sinuses Related to the Anus; Anal Fissure; Haemorrhoids; Prolapse of the Rectum; Pruritus Ani; Anorectal Pain of Uncertain Origin; Proctitis (Non-Specific); Benign Ulcers of the Rectum; Irradiation Damage of the Bowel; Benign Tumours of the Rectum; Carcinoma of the Rectum; Squamous Cell Carcinoma of the Anus and Anal Canal; Index.

UBRETID®
distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of **UBRETID** ampoules and tablets are available upon request.

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·83	£3·70	£4·27	£5·70	£5·69	£6·32	£7·74	£8·99

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 59. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St Martin's House,* 159 *Clapham High Street, London, SW4 7SU* (telephone 01-622 9225).

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

SURGERY OF REPAIR AS APPLIED TO HAND INJURIES

B. K. RANK, CMG, A. R. WAKEFIELD, and
J. T. HUESTON

1973 *Fourth Edition 408 pages 310 illustrations*
£4·00

Some Reviews of previous Editions

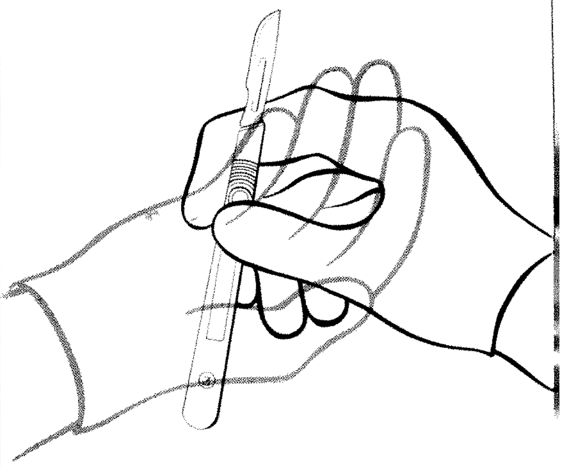
'When does a textbook become a "classic"? If we are to apply the term to describe the merits of a work as judged by its influence upon surgeons, there can be no doubt that this comparatively young Australian work has already proved itself a classic of contemporary surgical literature. The volume covers the entire field of hand injury, starting with a notable chapter on the social significance of hand injuries and working steadily through to cover every variety of injury, the treatment of both early and late cases as well as prognosis and final resettlement of seriously injured patients. It is essential reading for anyone dealing with any aspect of hand injuries. It is not possible to exaggerate the worth of this splendid book. The text, photography and diagrams could hardly be bettered.'—*Medical World*

'This is without doubt the most outstanding thesis on the surgery of acute hand injury. In addition it is a very considerable contribution to the principles of the surgery of repair outside the hand.'—*British Medical Journal*

'It has had a great impact on surgeons, general, plastic and orthopaedic, all over the English-speaking world. To it must certainly go some of the credit for the improved standard of care and the improved results seen today in the treatment of injuries of the hand.'—*Practitioner*

CHURCHILL LIVINGSTONE

23 Ravelston Terrace, Edinburgh, EH4 3TL



Another surgeon is about to use one of the world's finest surgical blades....
...this happens thousands of times every day!

It happens because the blades are by Swann-Morton, the people who meet the highest requirements in surgical knives.
We need say very little about our superiority. The world's surgeons have proved it for us!

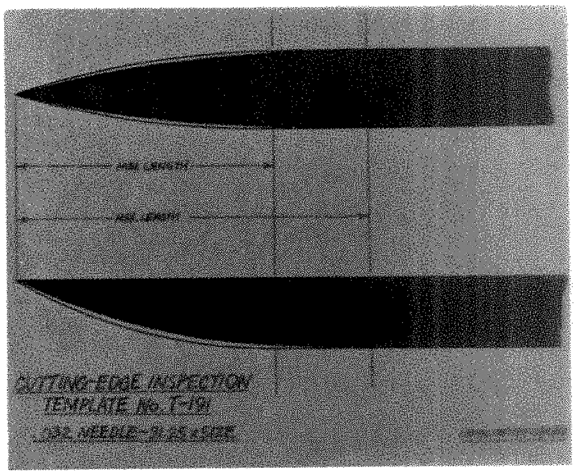
Donald Bremner sets his sights on surgical accuracy

In the early stages of making an ETHICON needle, a short length of steel wire is subjected to some thirteen different processes on a 20-foot journey past various cutting, forming, grinding and sharpening stations. Donald Bremner is using a special, very accurate, theodolite to align these processes with each other and with the needle.



Accurate setting means an accurate product – a needle tested by shadowgraph magnification to within 0·04mm (and that's the tolerance on a large, abdominal needle).

This is only the beginning. Throughout the Sighthill plant of ETHICON perfectionists like Donald Bremner are dedicated to giving the surgeon *precisely* what he wants.

ETHICON

ETHICON LIMITED, SCOTLAND

Tissue approximation needs ETHICON precision

Tolerances for ETHICON sutures range from 0·0002" (for gauge conformity in natural catgut) to 0·0001" (for 6 mm micro-surgical needles). For every ETHICON suture is shaped by the needs of the surgeon. It is our concern to meet these needs with precision.

ETHICON

Surgical Gut

Dependable strength and absorption properties. Chromic and plain gut presented for every field of surgery.

ETHICON

MERSILK*

BRAIDED SILK

Silk made to exacting surgical specifications. In many sterile presentations, including 80 MERSUTURES* Eyeless Needled Sutures.

ETHICON

Surgical Linen Suture

Specially prepared for maximum strength and knot security.

ETHICON

PROLENE*

MONOFILAMENT POLYPROPYLENE

The most inert suture known with knotting properties superior to those of any other monofilament.

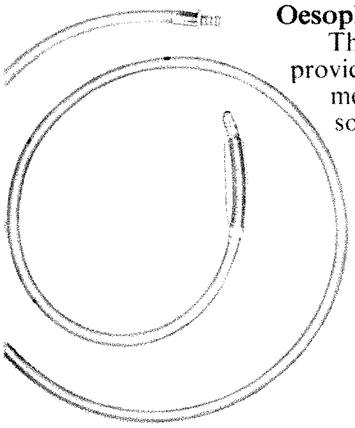
Add your experience to
ours and you have the
beginning of a successf
operation.

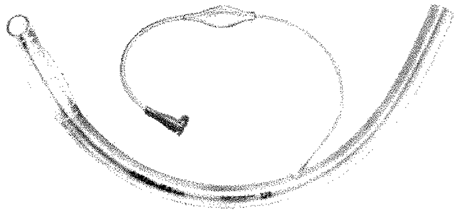
Our 30 years experience have been dicated to the advancement of surgical d medical practice throughout the rld. And although our contribution ay be small, we take great pains to ake it important.

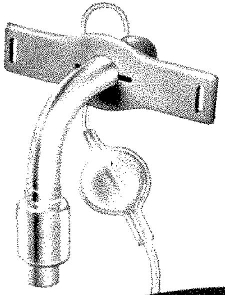
We maintain the highest andards of quality. Which is why our products need no modification to meet the regulations of the most demanding public health bodies.

But we are never satisfied with past and present achievements. Our continuing programme of research seeks to develop new products. The products you'll want tomorrow.



Oesophageal Stethoscope
This is a new product which provides a simple, yet highly efficient method of monitoring heart sounds. It is particularly useful during paediatric and neurosurgical procedures. Available in three sizes, all double wrapped and sterile.





Cuffed Blue Line Endotracheal Tube Designed with a new thin wall to give up to ½ mm larger lumen than before and with even better slip properties. The cuff is inflated symmetrically via the airline which is incorporated into the wall without reduction of lumen.

ue Line Tracheostomy Tube
The new Portex tracheostomy tube s an extra smooth non-irritant finish. signed to allow easier suction heterisation. The strong inert floppy f allows lower inflation pressures. ch tube is supplied with a one way ve and its own spool of neck tapes.

IN BRONCHITIS early optimism confirmed by further clinical experience

“On the basis of our earlier experience,[1] we said of trimethoprim that ‘we believe it to represent a major discovery and to have far-reaching therapeutic possibilities.’ Not only have we had no subsequent reason to alter this belief, but in our view some very promising possibilities have yet to be explored.”[2]

More effective than ampicillin or tetracycline

In the reduction obtained in sputum volume and purulence SEPTRIN* has been shown to be superior to either ampicillin or tetracycline.[3,4]

Highly active against both primary and secondary invaders

“. . . not only are the two primary pathogens *Strep pneumoniae* and *H influenzae* sensitive, but so are secondary invaders such as klebsiella which often replace them after antibiotic treatment.”[2]

“It is seldom at the completion of a clinical trial that authors are inclined to classify an antimicrobial . . . , but in this case, on our results, we feel that the combination of trimethoprim plus sulphamethoxazole can only be considered excellent on the criteria originally specified, namely the elimination of the infecting microorganism.”[5]

THE EFFECTS OF EARLY EXPERIMENTAL CRYPTORCHIDISM AND SUBSEQUENT ORCHIDOPEXY ON THE MATURATION OF THE GUINEA-PIG TESTICLE

BY P. M. ATKINSON
ST. MARY'S HOSPITAL, LONDON

SUMMARY

A histological study of experimental cryptorchidism in the immature guinea-pig and the results of subsequent orchidopexy are described.

Arrest of development of a testis was produced by delaying its descent into the scrotum. Subsequent orchidopexy at ages up to and beyond puberty allowed development to continue to active spermatogenesis.

The poor results following orchidopexy for natural cryptorchidism in man are discussed in relation to this experimental work and the existence of a primary testicular abnormality is suggested. The superficial inguinal pouch ectopic testicle and the retractile testicle are also discussed.

THE naturally occurring cryptorchid testicle of man has been the subject of extensive histological study (Robinson and Engle, 1954; Sohval, 1954). Its progress following surgical treatment has been studied to a lesser extent. The underlying cause of cryptorchidism and the reason for the poor fertility results following its surgical correction remain essentially unknown. It is still unclear whether a testicle is undescended because it is abnormal or is abnormal because it is undescended.

The situation might be clarified by comparing the results following surgical treatment of experimental cryptorchidism in animals with those found after orchidopexy for natural cryptorchidism in man. It may be suspected that the cause of naturally occurring cryptorchidism is due to a primary abnormality of the testicle itself. If this is true the abnormal testicle would behave differently from the experimental testicle which is initially normal. A discrepancy in their behaviour might be anticipated following reversion to a normal scrotal environment. However, if there is a primary environmental cause preventing natural testicular descent then both experimental cryptorchid and natural cryptorchid testicles should behave similarly when subsequently placed within a normal scrotal environment. The experimental work reported here is presented to test this hypothesis.

FIG. 1.—Age at which operative procedures were performed.

Previous studies have shown the effect of artificial cryptorchidism and subsequent orchidopexy in the experimental animal (Moore, 1924; Wangensteen, 1927; Nelson, 1951; Shirai, Matsushita, Kagayama, Ichijo, and Takeuchi, 1966). In those series, however, the animals were mature and the testicles had already reached a scrotal position prior to their replacement within the peritoneal cavity. In this study young animals were used in order to mimic the natural cryptorchid state as closely as possible. Normal young male guinea-pigs were used. Their testicles were found to lie within the inguinal canals at the age of 7 days and had not therefore experienced a scrotal environment by the time of their experimental replacement into the peritoneal cavity. Subsequent orchidopexy of the experimentally cryptorchid testicles was then performed at different ages from 20 days until after puberty (*Fig.* 1).

MATERIALS AND METHODS

Two groups of normal male Hartley-strain guinea-pigs were used. At the age of 7 days one group was made either unilaterally or bilaterally cryptorchid and the other group acted as controls for the first group. All the animals were returned to their mothers or foster mothers after operation and were not weaned until 30 days of age (Valenstein, Riss, and Young, 1955). General anaesthesia with intraperitoneal Nembutal was used for each operative procedure throughout the project.

Intraperitoneal Replacement of the Testicle.—When the guinea-pigs were 7 days old either one or both testicles were mobilized through a lower abdominal incision. The testicle was found to lie within a peritoneal sac and had not yet completed its descent to the scrotum. After biopsy the testicle was placed within the peritoneal cavity and a silk suture closed the inguinal ring to minimize the possibility of later testicular prolapse.

The control animals also had a lower abdominal incision and mobilization of one or both testicles. The testicle was placed in the scrotum after a biopsy had been taken. A loose silk suture was placed at the inguinal ring to prevent prolapse of the abdominal contents.

Orchidopexy.—Either unilateral or bilateral orchidopexy was performed at 20, 40, 60, 80, or 100 days. The peritoneal cavity was opened through a midline abdominal incision. The retained testicle was drawn from the peritoneal cavity, through the inguinal ring, into the scrotum by forceps inserted through a separate scrotal incision. A biopsy was taken and if there was a tendency for the retained testicle to prolapse from its intraperitoneal position it was noted at this stage. The control group of animals underwent a similar operation, with mobilization and biopsy of their already scrotal testicles.

Contralateral Orchidectomy and Biopsy.—At the postpubertal age of 120 days the animals which had undergone bilateral orchidopexy had testicular biopsies taken through bilateral scrotal incisions. The unilateral cases had a biopsy of the surgically treated or control testicle, and orchidectomy of the contralateral scrotal testicle. The orchidectomy was performed at this stage as part of a concurrent study of plasma-testosterone levels following surgical treatment of experimental cryptorchidism.

Table I.—CRITERIA BY WHICH THE SPERMATOGENIC INDEX WAS ASSESSED

SPERMATOGENIC INDEX	HISTOLOGICAL FINDINGS
1	No evidence of active spermatogenesis. Presence or absence of spermatogonia
2	Presence of primary spermatocytes
3	Presence of primary and secondary, or secondary spermatocytes
4	Evidence of spermatid production. Immature spermatids
5	Complete spermatogenesis with mature spermatids or spermatozoa

Table II.—NUMBER OF TESTICLES USED FOR THE ORCHIDOPEXY AND CONTROL PROCEDURES

	AGE AT OPERATION (d.)					
	20	40	60	80	100	Total
Number of orchidopexy testicles analysed	6	7 (1)	6	7 (1)	6	32 (2)
Number of control testicles analysed	6	7	4	7	5	29

Numbers in brackets relate to testicles which were discarded from further study because of premature prolapse from their intraperitoneal position.

Sacrifice at 180 Days.—All the animals were sacrificed in young adult life under anaesthesia by cardiac puncture exsanguination. The testicles were removed for histological analysis.

Histology and Measurements.—Testicular biopsy specimens were fixed in Bouin's fluid and stored in 70 per cent ethanol. Sections were cut at 5 μ thickness and stained with haematoxylin and eosin. The biopsies which had been taken at four stages in the animal's life were studied from two histological aspects.

Tubule Count.—A count was performed of the number of seminiferous tubules seen in one high-power microscope field of 0·52-mm. diameter. A part of each section was selected where as many of the tubules as possible were cut transversely. Tubules at the periphery of the field were counted only if more than half of a tubular cross-section was included within that microscope field.

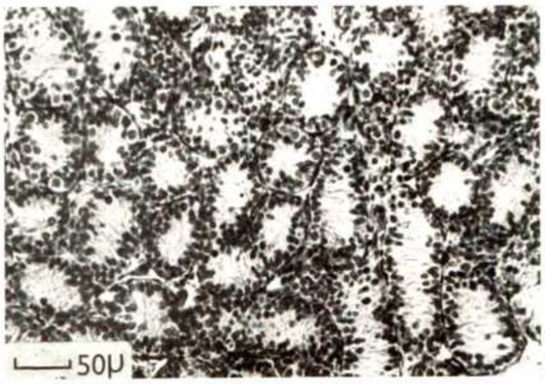

FIG. 2.—Guinea-pig testicular biopsy at 7 days of age, showing immature seminiferous tubules.

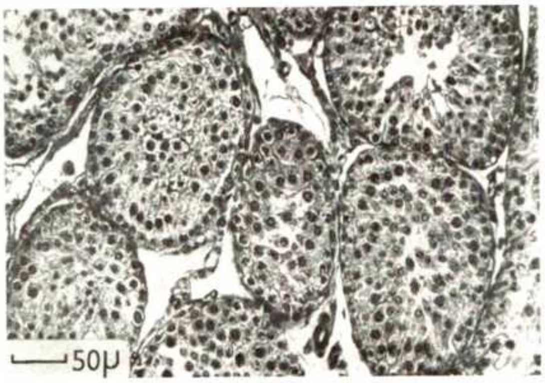

FIG. 4.—Biopsy of a control testicle at 60 days of age, showing spermatogenesis developing with enlargement of the tubules.

Spermatogenic Index—In order to assess the degree of spermatogenesis reached by the testicular biopsies the histological appearances were classified into five groups. The groups were numbered from 1 to 5 and the number was called the 'spermatogenic index'. The individual groups indicate the broad stages of spermatogenesis and are explained in *Table I*. In some cases the spermatogenesis was patchy. It was then necessary to judge which was the prominent stage of development and assign the appropriate index.

RESULTS

The number of testicles which were studied after unilateral, bilateral, and control procedures is shown in *Table II*. The testicles of animals which had undergone unilateral orchidopexy and of those which had had bilateral orchidopexy gave comparable results and have been grouped together for this study. The mean results of the two aspects of testicular histology are shown in *Table III*.

Tubule Counts.—The highest tubule counts were seen at the age of 7 days when all the animals had tightly packed immature tubules (*Fig.* 2). The average tubule number per high-power field (h.p.f.) for all the animals at this age was 41·5.

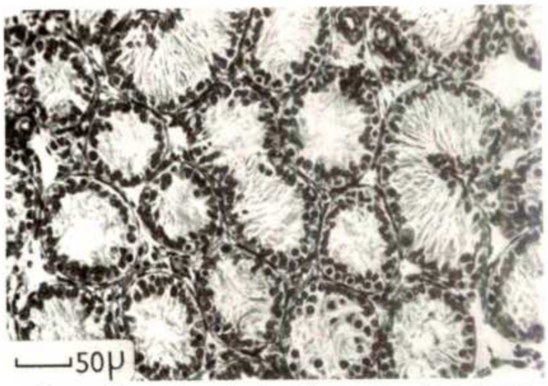

FIG. 3.—Biopsy of a retained testicle at 60 days of age, showing no evidence of active spermatogenesis but some tubule enlargement.

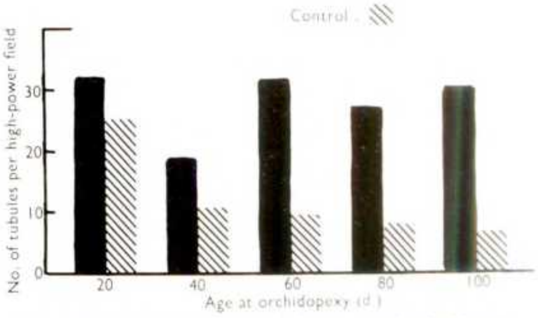

FIG. 5.—Tubule count per h.p.f. shown by testicular biopsies at the time of orchidopexy or the equivalent control operation.

Biopsies of the intraperitoneal testicles at orchidopexy showed that by 20 days of age the tubule count had fallen from 41·5 to 28 per h.p.f. There was then no further change during their intraperitoneal retention (*Fig.* 3), even when retained until 100 days of age.

The control testicles showed a gradual tubule development (*Fig.* 4) which was completed by 100 days of age (*Fig.* 5). As the tubules enlarge, the number of tubules seen in each high-power field diminishes.

At 120 days of age the tubule count of all the control testicles and those testicles which had had an orchidopexy at 20, 40, or 60 days (*Fig.* 6) was similar and low. Although the testicles which had undergone orchidopexy at 80 or 100 days also showed a decrease in tubule count at 120 days, this was much less marked than that of the control or early orchidopexy animals.

At 180 days of age all the control and orchidopexy animals had a similar low tubule count. Even the testicles which had been intra-abdominal until 80 or

100 days old had completed their tubular development by this age.

Consecutive Comparison of Tubule Counts.—Each animal had testicular biopsies at four stages in its life: in infancy, at orchidopexy, postpuberty, and at sacrifice in young adult life. Average tubule counts of surgically treated and control animals were taken for each stage. A consecutive comparison could then be made by representing the results diagrammatically (*Fig.* 7). The orchidopexy age was variable but had a mean age of 60 days. It can be seen from *Fig.* 7 that intraperitoneal replacement delays tubule development and subsequent orchidopexy allows the development to continue to normality by the time of sacrifice at 180 days.

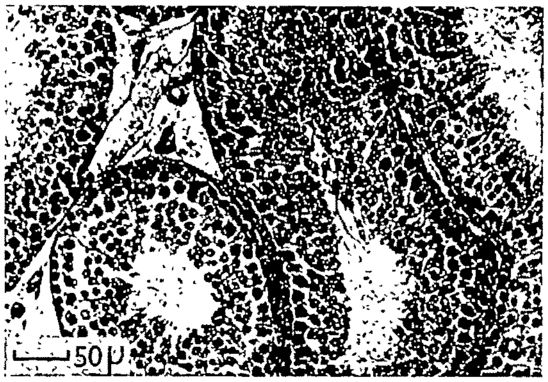

FIG. 6.—Testicular biopsy at 120 days of age, after orchidopexy at 60 days, showing complete spermatogenesis.

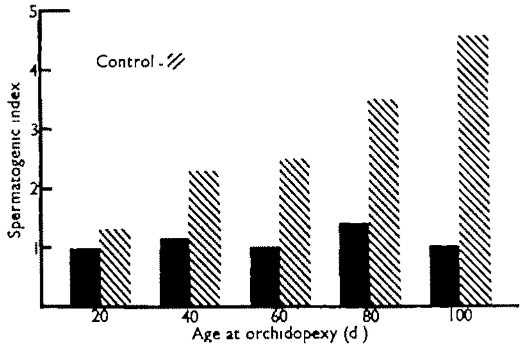

FIG. 8.—Spermatogenic index of testicular biopsies taken at the time of orchidopexy or the equivalent control operation.

Spermatogenic Index.—It was not surprising that all the testicular biopsies taken at 7 days of age showed no evidence of active spermatogenesis. They were given a spermatogenic index of 1.

At orchidopexy there was almost no evidence of active spermatogenesis in those testicles which had been replaced within the peritoneal cavity for periods of time up to 100 days of age. Two unilaterally cryptorchid animals were noticed to have prolapsed their testicles by the time of orchidopexy. Their testicular histology showed some evidence of active spermatogenesis at orchidopexy and they were therefore excluded from further study. In contrast to the cryptorchid animals the control animals demonstrated a gradual development of active spermatogenesis with increasing age (*Fig.* 8).

At 120 days of age all the control testicles and also the testicles which had had an orchidopexy at 20, 40 or 60 days showed a high spermatogenic index. The testicles which had been retained within the peritoneal cavity until 80 or 100 days of age showed some evidence of spermatogenesis but much less than that of the control animals.

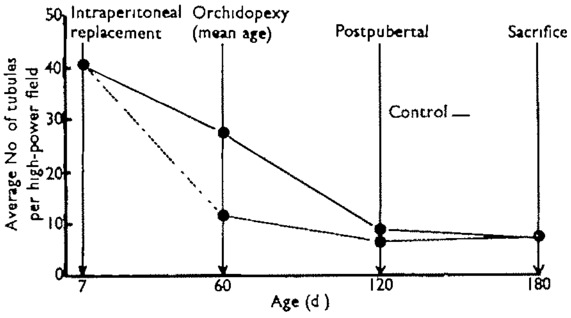

FIG. 7.—Consecutive comparison of average tubule counts per h.p.f. There is an inverse relationship between tubule number per h.p.f. and tubule diameter.

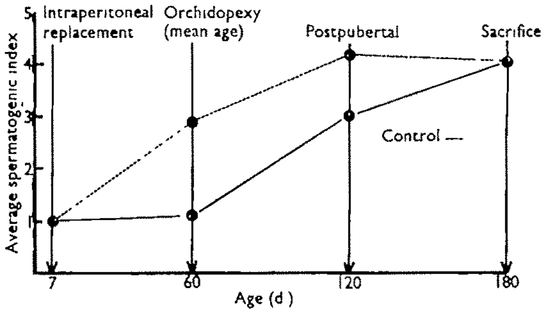

FIG 9.—Consecutive comparison of average spermatogenic index.

By the age of 180 days animals which had undergone a late orchidopexy had developed a high spermatogenic index, which was comparable to that of the control and early orchidopexy cases.

Consecutive Comparison of the Spermatogenic Index.—As shown for the tubule counts, the spermatogenic index of orchidopexy and control animals may be compared at the four stages in their lives when a testicular biopsy was taken. The results are best demonstrated in diagrammatic form (*Fig.* 9) and show that intraperitoneal retention of a testicle prevented active spermatogenesis. Subsequent orchidopexy allowed it to continue and at 180 days there was equally active spermatogenesis of both the treated cryptorchid and control testicles.

The results of the two aspects of testicular histology studied were subjected to statistical analysis. A significant difference was found in the results of both the spermatogenic index and the tubule count of the test group when compared with the control group at orchidopexy ($P < 0.005$). By the age of 180 days there was no significant difference in the results of the two groups of animals.

DISCUSSION

Normal development of the young guinea-pig testicle may be experimentally arrested by placing the animal's gonad within its peritoneal cavity. In this study the testicle was made cryptorchid before it had reached its natural scrotal position. The arrest of development persisted for as long as the intraperitoneal environment was maintained. The testicle was then able to continue normal development after orchidopexy, even if it had been retained within the peritoneal cavity beyond the age of puberty.

The two aspects of testicular histology which were used to monitor the fate of the testicle showed a close relationship. Counting the number of tubules per high-power field was found to be simpler than direct measurement of tubule diameters. The term 'spermatogenic index' has been used to express the stages of active spermatogenic development. It was necessary to compare the delay of spermatogenesis produced by the temporary retention of a testicle with that of the normally developing control testicle. A multistage index appeared more satisfactory in this particular situation than the tubular fertility index used by Mack, Scott, Ferguson-Smith, and Lennox (1961).

It may be seen from *Fig*. 9 that the spermatogenic index for both the treated cryptorchid and control animals was equal at 180 days of age. The fact that the index was less than 5 might be explained by the number of operations performed on each testicle.

John Hunter (1786) thought that the cause of cryptorchidism was an abnormality of the testicle itself. Astley Cooper (1841) and Bland-Sutton (1910) agreed with Hunter, but Curling (1843) said that the undescended testicle was normal and it was the mechanism for descent that was at fault. Wangensteen (1927) believed that the undescended testicle owed its imperfection to its abnormal position. Griffiths (1892–3) showed that experimental cryptorchidism in the dog caused arrest of spermatogenesis. Subsequent articles (Moore, 1924; Wangensteen, 1927; Nelson, 1951; Shirai and others, 1966) have shown that experimental replacement of a *mature* testicle within the peritoneal cavity is followed by recovery upon subsequent replacement into the scrotum. Nelson's experiments also suggested that prolonged retention of the mature testicle would prevent a return to normal. In contrast to previous work the present experiments have attempted to mimic more closely the natural cryptorchid state and its surgical correction. It is not *recovery* that has been studied but the ability of a cryptorchid testicle to continue normal development after it has been placed in the favourable scrotal environment for the first time.

The present work was confined to observation of the immature testicle and its development up to and just beyond puberty. Puberty is a gradual phenomenon in the guinea-pig as in other species. Accessory sex structures show a growth spurt around 35 days (Phoenix, 1970) and puberty is said to be complete at 81 days. This was shown by Webster and Young (1951) to be the mean age for the first appearance of a fertile ejaculate. Prolonged retention of the testicle into adult life was not studied. It seems possible that if short periods of retention of a normal testicle produce temporary arrest of spermatogenesis, then prolonged retention, as shown by Nelson (1951), might well cause permanent damage.

It has been shown in this study that the experimentally cryptorchid testicle, whose initial normality is accepted, achieves normal development after orchidopexy. However, it is known that the natural cryptorchid testicle of man often does not achieve normal development after surgical treatment. Kiesewetter, Schull, and Fetterman (1969) studied a series of prepubertal patients who had bilateral cryptorchid testicles operated upon individually at different prepubertal ages. They found that 70 per cent of the testicles which were operated upon first showed slight or no improvement when compared histologically with the cryptorchid partner at the second operation. Scott's (1962) review of the literature showed that following prepubertal surgical treatment one-quarter of unilateral and one-half of bilateral cryptorchid patients were not fertile. Scorer and Farrington's (1971) review of previous series of bilateral cases confirmed the poor results found by Scott (1962). It is unlikely that the poor results are due to peroperative trauma. Hecker and Hienz (1967) indicated that the risk of infertility caused by operative injury was about 1 per cent. It would therefore seem likely that the natural cryptorchid testicle of man is initially abnormal. This initial abnormality, as well as causing infertility, might also be an important aetiological factor in the failure of descent of the testicle.

A discussion of this experimental work would not be complete without mentioning both the superficial inguinal pouch ectopic testicle and the retractile testicle in relation to it. The superficial inguinal pouch ectopic testicle and the experimental testicle used in this study are comparable. Browne (1938) considered the superficial inguinal pouch ectopic testicle to be a different entity from that of the true undescended testicle. He stated that the superficial inguinal pouch ectopic testicle had been prevented from entering the scrotum by a fibrous barrier. This was caused by an abnormal attachment of the membranous layer of superficial fascia to the pubic bone. This theory was supported by Hand (1955), McNab (1955), and Jones (1958). Mack and others (1961) indicated that the proportion of seminiferous tubules containing germ cells at the time of orchidopexy was greater in ectopic testicles than in true undescended testicles. The present study has shown that arrest of development of an initially normal guinea-pig testicle will occur if it is prevented by mechanical means from descending. It has also shown that the development continues normally after surgical treatment. An ectopic testicle lying in the superficial inguinal pouch is often well developed with a cord of normal length and is not usually associated with an inguinal hernia. The true undescended testicle has remained on the natural line of testicular descent but has a short cord. It frequently has an abnormal appearance and is often associated with an indirect hernial sac. These factors would suggest that whereas the superficial inguinal pouch ectopic testicle may be quite normal initially, the true undescended testicle is probably not an initially normal testicle. So far, no comparison has been made between the subsequent fertility results of the two groups.

It is generally accepted that the retractile testicle will achieve a stable scrotal position at puberty without treatment. However, it has been suggested that although scrotal the previously retractile testicle may not have normal function because of its prepubertal residence within the superficial inguinal pouch. If it is assumed that the retractile testicle is initially normal but has an overactive cremasteric muscle, then the only cause for concern is the possibility that the temporary environment of the superficial inguinal pouch will cause permanent testicular damage before scrotal entry is maintained at puberty. The present animal experiments have demonstrated that a normal testicle will continue normal development after entry into the scrotum, in spite of abdominal retention beyond puberty. It is therefore likely that the retractile testicle, which is retained within the less harsh environment of the superficial inguinal pouch, will mature normally when permanent residence within the scrotum is gained at puberty. Operation would seem unjustifiable in these cases, provided that the diagnosis of retractile testicle is certain.

THE EFFECT OF UNILATERAL EXPERIMENTAL CRYPTORCHIDISM AND SUBSEQUENT ORCHIDOPEXY UPON MATURATION OF THE CONTRALATERAL SCROTAL TESTICLE OF THE GUINEA-PIG

BY P. M. ATKINSON
ST. MARY'S HOSPITAL, LONDON

SUMMARY

A study of the contralateral scrotal testicle of the guinea-pig before and after the surgical treatment of unilateral experimental cryptorchidism is described.

The contralateral scrotal testicle of the guinea-pig has been found to mature quite normally without any evidence of incomplete development. In man, however, the contralateral scrotal testicle of unilaterally cryptorchid patients often shows incomplete development. The difference in results suggests that in man the unilateral cryptorchid state may be associated with a bilateral testicular abnormality. This bilateral abnormality might be the cause of poor fertility and, if severe, might also be the cause of failure of descent of the cryptorchid testicle.

SOME impairment of fertility is shown by two-thirds of postpubertal patients who have an untreated unilaterally cryptorchid testicle (Scott, 1962). If prepubertal surgical treatment had been performed in these unilaterally cryptorchid patients 25 per cent of them would have been infertile subsequently. The fertility of a young man who has had a unilateral orchidectomy for conditions other than cryptorchidism is normal. These figures would suggest that in man the descended partner of a unilaterally cryptorchid testicle is not entirely normal in spermatogenic function.

Raboch and Zahor (1956) and Hecker, Hienz, Daum, and Hollmann (1967) noticed that there was incomplete maturation of the contralateral scrotal testicle in unilateral cryptorchid patients when compared with the expected normal histology for a given age. However, this incomplete maturation was less pronounced than that shown by the cryptorchid testicle.

In order to investigate the subject further a study was made of the effects of experimental unilateral cryptorchidism and subsequent orchidopexy upon the contralateral scrotal testicle of guinea-pigs. This study was performed during a concurrent investigation of the histological effects of surgical treatment upon the experimentally cryptorchid testicle (Atkinson, 1973).

MATERIALS AND METHODS

Procedure.—Twenty-eight immature male Hartley-strain guinea-pigs were made experimentally unilaterally cryptorchid at the age of 7 days. Intraperitoneal Nembutal anaesthesia was used for this and subsequent procedures. Unilateral orchidopexy and biopsy were performed at 20, 40, 60, 80, or 100 days. A biopsy of the contralateral scrotal testicle was taken at the time of orchidopexy, and a biopsy was taken from both testicles at the age of 120 days (*Fig.* 1).

Table I.—AVERAGE QUANTITATIVE RESULTS OF THE TWO ASPECTS OF TESTICULAR HISTOLOGY OF THE CONTRALATERAL SCROTAL TESTICLE

TIME OF TESTICULAR BIOPSY	ORCHIDOPEXY ANIMALS		CONTROL ANIMALS	
	Tubule Counts (per High-power Field)	Spermatogenic Index	Tubule Counts (per High-power Field)	Spermatogenic Index
At intraperitoneal replacement of the opposite testicle (7 days of age)	41	1	41	1
At orchidopexy or control operation of the opposite testicle (20–100 days of age)	12·1	3·4	13·4	3·6
At postpubertal age (120 days of age)	4·9	4·9	5·1	4·7

In a similar number of animals a control procedure was used in which both the testicles remained scrotal. Testicular biopsies were taken at the age at which orchidopexy was performed in the test group of animals and at the postpubertal age of 120 days. Puberty in the guinea-pig was said to be complete by 81 days of age (Webster and Young, 1951).

Histology.—Biopsy specimens from the body of the testicle were fixed in Bouin's fluid and stored in 70 per cent ethanol. Sections were cut at 5 μ thickness and stained with haematoxylin and eosin.

The histology was studied from two aspects. First, the number of tubules per high-power microscope field of 0·52 mm. diameter was counted. Secondly, the degree of active spermatogenesis reached by the tissue was assessed by the use of the spermatogenic index. If there were spermatozoa or mature spermatids present the testicular tissue was considered to have a spermatogenic index of 5. Immature spermatids indicated an index of 4, the presence of secondary spermatocytes an index of 3, and primary spermatocytes only, an index of 2. If there were only spermatogonia present an index of 1 was afforded.

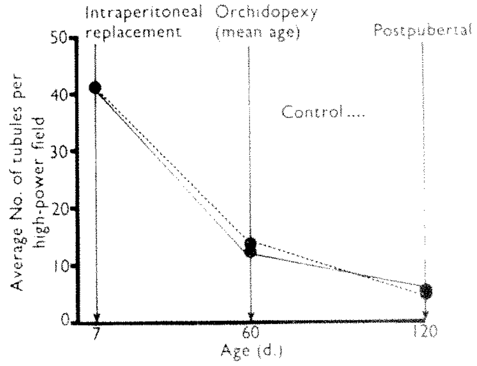

FIG. 2.—Consecutive comparison of average tubule counts per high-power field of contralateral scrotal testicles. Tubule counts per high-power field and tubule diameters have an inverse relationship.

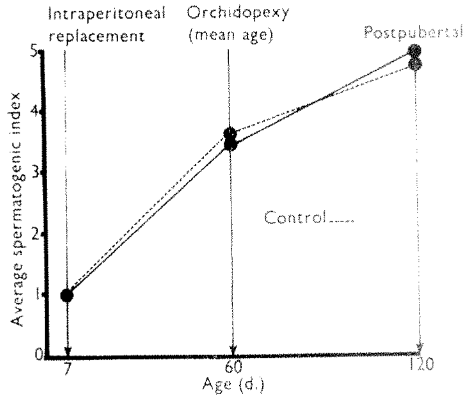

FIG. 3.—Consecutive comparison of average spermatogenic indices of contralateral scrotal testicles.

RESULTS

The study was made on the contralateral scrotal testicle of 28 guinea-pigs and a similar number of animals was used as controls. The results of studying the two aspects of testicular histology are shown in *Table I*.

Tubule Count.—The tubule count of the contralateral scrotal testicle of the animals undergoing orchidopexy and the contralateral scrotal testicle of the control animals for any given age was similar. As the tubules matured and enlarged the number of tubules seen in one high-power field clearly fell. At 120 days of age the tubule count of the contralateral scrotal testicle of both the animals which had undergone orchidopexy and the control animals was the same, and less than that seen at orchidopexy age (*Fig.* 2).

Spermatogenic Index.—At the orchidopexy age the average spermatogenic index of the contralateral testicle of both groups of animals was similar. There was no delay in development of the contralateral scrotal testicle in either group. At 120 days the average spermatogenic index of the contralateral scrotal testicle of both groups was 4·8 (*Fig.* 3).

The results of the two aspects of testicular histology studied were subjected to statistical analysis. No significant difference was found in the results of both the spermatogenic index and tubule count of the test group when compared with the control group at the age of orchidopexy and also at 120 days of age.

DISCUSSION

The contralateral scrotal testicle of unilaterally cryptorchid patients may show some evidence of incomplete maturation on histological analysis. It is not known why this abnormality should occur. There are two main possibilities to be considered. First, it may be that the testicles are both unequally affected by the same basic defect. This might explain why there is a poor fertility rate in patients with unilateral cryptorchidism who have not had the benefit of surgical treatment. It might also be postulated that if this basic defect was severe enough on one side it might prevent that testicle from responding to (or producing) the stimulus for its descent to take place. Secondly, and less likely, there is the possibility that the delayed maturity of the scrotal partner is produced in some way by hormonal influence. This might be promoted by the presence of an undescended testicle and coincidentally affect its scrotal partner.

It has been shown here that development of the contralateral scrotal testicle of the guinea-pig is not altered in any way by the presence of a cryptorchid testicle. It has also been shown that the contralateral scrotal testicle continues its development to full active spermatogenesis following surgical treatment of its cryptorchid partner. The only relevant previous experimental work is that of Shirai, Matsushita, Kagayama, Ichijo, and Takeuchi (1966). This was concerned with the observation of the contralateral scrotal testicle of experimentally cryptorchid dogs before and after surgical treatment. Their work was performed on an unstated number of mature dogs and they found that following intraperitoneal replacement of a *mature* testicle the contralateral scrotal testicle degenerated. Subsequent orchidopexy, however, allowed the contralateral scrotal testicle to resume some degree of spermatogenesis, but it was far below normal.

The reason why our results differ is not entire clear. The present work has used the immatu guinea-pig testicle which was placed within tl peritoneal cavity before it had ever experienced scrotal environment. This was done by design, as seemed to approach the situation of natural cryp orchidism more closely than did the intraperitone replacement of a mature testicle. This work h observed not the ability to recover but the ability achieve normal active spermatogenesis for the fir time. Shirai and others (1966) studied the recovery spermatogenesis after degeneration had occurred the mature testicle. They concluded that suppress spermatogenesis in the scrotal testicle of unilater cryptorchidism was induced in some way by tl degenerative changes in the cryptorchid testicle.

These guinea-pig experiments have shown that experimental situation, in which there was o cryptorchid testicle, allowed the contralateral scrot testicle to develop normally. This would suggest th the cryptorchid testicle did not induce a hormon effect to act upon the scrotal testicle.

It is suggested that this work gives support to t concept that there may be an inherent testicul abnormality in unilaterally cryptorchid patien which is often bilateral. This abnormality may be t cause of the poor results following surgical treatme in man. It is possible that if severe enough it may al be the cause of failure of descent of the cryptorch testicle. If the superficial inguinal pouch ectop testicle is excluded, the varying degree of no descent might indicate the severity of this bas abnormality. The underlying cause or nature of t basic abnormality remains unknown.

Acknowledgements.—I would like to thank t Joint Standing Research Committee of St. Mar Hospital, London, for its financial support, and al Mr. H. H. Nixon and Mr. C. W. Jamieson for th helpful criticism.

SINCIPITAL ENCEPHALOMENINGOCELES

By W. J. WHATMORE

DEPARTMENT OF SURGICAL NEUROLOGY, THE ROYAL INFIRMARY AND WESTERN GENERAL HOSPITAL, EDINBURGH

SUMMARY

A definition of cranial encephalomeningocele is presented together with a classification of the types of sincipital encephalomeningocele and a review of their frequency throughout the world. A series of 30 cases encountered in Burma is described, including the personal details, clinical presentation, diagnostic procedures, general management, operative treatment, and the observations at operation. The aetiology and pathogenesis of sincipital encephalomeningocele are discussed with reference to the literature, to the embryogenesis of the skull and brain, and consideration of the observations made in this series of cases.

ENCEPHALOMENINGOCELES are congenital herniations of cerebral tissue through the skull. They are usually composed of a meningeal sac containing brain tissue, cerebrospinal fluid, or both and are enclosed externally by skin and soft tissues. They pass through congenital defects in the skull and are usually continuous with their intracranial counterparts. Guthrie and Dott (1927), however, suggested that perhaps these lesions are not true herniations as the displaced tissues were present before the skull was developed and were not, therefore, originally intracranial.

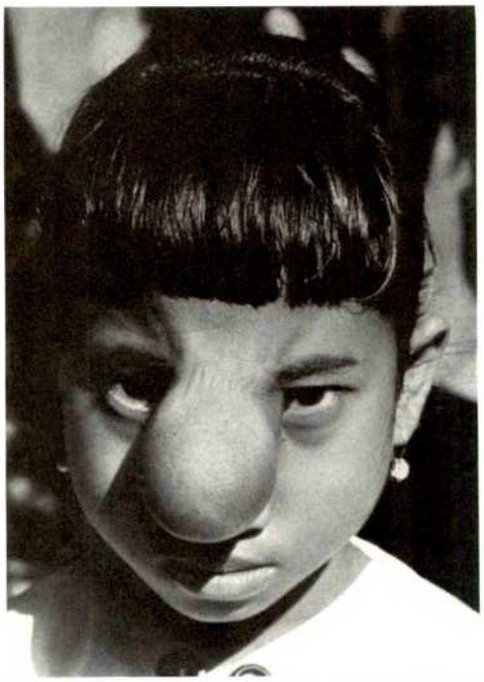

FIG. 1.—A nasofrontal encephalomeningocele, passing between the nasal and frontal bones and appearing in the midline at the root of the nose.

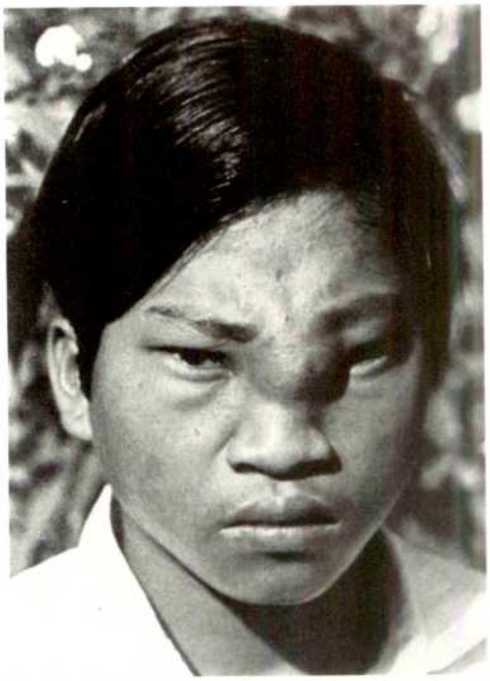

FIG. 2.—A left naso-ethmoidal encephalomeningocele, passing between the ethmoid, frontal, and nasal bones to appear on the side of the nose at the cartilaginous and bony junction.

They can occur anywhere in the midline sagittal axis of the cranium from the occiput to the nasofrontal region and only rarely appear lateral to this line. Mood (1938) stated that they are usually found at the sites of the fontanelles (occipital, frontal, sphenoidal, mastoid) or at the cribriform plate of the ethmoid, the foramen caecum, the foramen magnum, or occurring through a suture line.

Cranial encephalomeningoceles are encountered much less frequently than spinal encephalomeningoceles. Matson (1969) reported that in a 20-year period at the Harvard Clinic, 1390 spinal lesions were seen but only 265 cranial lesions. Gisselsson (1947) estimated the incidence of cranial encephaloceles as 1 in every 3500–4000 births and, of these, 15–20 per cent were anterior encephaloceles, while Lampert (1924) assessed the incidence of cranial encephaloceles at 2–3 per 10,000 births. In the Western world occipital encephalomeningoceles are the commonest variety, whilst in certain countries in the East anterior encephaloceles are more frequent. Of Matson's (1969) 265 patients, 14 had nasal encephaloceles, 4 nasopharyngeal, 17 frontal, 34 parietal, and 196 occipital. Van Nouhuys and Bruyn (1964) estimated the incidence of anterior encephaloceles to be 1 in every 35,000 live births, but Suwanwela and Hongsaprabhas (1966) assessed the incidence in Thailand to be 1 in every 5000 births.

The anterior encephalomeningoceles can be divided into two groups on the basis of their locations: the sincipital encephalomeningoceles occur near the root of the nose, and the basal encephalomeningoceles occur within the nose, the pharynx, or the orbit. Von

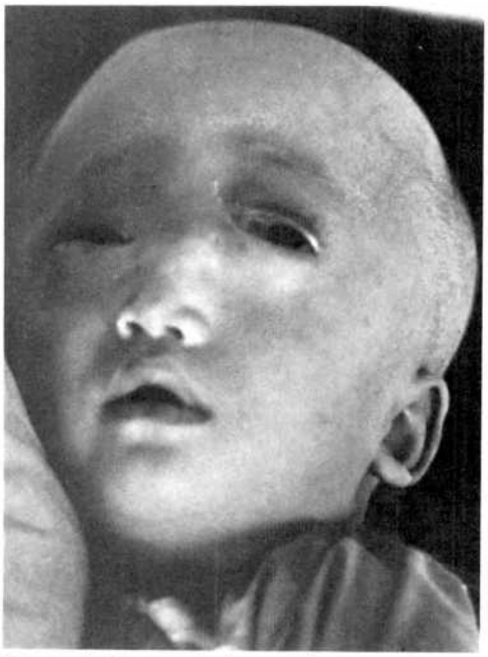

FIG. 3.—A left naso-orbital encephalomeningocele, passing between the ethmoid, frontal, and lacrimal bones into the anteromedial part of the cavity of the orbit.

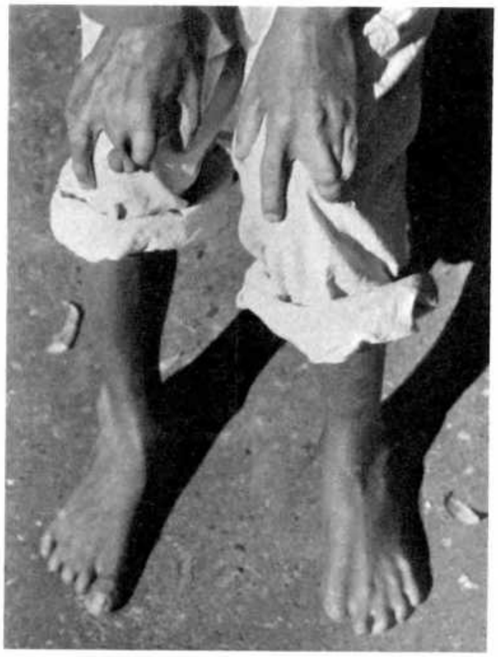

FIG. 4.—Congenital abnormalities of the fingers and toes in a patient who also had a nasofrontal encephalomeningocele which is seen in *Figs.* 10 and 11.

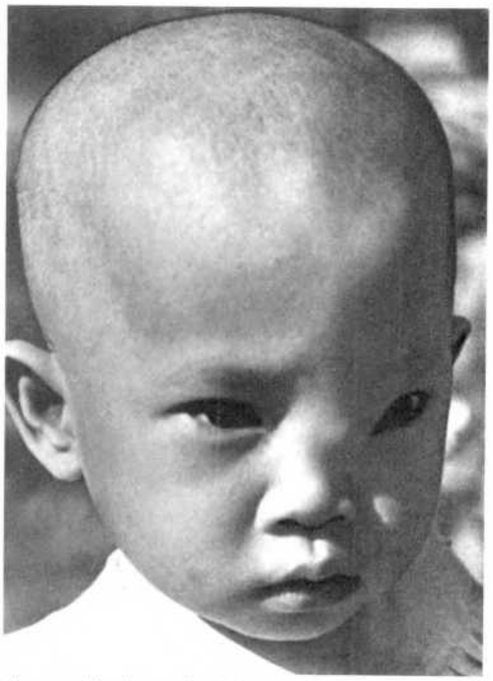

FIG. 5.—Simple, small, solid type of sincipital encephalomeningocele.

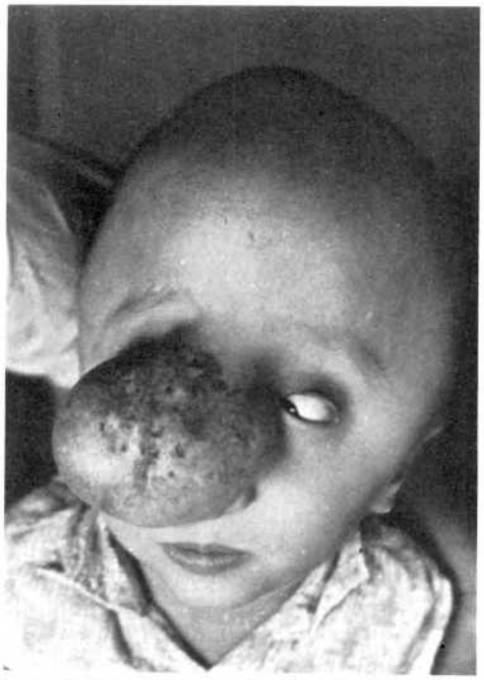

FIG. 6.—A large right naso-ethmoidal encephalomeningocele which contains a mixture of solid and cystic elements.

Meyer (1890) further classified the sincipital encephalomeningoceles into the following groups:—

1. Nasofrontal: Passing between the nasal and frontal bones and producing a rounded skin-covered mass in the midline at the root of the nose (*Fig.* 1).

2. Naso-ethmoidal: Passing between the ethmoid, frontal, and nasal bones to appear on the side of the nose at the cartilaginous and bony junction (*Fig.* 2).

3. Naso-orbital: Passing between the ethmoid, frontal, and lacrimal bones into the anteromedial part of the cavity of the orbit (*Fig.* 3).

CLINICAL MATERIAL

For a 9-month period from September, 1969, to May, 1970, the author was appointed as Colombo Plan Adviser in Neurosurgery to the Ministry of Health, Government of the Union of Burma. During this period over 50 cases of anterior encephalomeningocele were seen either in the Neurosurgical Unit in Rangoon General Hospital or in other parts of the country during lecture or inspection tours. Thirty of these cases were admitted for treatment to the Neurosurgical Unit in Rangoon and were studied in detail. Fourteen of these patients were operated upon.

Of the 30 patients studied, 19 were male and 11 were female. Ages ranged from babies of a few days old to a female of 39 years. There was an obvious regional distribution in Burma as 24 of the cases came from lower Burma, 4 from middle Burma, and only 2 from upper Burma. However, it is possible that overall population studies of Burma would show a proportional geographical representation. The age of the parents at the patient's birth was probably significant as 36 parents were over 30 years of age and 13 were over 40 years. The Burmese tend to marry while still young. Four of the mothers had febrile illnesses during the first 3 months of pregnancy but only 2 admitted to taking indigenous native medicines at that time. In 3 patients there was a family history of congenital abnormalities, none of which was an encephalomeningocele. All the patients were born at full term and were delivered by normal delivery. In 29 of the 30 cases a swelling was present at birth;

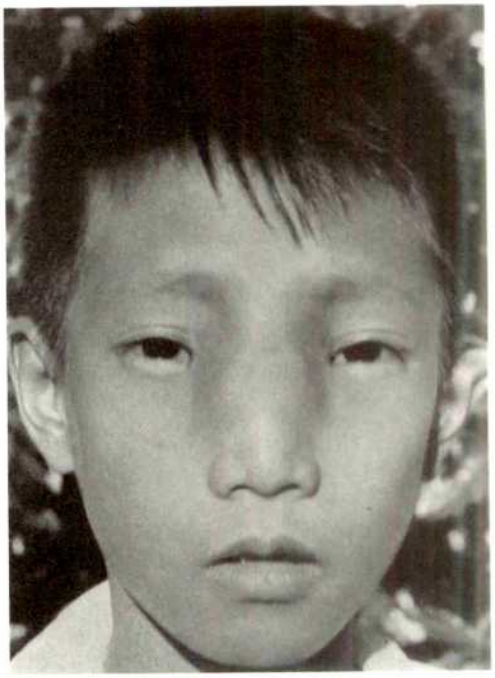

FIG. 7.—A diffuse type of nasofrontal encephalomeningocele.

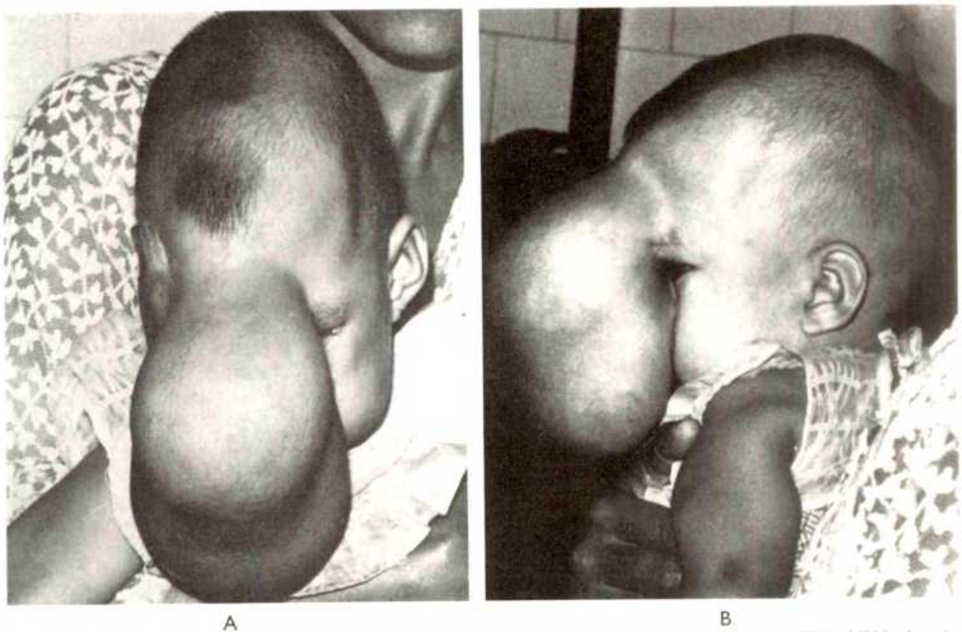


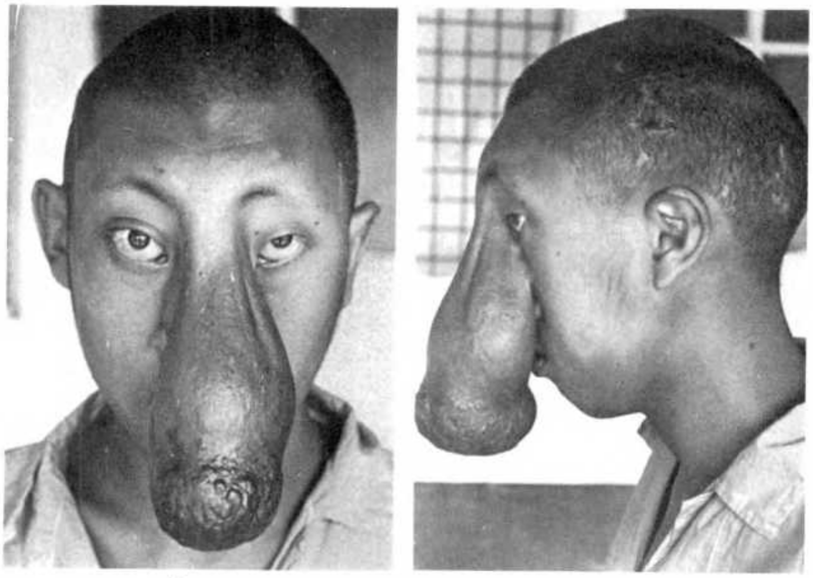
A

B

FIG. 8.—A rapidly enlarging cystic variety of encephalomeningocele encroaching on the eyes, nose, and mouth. This child had a microcranium and a hydrocephalus.

the remaining case developed hydrocephalus shortly after birth and a naso-orbital encephalomeningocele 3 months later. In 25 of the patients the lesion was still enlarging: in 7 cases the lesion was rapidly enlarging and in 18 cases slowly enlarging. Four patients had clinical evidence of hydrocephalus at the time of their admission and 3 infants had microcrania; 2 with a solid lesion and 1 with a cystic lesion. Three patients had other neurological deficits. A boy of 16 had a sixth-nerve paresis, a 3-year-old boy suffered from grand-mal epilepsy, and a 39-year-old woman was totally blind in her right eye and had a psychotic illness. One patient had associated congenital abnormalities with syndactyly of the fingers and toes (*Fig.* 4). Two patients had an encephalomeningocele which had recurred after previous external surgical repair.

Clinical Presentation.—Of the 30 patients studied, 21 patients had a nasofrontal encephalomeningocele, 8 had a naso-ethmoidal encephalomeningocele, and 1 patient presented with a naso-orbital lesion. As well as seeing all three varieties of sincipital encephalomeningocele there were many different presentations within these varieties. The commonest was the simple, small, hard, nasofrontal or naso-ethmoidal swelling which grew only slowly and, at this stage, presented only a cosmetic problem (*Fig.* 5). Large lesions tended to contain a mixture of solid and cystic elements and very advanced lesions of this type encroached on the eyes and nose and became urgent problems (*Fig.* 6). A diffuse nasofrontal variety was seen, extending in a flattened form down over the nose (*Fig.* 7). The most urgent type was the purely cystic type, rapidly growing and often associated with either hydrocephalus or microcrania and causing great problems with vision, breathing, and feeding (*Fig.* 8). Advanced examples of nasofrontal encephaloceles containing a mixture of solid and cystic elements assumed an 'elephant-trunk' form, hanging down over the nose and mouth (*Fig.* 9). Two cases which were seen had recurred after previous attempts at external excision of the lesion (*Fig.* 10).



A B

FIG. 9.—A huge 'elephant-trunk' type of solid and cystic nasofrontal encephalomeningocele.

The encephalomeningoceles varied in size from 1 to 19 cm. in the greatest diameter. All the cases had skin coverings to their lesions but in some the skin was extremely fragile and in 1 case the skin had perforated, resulting in a cerebrospinal fluid leak on the surface of the encephalomeningocele. Some lesions were hard and solid, while others were cystic, fluctuant, and translucent. The swellings were never tender on palpation but would often fill or become tense when the patient coughed, strained, or cried. In some cases a defect could be palpated at the neck of the lesion through the anterior facial bones. In many cases separation of the orbits was seen. None of the cases could be reduced by compression.

Diagnosis.—As other types of nasofrontal swelling such as dermoid cysts and teratomas were extremely rare in Burma, the diagnosis of sincipital encephalomeningocele was usually made with confidence on clinical grounds alone. Although such differentiation is academic the subvarieties of sincipital encephalomeningocele were easily recognized. There are only two radiological investigations of any value:—

1. Plain skull radiographs or tomograms to establish the presence, size, shape, and location of the bony defect. This opening in the skull was usually difficult to visualize, particularly in infants and children, but postero-anterior projections at various angles proved useful, as recommended by Suwanwela and Hongsaprabhas (1966).

2. A lumbar air encephalogram to reveal an established hydrocephalus. Air does not enter the encephalomeningocele sac probably because of the tight approximation of the meninges and brain to the bony-defect orifice. It was felt that there was no

lace for the direct injection of air or contrast naterial into the encephalomeningocele sac because f the risk of establishing a cerebrospinal fluid leak r promoting infection.

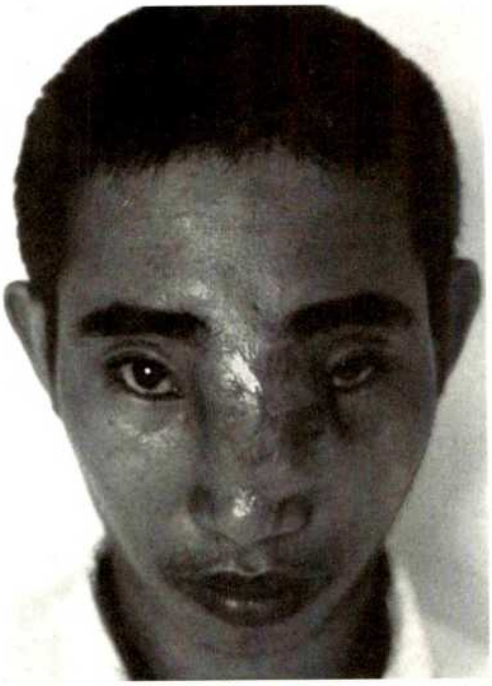


FIG. 10.—A recurrent left naso-ethmoidal encephalomeningocele. An external excision had been performed 12 years previously, but the lesion had started to recur after 3 years.

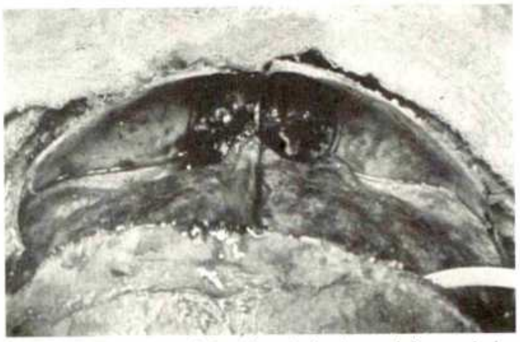

FIG. 12.—Exposure of the rim of the bony defect and the hernial contents after partial division of the meningeal sheath.

Management.—The only effective permanent treatment for suitable lesions is surgical repair. Contra-indications in Burma to surgical repair were small cosmetic lesions which were not rapidly enlarging and patients whose lesions were incompatible with survival or a useful independent life. Therefore the indications for surgical intervention were as follows:—

1. Rapidly enlarging encephalomeningoceles.
2. Encephalomeningoceles encroaching on the eyes, nose, or mouth.
3. Encephalomeningoceles in danger of rupturing.
4. Encephalomeningoceles associated with hydrocephalus.

Surgical treatment should be performed as early as possible in life to avoid further enlargement of the lesion, increasing brain damage, and a risk of development of hydrocephalus. In Burma, however, because of local conditions non-urgent cases were postponed until the child was older or until progression of the lesion necessitated intervention.

Surgical Procedures.—Direct therapeutic tapping of a cystic encephalomeningocele was felt to be contra-indicated because of the risk of establishing cerebrospinal fluid leak or causing infection. Direct external removal was not performed because of the risk of recurrence, infection, or cerebrospinal fluid leak.

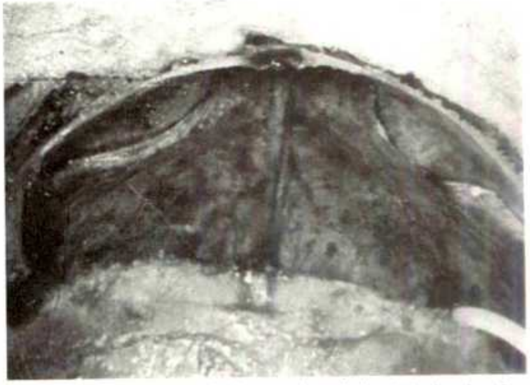

FIG. 11.—Exposure of the meningeal hernial sheath after bifrontal craniotomy and reduction of the intracranial pressure by ventricular drainage. The tube is slack and lying in the midline.

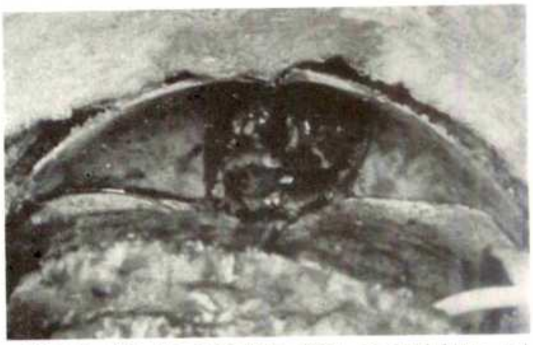

FIG. 13.—The rim of the bony defect, the dural fringe, and the encephalomeningocele contents after completion of division of the meningeal sheath.

If the patient was found to have an associated hydrocephalus a ventriculo-atrial shunt was first performed. In some patients who had a small, purely cystic encephalomeningocele this seemed the only procedure necessary as the external swelling deflated and shrank. However, to prevent the recurrence of the lesion if the shunting procedure should become blocked an internal repair was performed if the patient's condition would allow it.

An elective, direct, intracranial operation was thought to be the only real means of offering the patient a permanent non-recurrent repair. If the patient had an associated hydrocephalus this repair was performed 2 weeks after the shunting procedure. In all cases an extradural approach through a bifrontal craniotomy was used, as recommended by Suwanwela and Hongsaprabhas (1966). Intracranial tension was reduced by allowing the free flow of cerebrospinal fluid from an indwelling catheter placed in the frontal horn of the right lateral ventricle. Once this had been achieved the inner layer of dura was easily stripped from the anterior cranial fossa by blunt dissection and the hernial meningeal tube and its contents were identified as they passed forwards from the medial parts of the frontal lobes to the bony opening (*Fig.* 11). Although most of the circumference of the dural sheath could be mobilized and identified, there was usually difficulty in freeing the most inferior part from the dura of the anterior fossa and from remnants of the crista galli and the cribriform plate. This part of the dural sheath could only usually be identified when division of the rest of the sheath was near completion.

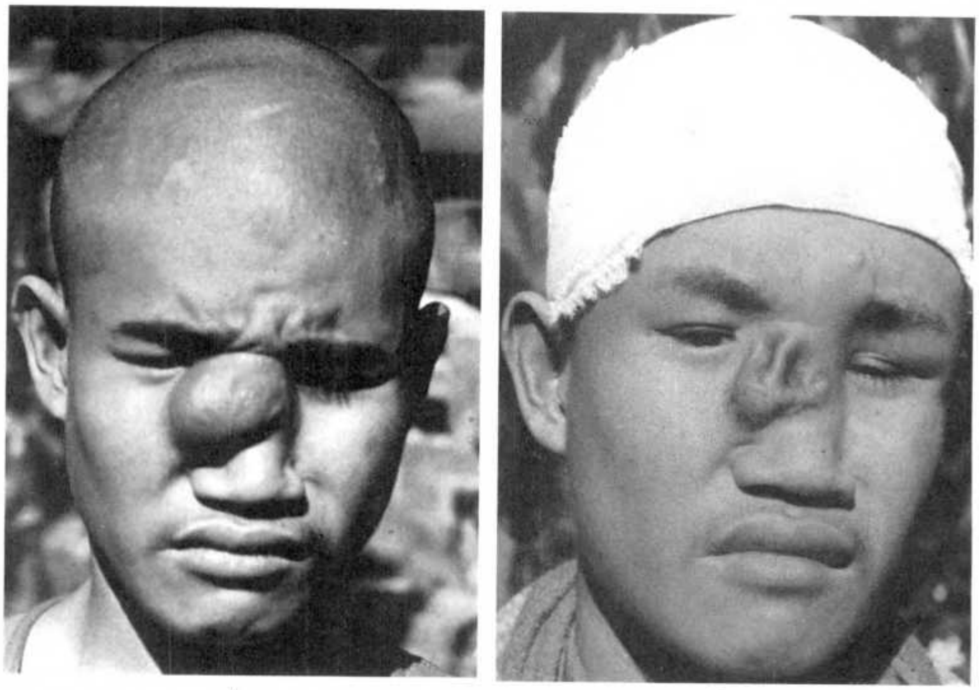

FIG. 14.—A small, cystic, right naso-ethmoidal encephalomeningocele before and 1 week after the intracranial repair.

The dural sheath was usually divided with a sharp knife, after diathermy coagulation, 1 cm. proximal to the bony opening, commencing on the superior surface and working laterally on either side. The contents of the sheath were divided by a mixture of sharp and blunt dissection (*Fig.* 12). The contents were never unduly vascular but contained strands of hard connective tissue passing into the depths of the bony opening. The inferior parts of the dural sheath were divided, after coagulation, as they became apparent. No attempt was made to remove the contents of the encephalomeningocele sac from within, but brain tissue was removed from the orifice of the bony opening to facilitate the subsequen closure (*Fig.* 13). The dural defect over the brain wa approximated by interrupted sutures, if this wa possible, without tension. In other cases the defec was repaired with a Teflon patch or simply covered with a sheet of Sterispon.

The permanent watertight closure of the skull defect is the most important single step of the operation. Workers in the past have recommended many different methods and have utilized various materials. The recommended materials include dura mater autografts, preserved human dura, temporalis fascia, fascia lata, pericranium, muscle patches, autogenous bone from the skull, ribs, ilium, or tibia, autogenous sliding bone-grafts, methyl methacrylate, Teflon, Dacron, Sterispon, bone wax, and oxidized cellulose. In 2 patients in this series the bony defect was covered with a Teflon patch, but great difficulty was encountered in suturing this into position as the dura mater of the surrounding anterior fossa in these cases is too thin and friable. For the same reason it was found impossible to cover the defect with a reflected or sliding autogenous dural flap. In 1 patient methyl methacrylate was used to plug the bony opening, but it proved unsatisfactory from three points of view: it was impossible to ensure a watertight approximation to the bony margin; it was difficult to fix securely in position; and it tended to assume a collar-stud shape distal to the bony opening which would hamper its removal should this prove necessary.

The method finally adopted for this closure was to utilize the dura of the hernial sheath. The sheath was divided as previously described, 1 cm. proximal to the bony opening. The contents were cleaned out level with the rim of the bony defect and then the dural sheath was itself closed in the midline vertically using nterrupted 000 silk sutures. A muscle patch or Sterispon patch was placed over the suture line. In all the cases in which this method was used the repair appeared to be watertight as judged by the postoperative shrinking of the encephalomeningocele. The craniotomy was closed in a standard fashion after removal of the ventricular drain. With large or solid encephalomeningoceles an external plastic repair was usually performed 1–2 months after the intracranial procedure.

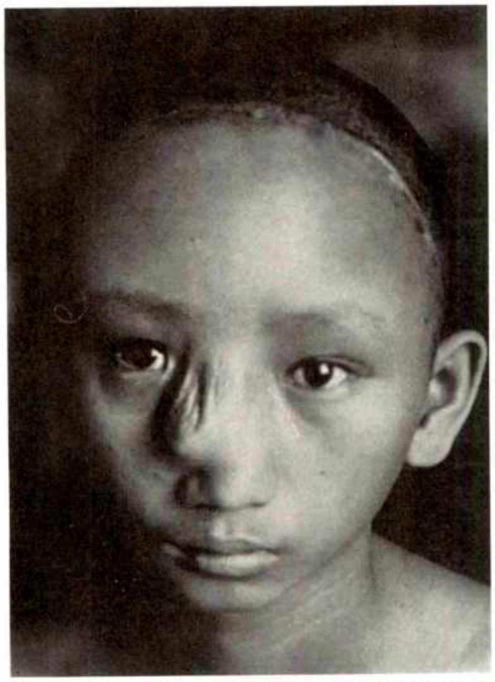

FIG. 15.—A right naso-ethmoidal encephalomeningocele 2 weeks after operation. A right frontal porencephalic cyst was pushing the interal bony defect over to the left. Note the domed right forehead and the postoperative shrinking of the lesion.

Surgical Statistics and Results.—Of the 30 patients reported, 14 patients were operated on, 20 operations being performed in all. Eleven patients received an intracranial repair, 3 of these being preceded or followed by a ventriculo-atrial shunt; 3 patients later had an external plastic repair. Three patients had shunt procedures alone.

In all the cases after intracranial repair or ventriculo-atrial shunt alone there was an immediate reduction in the bulk and tension of the encephalomeningocele except for the small solid types which were not appreciably affected at first. Within 2 weeks the small cystic varieties shrank until they were only apparent as skin folds (*Fig.* 14).

There were 2 deaths in this series, both in infants. One died from a postoperative aspiration pneumonia and autopsy showed no adverse intracranial complications. The other child died from respiratory arrest after operation when he developed status epilepticus and vomiting. Permission for autopsy was refused in this second case.

Observation at Operation.—

1. *Site of the Internal Bony Defect.*—Of the 11 patients who had a direct intracranial repair, 8 patients had a midline bony defect and in 7 of these it was at the site of the foramen caecum while 1 defect was slightly inferior to this with a small remnant of crista galli present superiorly. Seven of these 8 patients had a nasofrontal encephalomeningocele. In 3 cases the bony deficit was deviated from the midline and was situated over either the left or right anterior cribriform plate. A boy of 16 with a naso-ethmoidal encephalomeningocele was noted before operation to have a domed right forehead. At operation a large porencephalic cyst of 300-ml. capacity was found to be occupying the territory of the right frontal lobe (*Fig.* 15). The bony opening lay over the left anterior cribriform plate and the crista galli was split into two vertical portions, the superior one lying to the right of the defect and the inferior one bisecting the lower part of the bony deficit. The two parts of the crista galli had to be nibbled away before closure could be effected. In a boy of 12 years with a left naso-ethmoidal encephalomeningocele the bony opening was found at the bottom of a conical bony tunnel in the region of the left anterior cribriform plate. A small portion of the crista galli jutted out above and to the right of the opening. In a boy of 12 years with a left naso-ethmoidal encephalomeningocele the bony deficit was lying over the right anterior cribriform plate with the deformed oblique crista galli lying on its left side.

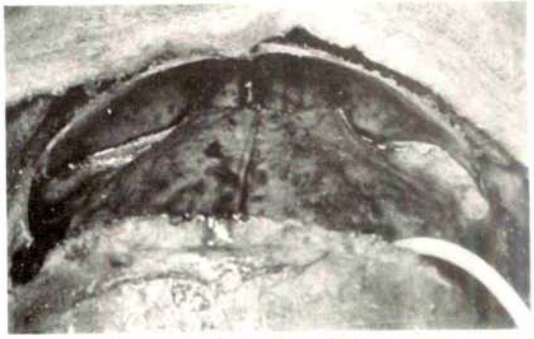

FIG. 16.—On opening the dural sheath, discrete prolongations of both frontal lobes were seen passing into the encephalomeningocele sac separated by a prolongation of the falx.

2. *Size of the Bony Opening.*—The bony deficit varied in size from 1½ to 2½ cm. in diameter; 9 of the 11 cases had an opening of 1½ cm.

3. *Shape of the Bony Opening.*—In all the cases the internal rim of the bony opening was circular or elliptical. In 1 midline case the crista galli only remained as a small superior jutting fragment. In 3 cases the crista galli was seen inferiorly. In 3 cases with a lateral bony deficit the crista galli was either split or lay to the left or right of the midline. In 4 cases the crista galli was not seen at all.

4. *The Meningeal Tube and its Contents.*—The meningeal tube usually consists of normal or thickened dura and was firmly attached to the rim and walls of the bony canal. It was usually not tense once the intracranial tension had been reduced with ventricular

drainage. It was not unduly vascular. There were often dense adhesions between the dura and the underlying arachnoid covering the brain tissue. Cerebrospinal fluid was observed to be lying in this space. The contents of the meningeal sheath were shown by pathological examination to be composed of brain, glial, fibrous, and connective tissues. In even the cystic cases there is very little escape of cerebrospinal fluid during the division of the tube. In no case was a connexion found between the lateral or third ventricle and the encephalomeningocele.

Usually the contents of the hernia were connected proximally to the medial sides of both frontal lobes and thus the proximal ends of the meningeal tube were central. In 1 case, however, on opening the dural sheath discrete prolongations of both frontal lobes were seen separated by a continuation of the falx—all three structures disappearing through the bony canal into the encephalomeningocele (*Fig.* 16).

5. *Postoperative Hydrocephalus.*—The patient with the largest lesion, a man of 20 years with a nasofrontal encephalomeningocele, developed hydrocephalus after the intracranial repair. Preoperative screening did not reveal hydrocephalus and at operation the ventricles were not enlarged. One week after surgery the patient's bone-flap started to elevate and investigation revealed a communicative hydrocephalus. It is interesting to note that there was no associated rise in tension of the encephalomeningocele, which, in fact, continued to shrink after operation. The patient's hydrocephalus was treated with a ventriculo-atrial shunt and the bone-flap settled back into position.

DISCUSSION

The pathogenesis of sincipital encephalomeningoceles is still in doubt. Mood in his paper on congenital anterior herniations of the brain in 1938 summarized the many and varied theories up to that date.

In 1827 Geoffrey St. Hillaire published his adhesive theory, attributing the lesions to adhesions between the dura, brain, and skin of the cranium resulting in maldevelopment of the bony vault and subsequent outgrowth of the brain. Himly (1829) and Serres (1832) suggested that during ossification and fusion of the skull-bones clefts were normally present and that the hernias formed through these clefts. Spring in 1854 concluded that many of the lesions were connected with the ventricles, and presumed that the encephalomeningoceles arose secondary to hydrocephalus. He assumed that frontal lesions arose from dilatation of the anterior horn of the lateral ventricles, trans-sphenoidal lesions from the third ventricle, and occipital lesions from the fourth ventricle. He explained the solid growths on the grounds of arrested hydrocephalus, reducing the cystic part of the lesion during intra-uterine life, leaving only protrusion of the solid part.

Klementowsky in 1868 thought that malformations of the skull occurred as a result of tabes, rickets, or syphilis and that the lesion protruded through a malformation. Ankermann (1882) believed that the cystic encephalomeningoceles were secondary to hydrocephalus but that the solid ones were due to microcranial maldevelopment with resultant extrusion of the brain. Berger in 1890 thought that the solid lesions were true new growths and called them 'encephalomata'.

Sternberg (1929) reviewed the available embryological knowledge on the closure of the neural groove and pointed out that the anterior and posterior ends close a week later than the rest of the tube. The anterior neuropore which closes at the beginning of the 4th week is situated at the site of the foramen caecum which in mature embryos lies at the level of the root of the nose between the eyes. This neuropore is separated from the skin by the ingrowth on each side of mesoderm which will later form the skull. If, however, this connexion with the skin persists mesodermal invasion is prevented, skull development is impossible, and a skull defect will form at this point, thus allowing herniation of the brain through the remaining thin epithelial membrane. When the mesodermal invasion is prevented entirely the brain and encephalomeningocele are connected with a pedicle. The corpus callosum originates from the region of the anterior neuropore, and Sternberg in 1929 reported a case of absence of the corpus callosum in a patient with an anterior encephalocele. Gardner in 1968 discussed states of hydrocephalus and hydromyelia which are physiological in embryonic life. He cited the studies on living pig embryos of Weed (1917), who showed that after closure the neural tube becomes distended with a protein-rich fluid before the appearance of the choroid plexus. With the advent of the choroid plexuses and secretion of cerebrospinal fluid the rate of neural tube distension increases and the diluted fluid begins to percolate through permeable areas in the rhombic roof to open up the subarachnoid spaces. Gardner (1968) stated: 'at this stage (6th–8th weeks) the head of the human embryo resembles a translucent bubble about to burst'. If the rhombic roof does not become adequately permeable at this stage fluid will not open up the subarachnoid spaces and a communicating type of hydrocephalus may persist. Gardner (1968) suggested that overdistension of the neural tube may distort the overlying cutaneous ectoderm and the surrounding mesoderm. Coalescence of general layers and adherence between the roof plate of the neural tube and the overlying cutaneous ectoderm may occur.

Holtzer (1952), in an experimental analysis of the development of the spinal column, showed that the diameter of the neural tube determined the diameter of the enclosing spinal canal. He stated: 'migrating pre-cartilaginous cells respond in a discriminatory and stereotyped fashion to the presence of any neural tissue by maintaining a characteristic distance from the neural tissue. The pre-cartilaginous cells are deployed in such a fashion that a lumen will eventually be formed in the cartilage whose size is a function of the enclosed nerve bundle.' This concept of maldevelopment could be applied to the bony skull defects that occur anteriorly in the causation of sincipital encephaloceles.

In order to understand the pathological defects that occur in the skull in these lesions the embryogenesis of the cranium will now be discussed. The bone of the vault of the skull and face are developed by ossification in membrane, and the base of the skull by ossification in cartilage. Most of the separate skull and face bones are ossified by the time of birth but they are mobile on each other and are fairly eadily disarticulated in the macerated skull. Their mobility on each other is most marked in the vault, and the power of overlap provides that moulding of he cranium which so generally occurs during parturition. The bones of the vault including the frontal bone do not interdigitate in sutures as in the adult but are separated by linear attachments of ibrous tissue (Last, 1956).

At the beginning of the 2nd month of intra-uterine ife the mesoderm surrounding the developing cerebral vesicles increases in thickness and forms ocalized masses. These localized mesodermal masses represent the earliest stage of formation of the skull. Early in the 2nd month mesodermal condensation surrounds the hypophysis and then extends forwards to form the basis of the pre-sphenoid and ethmoid bone and the nasal septum. These structures include the crista galli, cribriform plates, and ethmoid abyrinths. Chondrification of the base of the skull begins in the 2nd month of intra-uterine life and commences in the occipital plates. The sphenoid, the auditory capsule, the ethmoid, the roots of the greater and lesser wings of the sphenoid, and finally the nasal septum become chondrified in turn. The latter structure is well developed by the end of the 3rd month. The ethmoid bone is ossified from three centres, one for the perpendicular plate and crista galli, which appears during the first year after birth, and one for each labyrinth appearing during the 4th and 5th months of intra-uterine life. The cribriform plate ossifies from all three centres.

The vault of the skull first appears about the 13th day of intra-uterine life as mesodermal plates arising lateral to the developing brain and then extending superiorly to blend with each other and inferiorly to blend with the base. The ossification of the membranous part of the skull begins about the 8th week of foetal life with the appearance of four ossification centres on each side. The centres for the frontal bones are at the site of the frontal eminence. The two frontal ossifications fuse at the end of the first year, the metopic suture which separates them disappearing then.

At the end of the 3rd month of intra-uterine life the frontal and ethmoid bones are still apart although they are adjoining at birth. The nasal, lacrimal, and frontal processes of the maxillary bones are formed from membrane and are ossified in the membrane that overlies the cartilages of the nose. The centres of ossification of these bones appear about the 3rd month of foetal life.

To elucidate further the pathogenesis of encephalomeningoceles some of the pertinent findings at operation are re-emphasized. In 7 patients the site of the internal bony opening was at the foramen caecum in the midline and in 1 case it was slightly posterior to this. In 3 cases the defect was at the anterior ends of the left or right cribriform plate, in 1 of these cases the bony defect being pushed over by a porencephalic cyst. The internal rim of the bony defect was almost constant in size at 1½ cm. diameter; the 2 patients having defects larger than this (2 and 2·5 cm.) were the 2 patients with the largest external encephalomeningoceles. The defects were always smooth and rounded and clearly punched out. They were never cleft or split-like. This appearance would suggest that the meningeal and brain protrusions exist first and that the bony defect is later formed around them. The proximal end of the meningeal tubes were always in the midline. When a defect through the anterior end of the cribriform plates was present the crista galli was always present although deformed. In 4 cases of midline bony deficit the crista galli was not present at all and in 1 other case it was present but rudimentary. This would tend to suggest that the meningeal and brain protrusions occurred before the formation of the ethmoid and nasal septum at or about the 6th week of intra-uterine life. Chondrification of the crista galli and cribriform plates does not occur until the 3rd month. Four patients in the original series of 30 cases had clinical evidence of hydrocephalus at the time of their admission and 1 patient developed hydrocephalus after an intracranial operation.

Summarizing the theories of previous workers, noting the embryological facts of development of the skull and brain, and utilizing the observations made in this series of cases, the following explanation of the pathogenesis of encephalomeningoceles is offered.

With the closure of the neural groove the anterior neuropore, which closes last at the beginning of the 4th week of foetal life, is situated at the site of the future foramen caecum. Overdistension of the neural tube which occurs physiologically at this time plus unknown aetiological factors cause adhesions of the anterior neuropore to the overlying ectoderm. This prevents the primitive mesoderm from intruding and thickening between the developing brain in the region of the anterior neuropore and the overlying ectoderm and skin. Thus, a defect in the mesoderm is formed and it is further prevented from resolving by an actual protrusion of the primitive brain and its coverings which occurs when the neural tube becomes severely distended with cerebrospinal fluid as the choroid plexus is formed and secretes cerebrospinal fluid between the 6th and 8th weeks of foetal life. The mesodermal defect at the junction of the future frontal and ethmoid bones therefore persists and the surrounding mesoderm undergoes chondrification and ossification. If the cerebrospinal fluid in the developing ventricles does not penetrate the rhombic roof and open the subarachnoid space a state of communicating hydrocephalus will coexist with the encephalomeningocele. When the bony defect is laterally placed at the anterior cribriform plate one may postulate the existence of an abnormal pathological state of the developing brain or bone that pushes the early encephalomeningocele laterally. This pathological state may later disappear and therefore not be seen at operation or it may persist, as in the case of the porencephalic cyst in this series. The site of the externally emerging encephalomeningocele depends on the pathway taken through the developing bones overlying the internal defect. A nasofrontal lesion would emerge through a developmental defect at the junction of the frontal and nasal bones. A naso-ethmoidal lesion would pass through a defect at the junction of the ethmoid, nasal, and frontal processes of the maxillary bones and a naso-orbital lesion through a defect between the frontal and lacrimal bones.

At first the developing protrusion is formed from the enlarging lateral cerebral ventricles and their overlying neuro-epithelium, but as the development of the cerebral mantle of the forebrain proceeds the encephalocele loses its connexion with the ventricle. In time the subarachnoid space surrounding the herniating brain is developed and opened, providing a cerebrospinal fluid communication between the encephalomeningocele and the intracranial subarachnoid space.

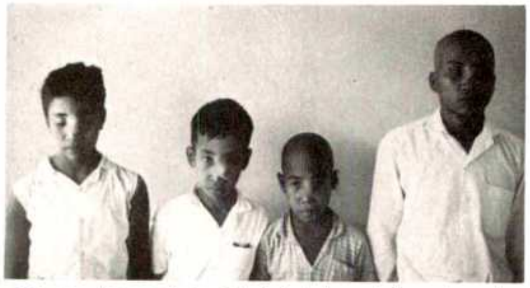

FIG. 17.—Four patients with sincipital encephalomeningoceles who were admitted to the neurosurgical unit in 1 week.

In 25 patients in this series it was stated on admission that the encephalomeningocele was enlarging. In 7 patients the cause of this enlargement was obviously increased intracranial pressure, as 4 of the patients had hydrocephalus and 3 had pathologically small skulls and were thus extruding excess brain or cerebrospinal fluid into the lesion. In the remaining 18 patients a persistent state of increased intracranial pressure was not apparent, but one can perhaps postulate two causes of increasing protrusion of the encephalomeningocele. First, a valve-like defect may exist in the subarachnoid space in the region of the meningeal tube to the internal bony rim. At times of intermittent increased intracranial pressure, as in straining or crying, cerebrospinal fluid may be forced into the lesion but prevented from returning to the intracranial compartment. Secondly, the plug of brain tissue and meninges is often adherent to the encephalomeningocele sac and therefore cannot retract. Intermittent increased intracranial pressure may further protrude the brain tissue. The five lesions that were not enlarging on admission may either have become firmly adherent at the internal bony rim or may have lost, through adhesions, the subarachnoid connexion.

The aetiology of this condition remains unknown. Many authors have stated that they are developmental, non-familial, and not necessarily associated with other congenital defects. Several cases have been reported which indicate that encephaloceles are not confined to man but are found in lower animals. Rawlings (1904) cited Norsa Gurrieri who described a case of encephalocele in an embryo of *Mus decumanus vel albinus* and stated that the developmental error involves bones of either cartilaginous or membranous origin. In the Burmese national press of January, 1970, there appeared a report and a photograph of twin piglets each weighing 4 kg. and bearing strange features: 'Both piglets had small tubes in the head suggestive of elephant trunks.'

There is no doubt that anterior encephaloceles are more common in the south-east Asia peninsula than elsewhere in the world (*Fig.* 17). Suwanwela and Hongsaprabhas (1966) commented on the frequency in Thailand and stated: 'It is interesting to speculate whether the mongolian type of head with its flat nose on a wide base contributes to the development of the lesion.' The majority of the patients in the present series were of pure Burmese stock, only one or two being thought to have mixed racial parentage. Racially the Burmese are thought to have derived from the same ancient Mongolian stock as the Thais. The author has also ascertained that anterior encephaloceles are found in increased frequency in certain parts of southern India, in East Pakistan, in Laos, and in Malaysia.

The aetiology of the cases in this series could be due to:—

1. Defective germ plasm inherent in certain races in the south-east Asia peninsula.
2. Infections in the mother during the first few months of pregnancy.
3. The effect of indigenous and perhaps pharmacologically unknown medicines during the first few months of pregnancy. Other congenital abnormalities are plentiful in Burma including thalidomide-like limb deformities although that drug has not been used in Burma.
4. The effect of some unknown inherent dietary factor.

Acknowledgements.—The author expresses his gratitude to his colleagues in Burma: Dr. U. Saw Nyunt, Dr. U. Aung Kyan, Dr. U. Wan Maung, and Dr. U. Maung Ohm for their advice and help.

HEREDITARY SACRAL AGENESIS ASSOCIATED WITH PRESACRAL TUMOURS

By JOHN S. KENEFICK
ROYAL FREE HOSPITAL, LONDON

SUMMARY

This paper reports a family in which 6 females and 3 males have sacral agenesis. Four of the female members of the family have associated presacral tumours: 1 meningocele, 1 dermoid, and 2 of an undetermined nature at present. Similar sacral lesions associated with presacral meningoceles in 4 female members of a family of 29 have been reported by Cohn and Bay-Nielsen (1969).

SACRAL ossification is an extremely complex process as all students of anatomy are well aware. Each sacral segment is ossified from three primary centres and multiple secondary centres. Considering the complexity of this process congenital sacral abnormalities are relatively rare. Sacral agenesis was first described by Hohl in 1852, and Werthein described a further case in 1857. Shands and Bundens (1956) reviewed the spinal radiographs of 700 children admitted to the Alfred du Pont Institute between 1940 and 1955 and found 136 cases with spinal abnormalities—an incidence of 19·4 per cent. There were 3 cases of partial or complete absence of the sacrum—an incidence of 0·43 per cent. By 1966 there were 111 cases of sacral agenesis on record, and of these, 69 had anterior sacral meningoceles. Sixty of these patients were females. Nash (1959) divided sacral defects into two types: sacral agenesis, which may be partial or complete, and sacral dysgenesis, which includes such defects as spina bifida.

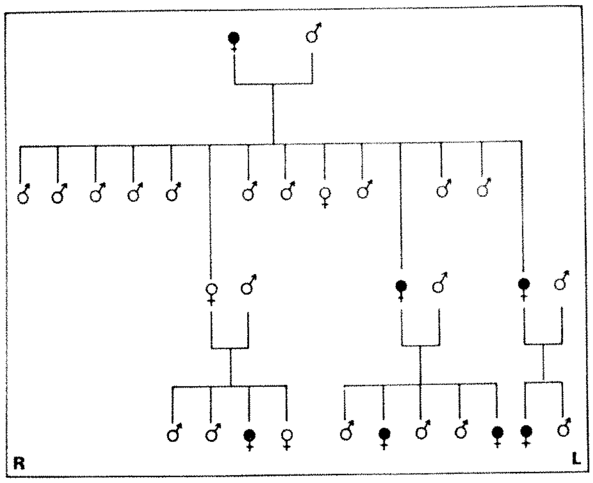

FIG. 1.—Family pedigree of the series reported by Cohn and Bay-Nielsen (1969).

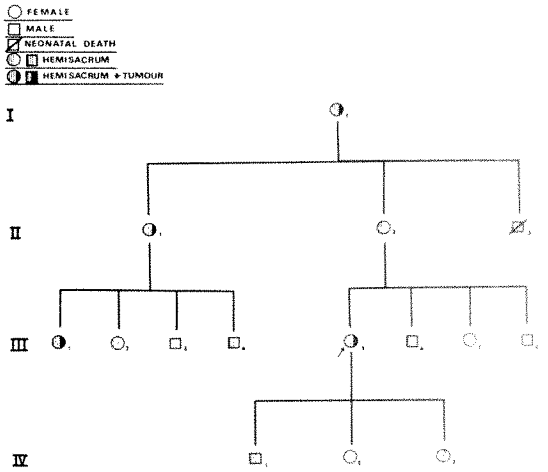

FIG. 2.—Family pedigree of the present series.

The aetiology of sacral agenesis is unknown. Cramer (1961) and Garner (1966) suggested that spinal abnormalities were due to increased pressure in the neural tube in embryonic life as a result of reduced permeability of the roof of the fourth ventricle. Meucke (1964) has shown that minute trauma in the embryo can produce cloacal exstrophy. Conditions analogous to sacral agenesis have been described in two animal species, the chicken and the mouse. The incidence of congenital abnormalities in children of diabetic mothers is considerably higher than normal (6·4 per cent compared with 0·9–2·1 per cent; Pedersen, Tygstrup, and Pedersen, 1964). Pouzet (1938) described an identical sacral defect in a father and son. The only other evidence of sacral defects occurring in one family is the very interesting report by Cohn and Bay-Nielsen (1969), who reported 2 females, aged 3 and 8 years, who were cousins with anterior sacral meningoceles and absence of the right half of the lower three sacral segments and of the coccyx. On investigating the remaining members of the family (*Fig.* 1), 4 others were discovered with identical sacral defects, 2 of whom had anterior sacral meningoceles. The cases extended over three generations and all the members with sacral agenesis were females. They suggested that the abnormality was transmitted as a sex-linked dominant trait.

The following case report is of a similar family, extending over four generations, in which 6 females and 3 males have congenital defects of the sacrum and coccyx. One of the females had a presacral dermoid tumour, another had a presacral meningocele, and 2 others have presacral tumours of an undetermined nature. There was no evidence of any tumour in the 3 males.

CASE REPORTS

Case 1.—The propositus, Mrs. J. G., aged 20 years (III, 5, *Fig*. 2), was admitted to the Royal Free Hospital in September, 1970, for investigation of vaginal bleeding. She had had three Caesarean sections performed for disproportion, and on each occasion the foetal head had failed to enter the true pelvis (*Fig*. 3). On rectal examination she was found to have a presacral tumour displacing the rectum and uterus forwards. She had no other symptoms or signs. A radiograph of the sacrum (*Fig*. 4) showed absence of the lower three sacral segments on the right side, and the lower left half of the sacrum and coccyx were curved forwards and medially. The tumour was also visible. Aspiration biopsy of the tumour through the perineum revealed a creamy-brown fluid which on microscopy consisted of masses of squamous cells (*Fig*. 5)

At operation through a left paramedian incision there was a multilocular presacral cystic tumour, measuring 15 × 10 × 10 cm. The tumour was attached to the upper margin of the sacral defect near the midline. The rectum was separated from the tumour and the lesion was excised completely. It was felt that the tumour was more likely to be a presacral meningocele, but the subsequent histological examination (*Fig*. 6) showed that the tumour was lined with squamous epithelium and was certainly a presacral dermoid cyst. The patient's postoperative course was uneventful.

Case 2.—Mrs. E. W., now aged 65 years (I, 1, *Fig.* 2), was admitted to the London Hospital in August, 1948, with acute retention of urine. On examination she had a full bladder, both buttocks were poorly developed, especially on the right side, and she had a perianal saddle-shaped area of anaesthesia. She had a presacral cystic mass, and a radiograph of the sacrum (*Fig.* 7) showed agenesis of the ower sacral segments. On 23 Aug., 1948, 325 ml. of cerebrospinal fluid were aspirated from the cyst. Total excision of the meningocele was performed through a posterior approach by Mr. D. W. C. Northfield, and her postoperative course was uneventful. Histological examination (*Fig.* 8) confirmed the diagnosis of a presacral meningocele.

Case 3.—Mrs. I. C., aged 38 years (II, 1, *Fig.* 2), attended for examination on request. She was asymptomatic and had had four normal vaginal deliveries. On rectal examination she had a presacral tumour approximately 5 cm. in diameter, and a radiograph of her sacrum (*Fig.* 9) showed sacral agenesis and a presacral tumour. At present we do not feel justified in pursuing further investigations.

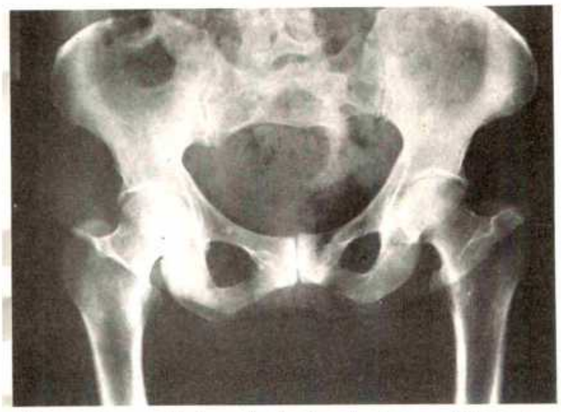

FIG. 7.—*Case* 2. Radiograph showing the absence of the lower sacral segments.

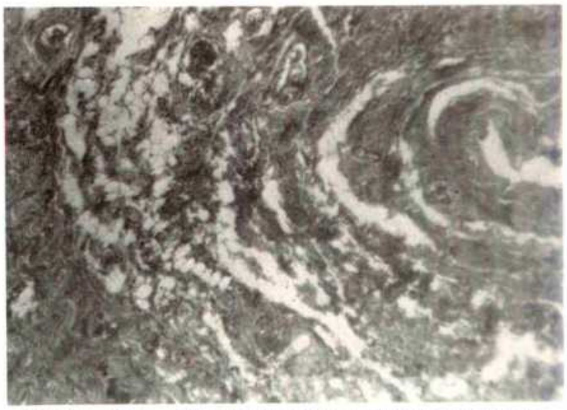

FIG. 8.—*Case* 2. Histological section showing the wall of the presacral meningocele. (× 40.)

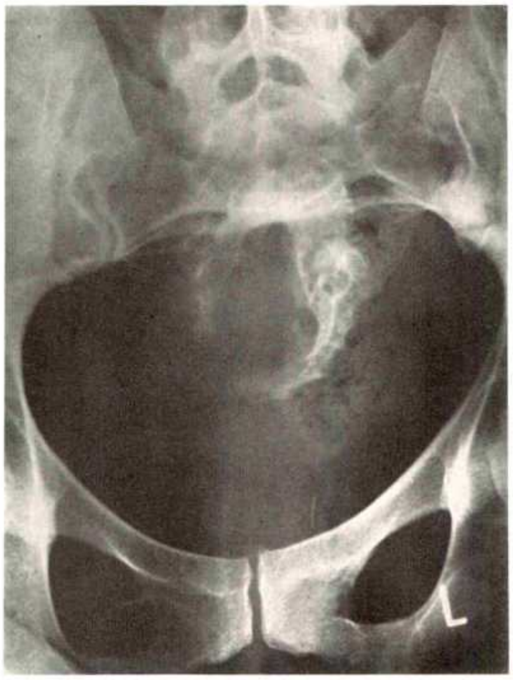

FIG. 9.—*Case* 3. Radiograph showing sacral agenesis and a presacral tumour.

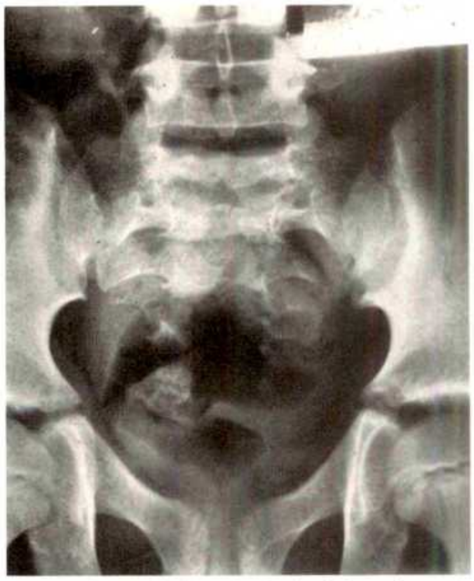

FIG. 10.—*Case* 7. Radiograph showing left sacral agenesis.

Case 4.—Miss J. C., aged 16 years (III, 1, *Fig.* 2), was found to have a presacral tumour, measuring about 5 cm., and sacral agenesis. She is asymptomatic and is being kept under observation as an out-patient.

Cases 5, 6, *and* 7.—The 3 male members of the family (III, 4 and 6; IV, 1, *Fig.* 2) all have a similar sacral defect with the absent segments on the left side (*Fig.* 10). Members III, 4 and 6 both have spina bifida of the first and second sacral segments. However, at present there is no evidence of any presacral tumour in the male members of this family.

DISCUSSION

Congenital deformities of the sacrum are frequently associated with other congenital abnormalities of the musculoskeletal system, genito-urinary tract, and lower gastro-intestinal tract. Of the 44 cases reported by Freedman (1949), 50 per cent had club-foot deformities and 18 per cent had congenital dislocation of the hip-joint. Spina bifida, hemivertebra, and fused ribs may also occur.

Visceral abnormalities were present in 35 per cent of Freedman's (1949) cases. The main genito-urinary disorders were neurogenic bladder, ureteric reflux, hydronephrosis, and duplication of the ureters. Williams and Nixon (1957) reported 8 cases of sacral agenesis with associated rectal disorders (mainly incontinence), and Koontz and Prout (1968) reported 8 further cases, 3 of which had an imperforate anus. Neurological disorders of the lower limbs vary from mild muscular paresis to total paraplegia. The more severe lesions tend to be associated with extensive sacral defects.

Presacral tumours have been classified by Lovelady and Dockerty (1949) into congenital abnormalities, bone tumours, neurogenic tumours, and miscellaneous tumours. The symptoms produced by these lesions are due to pressure on the pelvic viscera or associated neurological disorders. Pressure symptoms result in constipation, retention of urine, and dysmenorrhoea. Large tumours interfere with parturition and may necessitate Caesarean section. Neurological disorders are mainly due to loss of sphincteric control, sensory and motor deficiencies of the lower limbs, or intermittent increase in the cerebrospinal fluid pressure due to meningoceles. Infection in presacral dermoid tumours may result in unusual postanal discharges and sinuses.

In the cases reported in this paper one very consistent feature was constipation, and evacuation of the rectum was necessary in all the cases in order to obtain proper radiographs. The propositus (III, 5) had had three Caesarean sections performed. Members II, 1, and III, 1 have presacral tumours. Their nature has not been elucidated as yet but they are under out-patient supervision.

Member I had the presacral meningocele excised via a posterior approach while member II, 5 had her tumour removed via an abdominal approach. The surgical treatment of presacral tumours has been well documented and the main hazards are nerve injury and meningitis.

In the family reported in this paper 6 females and 3 males have a very similar sacral defect, suggesting that this condition is transmitted in this family as a dominant trait. The 4 patients with presacral tumours are all female, indicating that this lesion is transmitted as a sex-linked dominant trait. The only other report of a similar familial congenital sacral defect is the family reported by Cohn and Bay-Nielsen (1969) in which 6 female members of a family of 29 had congenital sacral agenesis, 4 of which were associated with presacral meningoceles. A search of the literature failed to reveal any record of sacral agenesis associated with a presacral dermoid tumour

Acknowledgements.—I wish to thank Mr. Emlyn Williams, F.R.C.S., the Royal Free Hospital, London under whose care the propositus was admitted. I would also like to thank Drs. E. H. Henderson G. Finlay, and M. Henry for assistance in tracing the other members of the family. My thanks are also due to Professor Doniac and the Records Department, the London Hospital, to Mr. C. Gilson, the Photographic Department, the Royal Free Hospital, and to Dr. J Cohn for permission to reproduce *Fig.* 1.

THE MANAGEMENT OF UPPER GASTRO-INTESTINAL TRACT HAEMORRHAGE

By M. M. HEGARTY,* R. T. GRIME,† and PHILIP F. SCHOFIELD‡
SURGICAL DEPARTMENT, ASHTON GENERAL HOSPITAL, ASHTON-UNDER-LYNE, LANCASHIRE

SUMMARY

Two hundred successive patients with upper gastro-intestinal tract haemorrhage were admitted to a surgical unit for management. One hundred and thirty-five patients (67·5 per cent) had a chronic peptic ulcer, 33 patients (16·5 per cent) had acute lesions (either an erosive gastritis or an acute gastric ulcer), and 32 patients (16 per cent) were a mixture of other diagnoses, of which 13 (6·5 per cent) were simple conditions but 19 (9·5 per cent) were conditions with a bad prognosis, e.g., carcinoma of the stomach, oesophageal varices, aortic aneurysm. Surgery was undertaken for massive, continuing, or recurrent bleeding and was as 'conservative' as thought possible. In duodenal ulcer this consisted of suture of the ulcer with vagotomy and pyloroplasty, and suture of the ulcer with vagotomy where possible in cases of anastomotic ulcer. In gastric ulcer only those less than 2 cm. in diameter were treated by suture with vagotomy and pyloroplasty. Ulcers greater than 2 cm. in size requiring surgery were treated by gastrectomy.

In the 181 patients whose underlying condition had a good prognosis there were 7 deaths (4 per cent). In this group 81 operations were carried out; 61 were 'conservative' operations for peptic ulcer, 2 were for repair of a hiatus hernia, and there were 18 gastrectomies, usually for a large gastric ulcer. There were 2 deaths among the operated patients; 1 after gastrectomy and 1 after a 'conservative' operation. There were 5 deaths among the 100 patients in the group which was treated non-operatively. There were 8 deaths among the 19 patients with underlying conditions of grave prognosis.

The case for the admission of patients with upper gastro-intestinal tract bleeding to a surgical unit is fully discussed and it is advocated together with a selective policy for operation. Where operation is necessary this should be as conservative as possible for bleeding duodenal ulcer, chronic gastric ulcer less than 2 cm. in size (ulcers of larger size may well respond but the method was not assessed for such ulcers), solitary acute gastric ulcer, and anastomotic ulcer. Gastric resection should be retained for the few patients with diffuse erosive gastritis requiring surgery and possibly for patients with a very large chronic peptic ulcer.

UPPER gastro-intestinal tract haemorrhage can be a life-threatening emergency, which it has been customary to manage in medical units, seeking the advice of the surgeon only in cases of massive or continuing bleeding. Even in a well-integrated hospital where surgeons work closely with doctors in the medical units and see all such patients on admission the surgeons' subsequent advice may be sought at a rather late stage, and it is possible that the patient could be better dealt with by primary admission into a surgical unit.

It is well established that the most frequent cause of upper gastro-intestinal haemorrhage is acute or chronic peptic ulceration and that many patients with these complaints will cease to bleed spontaneously, although surgery is indicated for massive, continuing, or recurrent bleeding. The type of surgery to be performed in the emergency situation is still not completely resolved, but the experience gained from a study of 40 consecutive gastrectomies carried out by one of us (R. T. G.) coupled with the reported high mortality of gastrectomy for upper gastro-intestinal tract bleeding from many other sources made us feel that we ought to adopt a policy of conservative surgery rather than radical resection in the emergency situation wherever possible. The results of these policies are reported in this paper.

CLINICAL MATERIAL

From January, 1967, all the patients presenting with upper gastro-intestinal tract haemorrhage were admitted to a surgical unit, and this report deals with the first 200 consecutive patients so managed. The patients were all treated initially by non-operative means with regular observations of the pulse and blood-pressure, and blood transfusion was given as indicated by these vital functions. Full blood-count, liver-function tests, and chest radiographs as well as early contrast radiology of the upper gastro-intestinal tract were carried out routinely. Operation was undertaken if the bleeding was massive, continuing, or recurrent. The operation carried out was as conservative as possible. This, in most instances, consisted of suture of the ulcer with unabsorbable material in addition to vagotomy and pyloroplasty. The only exception to this was in patients with chronic gastric ulcers greater than 2 cm. in diameter in whom it was felt that suture would be technically difficult, thus making control of bleeding dubious and presumably carrying a higher risk of re-bleeding. Gastric resection was carried out in this subgroup. All the operative treatment was undertaken by three consultant surgeons in accordance with this policy.

RESULTS

One hundred and thirty-five out of 200 patients (67·5 per cent) with upper gastro-intestinal tract bleeding had a chronic peptic ulcer. Thirty-three

---

* Present address: Manchester Royal Infirmary, Oxford Road, Manchester M13 9WL.

† Present address: Stepping Hill Hospital, Stockport.

‡ Present address: Park Hospital, West Manchester.

patients (16·5 per cent) had an acute gastric ulcer or erosive gastritis, making a total of 168 patients (84 per cent) who had bleeding from an acute or chronic peptic ulcer. There were 9 patients (4·5 per cent) with hiatus hernia, 9 patients (4·5 per cent) with carcinoma of the stomach, and 4 patients (2 per cent) with oesophageal varices. There were 10 patients (5 per cent) with other causes of gastro-intestinal tract bleeding (*Table I*).

It is clear that referring doctors find it far from easy to say whether a patient has bled from the upper gastro-intestinal tract. On many occasions a patient was admitted urgently with a diagnosis of bleeding but was found not to have bled from the upper gastro-intestinal tract. During the period under review 63 such patients were admitted, some of whom had vomited, but the vomit did not contain blood, some of whom had bled from the nose or lungs, and some who had neither vomited nor bled.

Table I.—DIAGNOSIS AND TYPE OF TREATMENT IN 200 PATIENTS WITH UPPER GASTRO-INTESTINAL TRACT BLEEDING

DIAGNOSIS	TOTAL NO. OF PATIENTS	NO. OF PATIENTS UNDERGOING OPERATION		NO. OF PATIENTS HAVING MEDICAL TREATMENT
		'Conservative'	Resection	
Duodenal ulcer	96	45	1	50
Gastric ulcer	28	7	13	8
Anastomotic ulcer	11	5	2	4
Gastritis	33	4	1	28
Hiatus hernia	9	2	—	7
Oseophageal varices	4	2	—	2
Carcinoma of the stomach	9	—	5	4
Mallory–Weiss syndrome	3	—	—	3
Pseudoxanthoma elasticum	1	—	1	—
Leiomyoma of the jejunum	1	—	1	—
Aortic aneurysm	1	—	1	—
Lymphosarcoma	1	—	—	1
Renal failure	2	—	—	2
Haemophilia	1	—	—	1

Operations were carried out on 90 of the 200 patients. Of these, 26 per cent are described as urgent (carried out within 24 hours of admission), 40 per cent are described as emergency (carried out between 24 hours and 7 days after admission), and 34 per cent were early elective procedures (carried out between 1 week and 1 month after admission). The overall mortality was 15 out of 200 patients (7·5 per cent). Nineteen patients had either tumours or non-ulcerative lesions with a bad prognosis, e.g., varices, aortic aneurysm, or a bleeding tendency such as uraemia or haemophilia. There were 8 deaths in this group of 19 patients. Of the other 181 patients with 'innocent' lesions, there were 7 deaths (4 per cent). In this group there were 2 deaths among the 81 patients having operations (3 per cent) and 5 deaths among the 100 patients (5 per cent) who were treated non-operatively.

Conservative surgery was possible in 45 out of 46 patients whose duodenal ulcer required operation, the only exception being one massive duodenal ulcer which it was felt better to treat by gastrectomy. Only 7 out of 20 operations for gastric ulcer were conservative because the ulcer was considered too large to be sutured in 13 cases. There were 7 operations for an anastomotic ulcer of which 5 were conservative (vagotomy and suture of the ulcer), 5 operations for acute erosive gastritis or acute gastric ulcer of which 4 were conservative, and 2 operations for repair of a sliding hiatus hernia.

Age and Sex (*Table II*).—There was a considerable predominance of male patients with a duodenal or anastomotic ulcer but there was a wide age range There seemed to be little difference between the average age and sex distribution in the operative and non-operative groups. However, the average age of the patients with anastomotic ulcer was rather younger than that of the other groups.

Table II.—AGE AND SEX OF PATIENTS WITH BLEEDING PEPTIC ULCER

DIAGNOSIS		NO. OF PATIENTS		AGE (yr.)	
		Male	Female	Mean	Range
Duodenal ulcer	All patients	83	13	54	20–91
	Operative	43	3	53	22–79
	Non-operative	40	10	55	20–91
Gastric ulcer	All patients	17	11	57	28–87
	Operative	14	6	52	28–68
Gastritis	All patients	19	14	47	14–81
Anastomotic ulcer	All patients	10	1	40	25–68

Table III.—MORTALITY AND INCIDENCE OF RECURRENT HAEMORRHAGE IN 181 PATIENTS WITH BENIGN CONDITIONS CAUSING UPPER GASTRO-INTESTINAL HAEMORRHAGE

TYPE OF OPERATION	NO. OF PATIENTS	NO. OF DEATHS	RECURRENT HAEMORRHAGE	TIME OF RECURRENCE
Vagotomy, pyloroplasty, and suture for chronic ulcers	57	0	2	8 and 12 d.
Vagotomy, pyloroplasty, and suture for erosions	4	1	1	Immediately
Gastrectomy	18	1	1	2 mth.
Repair of a hiatus hernia	2	0	1	8 d.
None	100	5	—	—

Further Bleeding (*Table III*).—Sixty-one cases had vagotomy and suture of a peptic ulcer. Of these, 3 had significant further bleeding. One was a patient with multiple gastric erosions and undoubtedly the bleeding continued from this erosive gastritis. Two patients re-bled after suture of a chronic duodenal ulcer at 8 and 12 days. They were treated by further surgery; 1 had simply a resuture of the ulcer but the other patient had a Polya gastrectomy. In both these patients the second procedure produced a satisfactory result. In 18 patients who had a gastrectomy as the primary operative procedure there was one recurrence of the bleeding. This occurred in a young patient who had a massive posterior gastric ulcer which had probably been induced by radiotherapy carried out 18 months previously for a left renal tumour. Two months after his gastrectomy he bled again massively and fatally and was found at post-mortem examination to have a recurrent massive gastric ulcer. One of the 2 patients who had a repair of a hiatus hernia re-bled 8 days after operation, and laparotomy showed that this elderly woman had a chronic duodenal ulcer which had been overlooked at the first operation. She made a satisfactory recovery after the ulcer had been dealt with by vagotomy, pyloroplasty, and suture.

Mortality.—The 8 deaths in the group of patients with malignant or vascular disease were probably inevitable owing to the nature of the disease process (*Table IV*). There were 2 deaths after the 81 operations for peptic ulcer; 1 of these was caused by massive, continuing bleeding from an erosive gastritis which was not controlled by suture. It might have been better to do a gastrectomy in this case. The other death was in the patient who had had previous radiotherapy and had a recurrent massive gastric ulcer with fatal bleeding 2 months after operation (*Table III*).

Table IV.—HOSPITAL MORTALITY IN 19 PATIENTS HAVING CONDITIONS WITH A BAD PROGNOSIS

DIAGNOSIS	NO. OF PATIENTS	OPERATION	NO OPERATION	NO. OF DEATHS
Carcinoma of the stomach	9	5	4	5*
Lymphosarcoma	1	0	1	0
Leiomyoma of the jejunum	1	1	0	0
Renal failure	2	0	2	1
Oesophageal varices	4	2	2	2†
Aortic aneurysm	1	1	0	0
Haemophilia	1	0	1	0

* Two postoperative. † One postoperative.

There were 5 deaths among the 100 patients who were not treated by operation. Two patients (1 with a chronic duodenal ulcer and 1 with a chronic gastric ulcer) were moribund on admission and despite massive blood transfusion died before they could be brought to operation. Three deaths occurred in patients with a chronic duodenal ulcer in all of whom other severe coexistent medical conditions were present. None of these patients died from exsanguination; in fact, there was considerable evidence that the bleeding had stopped. One patient died of a coronary thrombosis and 2 of congestive heart failure. It is unlikely that these patients would have done any better had they been subjected to surgery but, of course, their inclusion in the non-operative group biases the figures slightly. The overall mortality is 7 out of 181 'benign' cases (4 per cent) and the total mortality in all the patients is 15 out of 200 cases (7·5 per cent).

Influence of Drugs.—All the patients were closely questioned about the ingestion of aspirin or steroid-containing compounds. There was a highly significant difference between the general group of patients in whom 12 per cent gave a history of aspirin ingestion and the patients who had an erosive gastritis or an acute gastric ulcer in whom 50 per cent gave such a history. Certain patients appeared to have developed a chronic duodenal or gastric ulcer whilst on steroids, but the significance of steroid ingestion was impossible to evaluate.

Blood Transfusion.—There was a significantly greater amount of blood given to the patients requiring operation, as one would expect from the policy of selection. In the patients with a duodenal ulcer, those who came to operation required a mean of 6·7 pints of blood, whilst those who were treated non-operatively required a mean of 4·6 pints. This difference was even more marked in the patients with gastric ulcer, of whom those who were treated operatively required a mean of 9·2 pints of blood whilst those who were treated without operation required a mean of 2·5 pints of blood.

DISCUSSION

Haemorrhage from the upper gastro-intestinal tract is a common cause of hospital admission and is responsible for 45 per cent of deaths in patients with a peptic ulcer (Weinberg, 1961; Read, Huebl, and Thal, 1965). There are many causes of bleeding from the upper gastro-intestinal tract but the commonest cause—a peptic ulcer—should be readily treated and have a good prognosis. In the present series of 200 consecutive patients with bleeding from the upper gastro-intestinal tract, 67·5 per cent had a chronic peptic ulcer (either gastric or duodenal or anastomotic) and a further 16·5 per cent had erosive gastritis or an acute ulcer. These figures compare with those of Zollinger and Nick (1970) in which 61 per cent had a peptic ulcer and 8 per cent had gastritis and of Halmagyi (1970) in which 59 per cent had a chronic ulcer and 7·5 per cent had erosions.

The common method of hospital care for patients with an upper gastro-intestinal tract haemorrhage is for them to be admitted under the care of a physician and for the surgeon to be involved subsequently. This policy presumably evolved to allow the physician to select the correct patients for surgery. Read and others (1965) stated that only 31 per cent of a randomly selected group of patients with upper gastro-intestinal haemorrhage responded satisfactorily to medical measures alone and that this group had a significantly higher mortality-rate of 15·4 per cent compared with 9·8 per cent in a group which was treated by immediate surgery. Enquist, Karlson, Dennis, Fierst, and Shaftan (1965), who treated three groups, one by immediate operation, one by selection for operation, and one by no operation, found the lowest mortality (14·1 per cent) in the selected operation group. This supports a policy of selection, and we believe that our criteria for selection have been justified by the results in the present series.

Having accepted the desirability of a selective policy, the question arises of whether more may be lost by delaying surgery in the common group of haematemeses, viz., peptic ulcer, than is gained from the increased diagnostic sophistication of the physician in the rare group. It should be recalled that Jones in 1969 found that only 5 per cent of cases of upper gastro-intestinal tract haemorrhage were due to rare causes. A diagnosis can usually be made with confidence when a detailed history has been taken, a physical examination has been made, and the necessary investigations, including contrast radiology, have been carried out. We have found this latter investigation most useful, in contrast to Herrington (1964) and Read and others (1965), who concluded that a barium meal interfered with the comfort and treatment of dangerously ill patients and was a poor diagnostic aid.

Schiller, Truelove, and Williams (1970) point out that despite improved diagnosis, treatment, and operative technique over the past 15 years there has been little improvement in the mortality for upper gastro-intestinal haemorrhage. This is probably due to failure to bring all the patients who will require surgical treatment to operation at a sufficiently early stage. A more ready recourse to operation can be achieved by admitting the patients to a surgical ward, for if the bleeding has to be stopped by operation it is advisable for the surgeon to have the patient under his direct supervision so that operation can be carried out at the optimal time with due urgency. In our series, 45 per cent of the patients required surgical treatment and no less than 26 per cent of these had their operation within 24 hours of admission. We agree with Schiller and others (1970), who advocated a more aggressive approach to upper gastro-intestinal tract bleeding, and believe that this has been achieved by admitting the patients to a surgical ward directly.

A wide age range was present in both the patients undergoing operation and those treated by medical measures alone, and there is no significant difference between the two groups. This would tend to support Northfield (1971) in his view that continuing or repeated bleeding is not necessarily more common in the elderly. Patients presenting with erosive gastritis or acute gastric ulcer were slightly younger than the other patients, but of greater significance was the increased incidence of aspirin ingestion in the former patients. This observation agrees well with previous reports (Goulston and Coome, 1968; Valman, Parry, and Goghill, 1968; Blane and Fryers, 1970; Langman, 1970a, b).

Gastrectomy for the patient with a peptic ulcer without haemorrhage has an acceptable mortality, but when the gastrectomy is for a bleeding ulcer this figure rises to an unacceptable level, such as the 15 per cent reported by Ward-McQuaid, Pease, Smith, and Twort (1960) and the 12 per cent observed by one of us (R. T. G.) in an unpublished series of 40 gastrectomies for bleeding peptic ulcer. Vagotomy and pyloroplasty with undersewing of the bleeding point as an alternative to gastrectomy in the emergency treatment of bleeding duodenal ulcer was suggested by Smith and Farris (1958) and has received support from other observers (Dorton, 1961; Carruthers, Giles, Clark, and Goligher, 1967; Schiller and others, 1970; Boulos, Harris, Wyllie, and Clark, 1971; Bradley and Pollock, 1972). These workers have all reported a reduced mortality without a significant increase in re-bleeding, and our findings would tend to support this.

Treatment of gastric ulcers by a conservative operation is still controversial although it has its advocates (Burge, 1964; Hendry and Bahram, 1965), but little has been written about the treatment of a bleeding gastric ulcer by these means although Read and others (1965) expressed their approval. We have treated gastric ulcers with a diameter of 2 cm. or less by this method with uniformly good results and we consider that even larger gastric ulcers may also be suitable. Acute gastric erosions or gastritis in general respond well to medical treatment, and only 5 out of 33 of our cases required surgery. This agrees with the findings of Schiller and others (1970). Our experience of surgery in this group is too small for any firm conclusion to be drawn, although of the 4 cases treated by conservative operation, 1 continued to bleed and eventually died of blood-loss. One other patient had satisfactory control of the bleeding by the undersewing of four separate acute ulcers. This indicates the principal difficulty in this group, namely the potential multiplicity of ulcers, and clearly it is possible to overlook a significant bleeding ulcer. It has proved possible to carry out a 'conservative operation' in 5 out of 7 anastomotic ulcers with control of the bleeding in all 5 patients.

A conservative operation was performed in 61 patients while resection was carried in only 18 patients (13 of these were for gastric ulcers greater than 2 cm.). Of the 61 conservative operations with suture of the ulcer, there were only 3 patients in whom there was failure to control bleeding. One of these was a patient with erosive gastritis and must be considered to have been a bad selection, 1 was a patient with a large duodenal ulcer which re-bled 8 days after operation, and the other was a patient with a smaller duodenal ulcer. The 2 patients with duodenal ulcers required reoperation at which the bleeding was successfully controlled. There was no re-bleeding after suture of a gastric ulcer with vagotomy and pyloroplasty and we feel that perhaps ulcers greater than 2 cm. could be treated by this means. The only death after a conservative operation was the patient with erosive gastritis who continued to bleed.

It seems that in the case of duodenal ulcers, anastomotic ulcers, and gastric ulcers with a diameter of less than 2 cm. vagotomy, pyloroplasty, and suture of the ulcer comprise a safe and efficacious operation with a low mortality and little danger of re-bleeding. Treatment of solitary acute gastric ulcers by this method appears to be equally satisfactory, but diffuse erosive gastritis not responding to medical measures still requires gastric resection.

GASTRODUODENAL ULCERATION AND HAEMORRHAGE OF NEUROGENIC ORIGIN

BY ELIZABETH A. LEWIS*
NEUROSURGICAL UNIT, ROYAL CHILDREN'S HOSPITAL, MELBOURNE, AUSTRALIA

SUMMARY

The incidence, clinical experience, and management of gastroduodenal ulceration following intracranial disease over a 5-year period at the Royal Children's Hospital, Melbourne, are reported.

Usually the children present with a decline in the conscious state and falling blood-pressure. The maximum danger period is the first 7–10 days after an acute episode of brain-stem compression. The gastro-intestinal bleeding may not be overt, but the haemoglobin falls steadily. Small premonitory haemorrhages may herald torrential blood-loss. Early vagotomy and pyloroplasty with oversewing of the ulcer provide the best operation for these children, and there have been no major postoperative gastrointestinal symptoms in a short-term follow-up.

IT has been known for many years that there is an association between ulceration of the stomach and duodenum and brain disease. This is not a common clinical problem, but it has been noted to be increasing over the past 10 years, possibly due to the increased survival of neurosurgical patients.

The terminology is confusing, as the pathological mechanisms are unknown in spite of much experimental work. 'Stress ulcer' and 'Cushing's ulcer' are common terms, and examination of the literature shows that there is confusion between multiple small ulcers, gastric softening, and the punched-out single large ulcer in the duodenum, which is referred to here as a 'neurogenic' ulcer.

Clinical recognition of gastroduodenal bleeding or ulceration can be difficult, particularly in the unconscious patient. The risk of the use of steroids (knowing their possible role in ulceration) is ever present.

Treatment is controversial; many workers advocate a non-operative approach, whereas others insist on radical excision.

This paper attempts to reappraise the clinical situation by giving a short historical review, presenting some new cases, and examining clinical experience.

HISTORICAL REVIEW

At a time when gastroduodenal ulceration was almost unknown as a clinical entity to physicians and pathologists, Schiff (1867) wrote: 'In the study of human pathology it has long been recognized that certain diseases of the brain and especially disturbances of the base are associated with particular disorganization of the mucosa of the stomach characterized by haemorrhagic spots and partial softening, and most of these observations have been made on infants.' Schiff quotes other writers on this subject, but he seems to have been unaware of the significant contribution of John Hunter some 100 years before. Hunter, in 1772, had already noted a connexion between head injury and 'gastromalacia'. Rokitansky in 1841 (cited by Cushing, 1932) described this association and mentioned hyperacidity as a probable cause of the gastric lesions.

Cushing made a further contribution to this subject in his Balfour lecture of 1932 when he described a series of patients some of whom were found at autopsy to have gastromalacia similar to that described by Hunter. Other cases in this series had gastric or oesophageal erosions or ulceration.

Meanwhile Curling in 1842 had described acute lesions of the duodenum occurring as a complication of severe burns in young people. He described 4 personal cases and collected a further 8 from the literature in whom death occurred as a result of massive haemorrhage from an ulcer situated on the posterior wall of the first or second part of the duodenum. These ulcers measured up to 2 cm. in diameter. According to the clinical records of the Royal Children's Hospital, Melbourne, the gastroduodenal lesions that have occurred in acute intracranial disorders corresponded more closely to Curling's description than that of Cushing and previous writers, and therefore they are currently referred to as 'neurogenic' ulcers.

In the subsequent literature dealing with the relationship between lesions of the nervous system and gastroduodenal ulceration or haemorrhage (Schiff, 1867; Cushing, 1932; Heslop, 1938; Watts and Clark, 1969) three facts emerge:—

1. This is an association which occurs especially in infancy and childhood.
2. It is a complication of acute rather than of chronic lesions of the brain, often occurring after operation.

---

* Present address: Department of Neurology and Neurosurgery, Addenbrooke's Hospital, Hills Road, Cambridge CB2 2QX.

3. It is not related to any single brain pathology, having been described as a complication of tumour, trauma, infection, haemorrhage, or ischaemia, or of the immediate postoperative period following craniotomy for any of these lesions. No particular region of the brain can be shown to be responsible.

Table I.—INCIDENCE OF GASTRO-INTESTINAL LESIONS RELATED TO THE SITE OF THE BRAIN TUMOUR AT AUTOPSY (1958–68)

SITE OF TUMOUR	NO. OF GASTRO-INTESTINAL LESIONS	TOTAL NO. OF CASES	PERCENTAGE INCIDENCE
Brain-stem, thalamus	3	8	37·5
Supratentorial	3	15	20
Infratentorial	3	29	10
Total	9	52	

Physiologists from the late nineteenth century onwards have demonstrated that erosions and ulcers of the stomach can be produced by lesions of the hypothalamus and brain-stem. More recent work (Beattie and Sheehan, 1934; Heslop, 1938; French, Porter, Van Amerongen, and Raney, 1952; Porter, Movius, and French, 1953; Feldman, Burnbaum, and Behar, 1961; Leonard, Long, Thomas, Nicoloff, and Wangensteen, 1963) suggests that the two most important systems are the anterior and posterior hypothalamus and their connexions with vagal nuclei in the medulla. Gastroduodenal lesions occur as a result of stimulation of the anterior hypothalamus or of ablation of the posterior hypothalamus. This experimental work, however, has added little to the knowledge of the cause of gastroduodenal ulceration, as no relationship to the clinical situation has been found.

CLINICAL EXPERIENCE

During a 5-year period from 1965 to 1970 at the Royal Children's Hospital, Melbourne, approximately 100 tumours and 1600 head injuries were admitted.

Table I shows the incidence of gastro-intestinal lesions related to the tumour site at autopsy in a series of children with tumours. Note the high incidence (37·5 per cent) of lesions in the brain-stem and thalamus.

Table II.—DETAILS OF CHILDREN WITH CEREBRAL LESIONS AND CLINICAL HAEMORRHAGE FROM THE GASTRO-INTESTINAL TRACT IN THE PRESENT SERIES, 1965–1970

16	7 yr.	Astrocytoma of lateral wall of third ventricle	Duodenum	+	Non-operative	Satisfactory	Death 3 weeks after diagnosis from effect of tumour

Clinical experience with this form of gastro-intestinal haemorrhage comprises 16 patients, including 10 with cerebral tumours, 4 with acute haematomas, and 2 patients with massive cerebral oedema (*Table II*). In every child there was acute and severe embarrassment of brain-stem function at some stage, and this was sufficient in several cases to cause respiratory arrest for periods of up to 30 minutes.

Every child who needed operation had major blood-loss, which in some cases amounted to almost complete exsanguination. The time interval between injury and haemorrhage varied from 48 hours to 10 days. There was no constant relationship between the state of the patient and the time of the haemorrhage.

CASE REPORTS

Case 1.—A 10-year-old boy presented with a 2-month history of back pain, ataxia, and headache. On examination he showed bilateral papilloedema, nystagmus on looking to the left, and poor co-ordination on both sides. The gait was broad-based and Romberg's sign was positive. Investigation confirmed the presence of a posterior fossa tumour, and at operation a large cystic and solid astrocytoma was removed from the right cerebellar hemisphere. It had spread to the left side and was continuous with the ependyma of the fourth ventricle.

Postoperatively the patient was slow to regain normal consciousness, and he required daily lumbar puncture to reduce his intracranial pressure. He was improving when on the sixth postoperative day he suddenly had a haematemesis, followed by melaena stools. The haemoglobin fell from 13·3 to 9 g. per cent over 12 hours.

Laparotomy was performed within 24 hours of the start of bleeding, but no localized ulcer was found. The haemorrhage was coming from multiple gastric surface ulcers. Vagotomy and pyloroplasty was performed, and the bleeding stopped. His subsequent course was of continued slow improvement, further lumbar punctures being necessary for the relief of high intracranial pressure. He was finally discharged 8 weeks after admission and 6 weeks after his haemorrhage.

Case 5.—A boy of 3½ years presented with a history of vomiting for 3 months, clumsiness for 2 months, and increasing ataxia. On examination he was a well-nourished boy with a head tilt to the right, nystagmus on gaze to left, wide-based gait, and bilateral intention tremor. Bilateral papilloedema developed in hospital.

Investigation confirmed the presence of a posterior fossa tumour and a ventriculo-atrial shunt was performed. A preoperative dose of vincristine per 2 mg. m.^{2} was given. Two days later a medulloblastoma was removed from the fourth ventricle. During the removal of the last portions of the tumour from the floor of the fourth ventricle, bradycardia and then respiratory arrest occurred. Both these continued for a period of 30 minutes.

Postoperative recovery was uneventful, although the patient had a right hemiparesis and right abducens palsy at this stage. He commenced nasogastric feeding the morning after operation. On the third postoperative day he developed a tachycardia of 130–160 per minute, which was followed over several hours by pallor and a fall of blood-pressure to 70 mm. Hg and of haemoglobin to 5 g. per cent. There was no external evidence of blood-loss, no blood in the gastric aspirate, no melaena, and no abdominal distension or tenderness.

Anaemia due to infection was suspected, but a normal white-blood count appeared to exclude this. A blood transfusion was given and the patient responded satisfactorily. Twelve hours later his pulse again rose, the blood-pressure fell, and the haemoglobin was 6 g. per cent; more blood was given. Twenty-four hours later he had his first melaena and some blood was seen in the gastric aspirate. Further large melaenas occurred and two transfusions of fresh blood were given. Bleeding continued, with further melaena stools and fresh blood aspirated from the nasogastric tube. Rapid transfusion just maintained a peripheral pulse in a pale unconscious child, and a moribund patient was presented to the surgeon.

Laparotomy revealed the whole gut to be distended with blood. On opening the duodenum the gastroduodenal artery pulsated in the base of a large posterior duodenal ulcer. The vessel was underrun with a silk suture, and routine vagotomy and pyloroplasty were performed. Two and a half litres of blood were transfused in the operative and immediate postoperative periods. The haemoglobin was 13·2 g. per cent on the day after operation. No further fresh bleeding occurred and the boy made an uneventful recovery from this operation. Total blood replacement over the whole period was 4 litres.

The patient was discharged well after radiotherapy and cytotoxic therapy 2 months after admission. He was readmitted 10 months later with an abdominal wound infection, which was drained, but he developed septicaemia and died. At his death there was a recurrence of the tumour, but no clinical evidence of further ulceration. Autopsy showed a scar in the posterior wall of the first part of the duodenum.

Case 9.—This child first presented to the Royal Children's Hospital, Melbourne, when aged 3½ years, with vomiting, headache, and neck stiffness. Lumbar puncture revealed blood-stained cerebrospinal fluid, but investigations failed to find a cause for this. After recurrent subarachnoid haemorrhages he had a posterior fossa exploration, which showed the presence of blood-clot only, followed by a second operation 1 month later which revealed a medulloblastoma on the floor of the fourth ventricle. His course during this time was stormy, but after the second operation he began to improve and was finally discharged from hospital with residual right facial weakness and mild spasticity of the legs. One year later he presented with sudden onset of drowsiness, slurred speech, ataxia, and left-sided fits. Investigations revealed a right subdural collection which was aspirated and he made a good recovery. A ventriculo-atrial shunt was performed for developing hydrocephalus 3 years after his presentation. A shunt infection occurred and the shunt had to be removed. Two months later he was readmitted following haematemesis, from which he died 3 years and 2 months after his initial presentation. At autopsy there were multiple superficial ulcers of the oesophagus and stomach with residual tumour around the operation site and down the spinal cord. There was recent cerebral and spinal cord haemorrhage.

These 3 cases illustrate the full range of clinical manifestations in the series. The first boy (*Case* 1) presented with bleeding while he was clinically improving, having had complete removal of his tumour, 1 week after operation. The second boy (*Case* 5) presented early in the postoperative period. In this child the severity of the bleeding was not recognized early, and a severely shocked child was presented for surgery. The third boy (*Case* 9) bled as a terminal episode with recurrent tumour 3 years after surgery.

Eight patients came to operation (*Table II*). Of these, 7 had a large penetrating ulcer on the posterior aspect of the first or second part of the duodenum, eroding the gastroduodenal artery. The only patient in the series who died following operation for gastroduodenal bleeding had three operations (*Table II*, *Case* 2). On the first occasion a simple suturing of the ulcer was performed. Because of recurrent bleeding this was followed successively by partial gastrectomy, and finally vagotomy 1 month after the initial haemorrhage.

One child who had vagotomy and pyloroplasty (*Table II*, *Case* 13) had further ulceration for two reasons: (1) severe head trauma with cerebral oedema; (2) large doses of steroids. Although vagotomy and pyloroplasty controlled the gastro-intestinal haemorrhage he continued to be unwell, and after 9 days there was marked abdominal distension with evidence of small-bowel obstruction on radiography. On re-exploration there were subphrenic abscesses on both sides, and the suture line of the pyloroplasty had broken down. A Polya-type gastrectomy was performed but sepsis continued and the suture line parted, discharging fluid through the abdominal wound. At the third operation this suture line was reconstituted with a few wide sutures and the area was drained. As the child improved, the wound slowly healed. The failure of vagotomy and drainage was probably due to a combination of sepsis and large doses of steroids.

Overall the methods of treatment may be considered in three groups:—

Group I (8 patients): Non-operative treatment.

Group II (5 patients): Conservative régime followed by operation.

Group III (3 patients): Early operation.

Of the 8 patients in group I, 2 patients were considered to be of hopeless prognosis owing to the nature of the cerebral lesion (*Table II*, *Cases* 9 and 16), while the remainder had small haemorrhages which at no time produced major changes in their haemodynamic state.

The children in the remaining two groups had major blood-loss, and in all the cases in group II conservative treatment with alkalis, cholinergic drugs, and carbenoxolone for several days failed to prevent massive recurrent haemorrhage. This is hardly surprising in view of the operative findings of large penetrating ulcer craters with the erosion of a major vessel. This finding is the main reason for the bias towards early surgery in these children. An ulcer which erodes a major vessel will not heal, and early operation avoids the complications caused by severe blood-loss and multiple blood transfusions.

Most gastro-enterological surgeons now favour vagotomy and some form of gastric drainage (usually pyloroplasty) as the treatment for duodenal ulcer; therefore this method was selected for the children who required surgery. As only 1 of these patients had either recurrent bleeding or gastro-intestinal symptoms (*Table II*, *Case* 13) during ensuing periods of up to 2½ years, the selection of this method appears justified. In addition, its simplicity when compared with the alternative procedure of gastrectomy seems desirable in the very sick patient. It may also avoid the long-term complications of gastric resection in childhood.

DISCUSSION

In previous papers much emphasis has been placed on experimental work, stimulating or destroying areas of the hypothalamus, or measuring the acidity of gastric juice, but too little on the relationship between the two.

There are two postulated physiological pathways by which the brain can influence gastric function to produce ulceration: (1) via the pituitary–adrenal axis, by corticosteroid release; (2) via the vagus, stimulating (*a*) parietal-cell activity or (*b*) gastrin release.

Some earlier workers implicate the pituitary–adrenal axis. Porter, Movius, and French (1953) showed that stimulation of the posterior hypothalamus produced a later increase in gastric secretion which was not abolished by vagotomy or cervical chordotomy but was abolished by adrenalectomy which he attributed to a humoral pathway via adrenocorticotrophic hormone and the adrenal cortex. However, the importance and even the presence of this pathway have since been in doubt (Davenport, 1966), and cannot be used at this stage to explain gastroduodenal ulceration.

It is simple to postulate that vagal overactivity occurs for two reasons:—

1. Although there is a diversity of cerebral lesions which can produce gastric or duodenal ulceration, the common factor is usually cerebral oedema, and its impact is predominantly on the hypothalamus and brain-stem, producing distortion or displacement. This indirect effect can lead to thrombosis of vessels, oedema, and petechial haemorrhage in the area. The vagal nuclei in the brain-stem are affected, and vagal stimulation, or lack of inhibition, occurs.
2. The success of vagotomy and drainage as a treatment in these patients points to vagal overactivity being a factor.

The crux of the matter seems to be whether there is hyperacidity associated with ulceration or ulceration due to some other mechanism. The literature is divided on this point (Feldman and others, 1961, Watts and Clark, 1969). Rokitansky, as early as 1841, suggested that uninhibited action of the vagus was the most likely cause of the ulceration owing to 'extreme acidification of the gastric juice'.

If gastric hyperacidity is not implicated there must be either a vascular effect or a local change in the mucus secretion to account for ulceration. These latter two changes would explain the common finding of multiple petechial spots or superficial ulcers in the gastro-intestinal tract after acute cerebral disorders, but it is hard to see how they may cause a single 'punched-out' ulcer in the duodenum.

Steroids have long been implicated as a major factor in the formation of gastric or duodenal ulcers in neurosurgical patients. They are known to change the constitution of the gastric mucus and to delay the normal regeneration of gastro-intestinal mucosal cells, which are continuously being lost, but exogenous steroids cannot be the only factor. Six patients in the present series did not receive steroids.

It is important to note that the patients reported in this series were all seriously ill, and yet with early operation the prognosis was good. Many of the patients were unconscious or semiconscious, and the first indication of the haemorrhage was a noticeable decline in the state of consciousness which, of itself, seemed to point to some intracranial complication. In every case, however, the decline in consciousness was accompanied by a significant fall in the blood-pressure, which is unusual in acute cerebral disturbance. A falling haemoglobin level established the fact that bleeding was occurring. The initial warning haemorrhage was followed by further episodes, and in 7 patients catastrophic bleeding occurred with a severe fall in blood-pressure, sometimes within a few hours of the onset of symptoms. In earlier patients in the series surgery was often postponed until this stage, and the operation was performed on a severely shocked patient, with all its added hazards. The reason for such delay is obvious, as the patients were in the early postoperative phase after intracranial surgery. However, early operation was followed in all cases by a good result. In the 2 patients who required more than one operation, one case was diagnosed late and had four ulcers (*Case* 13, *Table II*), and the other was so ill that the shortest procedure possible was chosen (*Case* 2, *Table II*) but further bleeding occurred and the patient died.

Early treatment depends on an awareness of gastro-intestinal haemorrhage as a complication of brain disease, and very close observation from the time that warning blood-loss occurs. Blood must be available at this time to avoid adding hypovolaemic shock in an already seriously ill patient. A continuing fall in the haemoglobin level and continued need for blood replacement are indications for operation. In children the operation of choice is vagotomy and gastric pyloroplasty drainage with direct control of bleeding points where possible.

Acknowledgements.—Part of this work was supported by a grant from the Research Foundation of the Royal Children's Hospital, Melbourne, to whom I am grateful. My thanks are due to the neurosurgeons who allowed me to report these cases and to the surgeons of the hospital who performed the surgery.

CARCINOMA OF THE PROSTATE

A RETROSPECTIVE ANALYSIS OF CONVENTIONAL MANAGEMENT IN 110 CASES

By D. A. AUBREY
THE UNIVERSITY DEPARTMENT OF SURGERY, WELSH NATIONAL SCHOOL OF MEDICINE

and W. B. PEELING
THE ROYAL GWENT HOSPITAL, NEWPORT

Summary

This paper reports a retrospective analysis of the results of conventional management of prostatic carcinoma in 110 patients. The 5-year probability survival was 23 per cent. A correct initial diagnosis was made in only 53 per cent of the patients. Indices of prostatic carcinoma as opposed to benign prostatic hypertrophy would appear to be a higher age-group, the occurrence of retention without preceding prostatism, and obstructive uropathy disproportionately severe in relation to symptoms. A normal serum prostatic acid phosphatase does not preclude the diagnosis of carcinoma of the prostate.

Treatment with oestrogenic hormones produced regression of the primary neoplasm in 60 per cent of the patients but rarely affected metastatic lesions. The principal cause of death was not metastatic disease but lower urinary-tract obstruction or operations for its relief.

In England and Wales in 1968, 3390 men died from prostatic cancer and 4228 from accidents (Registrar General's statistics). The accident figures regularly provoke considerable public concern, whereas the comparable and more miserable mortality from prostatic carcinoma is fatalistically accepted, largely because the disease affects older men whose life span is already limited. The established views on the anatomy of the prostate, on the pathogenesis of prostatic carcinoma, and on the efficacy of hormonal treatment of this disease have been seriously questioned (Herbst, 1941, 1942; Huggins and Hodges, 1941; Huggins, Stevens, and Hodges, 1941; Nesbit and Baum, 1951; Franks, 1956; McNeal, 1965, 1968, 1969), with the result that the average clinician treating cancer of the prostate finds the situation confusing. In an attempt to gain an overall view of this disease and to assess the results of its conventional management we have reviewed the clinical data of 110 patients with cancer of the prostate attending a large regional hospital. While retrospective studies must always be interpreted with care, in the absence of information and guidance from controlled prospective clinical surveys we feel that a comprehensive clinical review may give perspective to the problem of prostatic cancer.

MATERIAL AND METHODS

The case records of 110 patients who had attended St. Woolos and the Royal Gwent Hospitals, Newport, between 1960 and 1969 inclusive were analysed. Only adequately documented patients were included. Complete follow-up was obtained in 86 per cent of patients.

RESULTS

Age.—Most of the patients (91 per cent) were aged between 60 and 80 years, with the peak incidence in the eighth decade (*Fig.* 1). Only 1 patient was less than 50 years old and 10 were aged under 60 years.

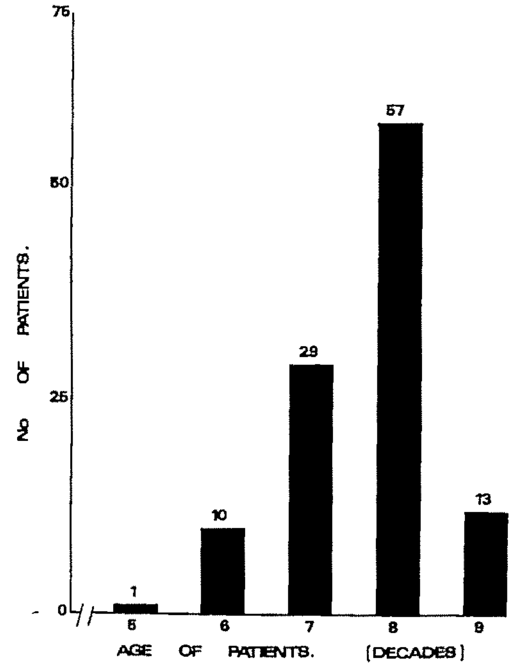

FIG. 1.—The age distribution in 110 patients with prostatic carcinoma.

Clinical Features.—The reasons for clinical presentation are shown in *Table I*. The commonest cause of presentation was retention of urine (acute or chronic) and it was interesting that in many instances retention was not preceded by significant symptoms of prostatism. At presentation, 34 patients (31 per cent) had metastatic disease (*Table II*) and of these, 17 (15 per cent) had symptoms due solely to metastases. Symptomless bone secondaries were present in only 2 patients. The bones of the rib-cage, upper limbs, and skull were affected by metastases only in the presence of advanced carcinomatosis. In 98 patients (90 per cent) symptoms had been present for under 1 year and 38 of those presenting with lower urinary-tract obstruction had been previously symptom-free.

Table I—REASONS FOR CLINICAL PRESENTATION

Reason for Presentation		*No. of Patients*
Urinary retention		63
Acute retention with prostatism	12	
Acute retention without prostatism	38	
Chronic retention with overflow incontinence	13	
Prostatism (without frank haematuria)		26
Metastases (local or general)		17
Haematuria		3
Rectal pain		1
Total		110

Investigations.—Severe anaemia was present in only 2 patients and both were moribund at presentation (*Table III*). The blood-urea was elevated in 44 per cent of patients and 8 patients were sub-uraemic at presentation. The serum prostatic acid phosphatase (S.A.P.) was elevated in 31 patients (30 per cent). Microscopic haematuria was common. Although intravenous pyelograms were performed in only 52 patients (47 per cent), in a third of these there was evidence of upper urinary-tract abnormality —hydro-ureter, hydronephrosis, or a non-functioning kidney.

Table II.—SITES OF METASTATIC SPREAD IN 34 PATIENTS AT PRESENTATION

Metastatic Involvement		*No of Patients*
General skeletal carcinomatosis		16
Solitary osseous metastases		13
Lumbosacral spine	8	
Pelvis	4	
Femoral head	1	
Lateral pelvic walls, with oedema of the legs		4
Rectovesical fistula		1
Total		34

Table III.—SUMMARY OF THE CLINICAL INVESTIGATIONS AT PRESENTATION

INVESTIGATION	FINDINGS	NO. OF PATIENTS
Haemoglobin	<50 per cent 50–70 per cent Normal No record	2 10 90 8
Blood-urea	>100 mg. per cent 40–100 mg. per cent Normal No record	8 33 53 16
Erythrocyte-sedimentation rate (Westergren)	>50 mm. per hr. 21–50 mm. per hr Normal No record	15 20 32 43
Serum prostatic acid phosphatase*	>10 units per ml 4–10 units per ml Normal No record	16 15 71 8
Midstream specimen of urine	Pyuria alone Microscopic haematuria alone Pyuria and microscopic haematuria Normal No record	13 11 44 25 17
Intravenous pyelography	Prostatic filling defect Upper urinary-tract abnormality Normal No record	8 21 33 48

* Assayed before the commencement of oestrogenic hormone therapy (normal <4 units per ml.).

Diagnosis and Management.—Even with the help of laboratory and radiological investigations, a correct initial diagnosis was made in only 58 patients (53 per cent; *Table IV*). Forty-four patients were diagnosed as having benign prostatic hypertrophy and in these cases the correct diagnosis became apparent only when difficulty was experienced at prostatectomy or when material became available for histological examination.

All the patients except the 2 who were moribund at presentation received oestrogenic hormone therapy, and in 40 (36 per cent) this was the sole method of treatment. Operative procedures were carried out in 71 patients (64 per cent; *Table V*), mostly to relieve urinary obstruction. No patient underwent pituitary or adrenal ablation.

Table IV.—METHODS OF FINAL DIAGNOSIS OF PROSTATIC CARCINOMA

INITIAL DIAGNOSIS	NO. OF PATIENTS	METHOD OF ESTABLISHMENT OF FINAL DIAGNOSIS	NO OF PATIENTS
Benign prostatic hypertrophy	44	Histology following 'Prostatectomy'	31
		Transurethral resection	13
Fibrous prostate	3	Histology following transurethral resection	3
Prostatic calculi	3	Histology following transurethral resection	3
Urethral stricture	1	Histology following transurethral resection	1
Vesical neoplasm	1	Histology following transurethral resection	1
Prostatic carcinoma	58	Clinically (per rectum; S.A.P.; osseous metastases on radiograph)	37
		Elevated S.A.P.	8
		Osseous metastases on radiograph	2
		Histology following transurethral resection	9
		Autopsy	2

Table V.—OPERATIVE PROCEDURES PERFORMED IN 71 PATIENTS

Operation	*No. of Patients*
Prostatectomy	28
Attempted prostatectomy	3
Transurethral resection	30
Suprapubic cystostomy	7
Orchidectomy	3
Total	71

Histological Diagnosis.—Material for histological study was obtained in 66 patients (60 per cent); the neoplasm was poorly differentiated in 23 cases and well differentiated in 33. Carcinoma of the prostate coexisted with benign prostatic hypertrophy in 10 patients (9 per cent); in 7 cases the neoplasm represented a focal lesion in an adenomatous area, whereas in the remaining 3 cases it was situated peripherally and was incompletely removed at 'prostatectomy'.

Response to Oestrogenic Therapy.—The response of the primary tumour to oestrogens could be assessed in 53 patients who received no treatment other than these hormones. In 30 patients (60 per cent) there was objective evidence of regression of the primary lesion, in that spontaneous micturition was established and the prostate became softer. Conversely, in 23 patients there was clear evidence of progression of the disease while on oestrogen therapy; in 13 patients within 1 year, and in a further 8 within 2 years. These patients developed lower urinary-tract obstruction with evidence of local extension of the primary lesion.

The response of the primary tumour to oestrogens did not appear to be related to the level of the S.A.P. at presentation. Thus, regression of the primary lesion occurred in 16 of 29 patients with a normal S.A.P. and in 11 of 18 patients with an elevated S.A.P. During the first 2 years after presentation there was no difference in the survival of patients with normal or elevated levels of S.A.P. at presentation.

The response of metastatic lesions to oestrogens could be assessed in 28 patients. There was objective evidence of regression in 2 patients, and in a further 2 cases the disease appeared to have been arrested. In contrast, 24 patients appeared to derive no, or at best minimal, benefit from oestrogenic hormone therapy, for new metastatic lesions appeared within 3–12 months.

Table VI.—CAUSES OF DEATH IN 81 PATIENTS

Cause of Death	*No. of Patients*	
Prostatic carcinoma		47
Carcinomatosis	19	
Uraemia due to obstructive uropathy	15	
Hospital deaths directly attributed to post-operative complications (e.g., shock, secondary haemorrhage, sepsis, anaesthesia)	13	
Causes unrelated to prostatic carcinoma		26
Cardiovascular disease (myocardial infarction, pulmonary embolus, cerebrovascular accident)	15	
Unknown		8
Total		81

Table VII.—CAUSES OF HOSPITAL DEATHS IN 26 OF 71 PATIENTS WHO WERE SUBJECTED TO SURGERY

Cause of Death	*No. of Patients*	
Postoperative complications (excluding cardiovascular disease)		13
Following prostatectomy	7	
Following transurethral resection	6	
Cardiovascular complications		8
Following prostatectomy	4	
Following transurethral resection	3	
Following suprapubic cystostomy	1	
Uraemia following suprapubic cystostomy		3
Carcinomatosis following suprapubic cystostomy		2
Total		26

Fate of the Patients.—Complete follow-up data were available for 95 patients (86 per cent), of whom 14 were alive and 81 dead (*Table VI*). Most of the deaths occurred within 1 year of presentation and no patient with metastases at presentation was alive 3 years later. The overall 5-year probability survival was 23 per cent. Relatively few patients died from carcinomatosis. Thus, although 34 patients had evidence of metastatic disease at presentation and a further 11 developed osseous metastases during the course of treatment with oestrogens, only 19 (16 per cent) actually died from the effects of distant disease. In contrast, 28 patients died from local disease, i.e., lower urinary-tract obstruction or operations for its relief. Of the 26 patients who died from causes unrelated to their carcinoma, 15 died from cardiovascular disease.

There was a crude correlation between the level of the S.A.P. at presentation and survival. Thus, no patient with an elevated S.A.P. at presentation was alive 5 years later, whereas all 5-year survivors had a normal S.A.P. at presentation. This is in keeping with our findings that elevated levels of S.A.P. were found in 30 per cent of patients with poorly differentiated primary lesions but in only 10 per cent of patients in whom the primary was well differentiated.

Of the 71 patients who were subjected to surgery, 26 (36 per cent) died in the postoperative period (*Table VII*).

DISCUSSION

The meagre 5-year probability survival emphasizes that prostatic carcinoma is indeed a lethal disease. Moreover, the fact that some 30 per cent of patients had metastatic disease at presentation indicates that initially the condition may produce trivial or no symptoms. Even when symptoms do arise the diagnosis is often missed. From an analysis of our clinical material the following features would seem to be useful indices in differentiating prostatic cancer from benign prostatic hypertrophy:—

1. The condition has a higher peak age incidence.
2. It often presents as retention without previous prostatism or with only a short history of urinary-tract symptoms.
3. The degree of upper urinary-tract obstruction is often disproportionately severe in relation to the short duration of symptoms.

The fact that the S.A.P. was elevated in less than 30 per cent of the patients needs emphasis. Thus, although an elevated S.A.P. provides useful corroborative evidence of carcinoma, a normal assay in no way refutes this diagnosis. In our series the diagnosis of carcinoma was made on the basis of an elevated S.A.P. alone in only 8 patients (7 per cent; *Table IV*).

Although surgery for the relief of urinary obstruction may become mandatory in patients with carcinoma of the prostate, patients with this condition are clearly poor operative risks, for of 71 patients who underwent operation, 26 died in the post-operative period and 9 more within 1 year. Indeed, it seems worth re-emphasizing that more patients died from lower urinary-tract obstruction or from operations for its relief than from carcinomatosis. Clearly, therefore, operation should be avoided wherever possible in patients with prostatic carcinoma, and more effective drug treatment of the primary lesion without recourse to surgery might be expected significantly to improve survival. In our series many patients were subjected to surgery in the mistaken belief that they were suffering from benign prostatic hypertrophy. If the correct diagnosis had been established initially then fewer patients would have undergone surgical procedures. Hence, more accurate diagnosis, with perhaps resort to prostatic cytology and biopsy, might favourably influence survival.

Treatment with oestrogenic hormones produced regression of the primary neoplasm in approximately 60 per cent of patients. In contrast, metastat lesions appeared to be more often hormone resistan The latter finding is disturbing, since recent wo has suggested that treatment with oestrogens m precipitate or aggravate cardiovascular disea (Arduino, Moines, Bailar, and others, 1967), and the present series 15 patients died from such cause Since our results showed that metastases were rare responsive to oestrogenic hormones, our finding contrary to those in the report of Arduino and othe (1967), would suggest that these hormones be us only in the treatment of the primary lesion. Whi we appreciate that the present study is a retrospecti one we feel that our figures indicate the necessity f a prospective controlled trial designed to define t usefulness or otherwise of oestrogenic hormones i the treatment of metastatic prostatic carcinoma.

It is interesting to speculate as to whether prostat carcinoma passes through two phases: an initi phase, when the primary lesion is hormone sensitiv and a later phase, when the metastatic lesions an possibly the primary are hormone resistant. Altern tively there may be two distinct types of prostat carcinoma: one which is hormone sensitive and t other hormone resistant *ab initio*.

INTRAPELVIC DERMOID CYSTS IN ADOLESCENT GIRLS PRESENTING WITH URINARY RETENTION

A REPORT OF 2 CASES

By C. J. L. STRACHAN*
WESTERN INFIRMARY, GLASGOW

RETROVERTED gravid uterus, uterine fibroids, pelvic abscess, or ovarian carcinoma are well-recognized causes of acute retention of urine in females. However, although urinary symptoms of frequency, dysuria, and suprapubic pain are mentioned in large reviews of ovarian dermoid cysts (Peterson, Prevost, Edmunds, Hundley, and Morris, 1955; Forshall, 1960; Boles, Hardacre, and Newton, 1961; Thatcher, 1963) only 1 case of acute retention of urine can be found (Glinski, 1969). Retroperitoneal dermoid cysts arising from the sacrum are much less common. One previous case of a presacral dermoid cyst in a 40-year-old male producing an acute retention of urine has been reported (Talbot, 1959). Two cases are reported here, one a presacral dermoid cyst and the other an ovarian dermoid cyst, in patients who presented with acute retention of urine.

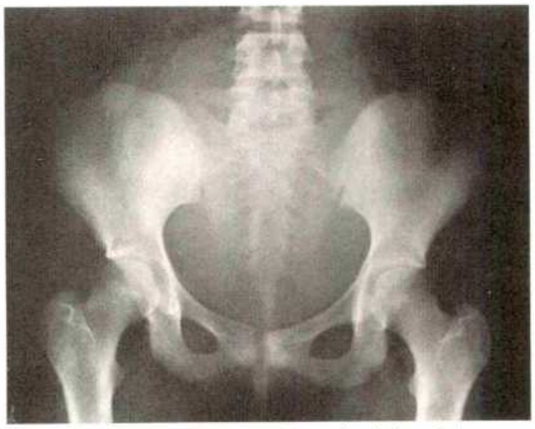

FIG. 1.—*Case* 1. Plain radiograph of the pelvis.

CASE REPORTS

Case 1.—A 13-year-old girl, who was on holiday in Scotland, was admitted to the Western Infirmary, Glasgow, on 17 April, 1969, with acute retention of urine. She had not voided urine for 14 hours and on examination her abdomen was dull to percussion up to her umbilicus. A catheter was passed and produced only 450 ml. of urine. The lower abdominal swelling persisted and a rectal examination revealed a fluctuant retroperitoneal mass just above the anal canal.

A straight radiograph of the abdomen at this stage showed a round radio-opaque mass 15 cm. in diameter centred over the anterior of the sacrum (*Fig.* 1). Diagnostic ultrasound reported 'a large transonic cystic mass, containing a few scattered solid areas, arising out of her pelvis; consistent with a dermoid cyst' (*Fig.* 2).

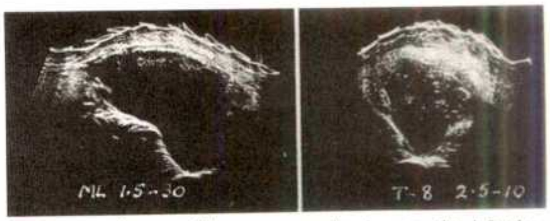

FIG. 2.—*Case* 1. Ultrasonogram showing on the left the inferior edge of the cyst outlining the anterior aspect of the sacrum.

As the patient was in Glasgow for only a few days, she returned home to Bournemouth where she was operated on 2 weeks later. The cyst was aspirated and over 4 litres of sebaceous-looking fluid were obtained. Her postoperative recovery was slow owing to a pelvic abscess. Since discharge from hospital she has had no urinary symptoms.

Case 2.—A 13-year-old girl was first seen at the Western Infirmary, Glasgow, on 10 Nov., 1967, with acute retention of urine. She was catheterized and 800 ml. of urine were

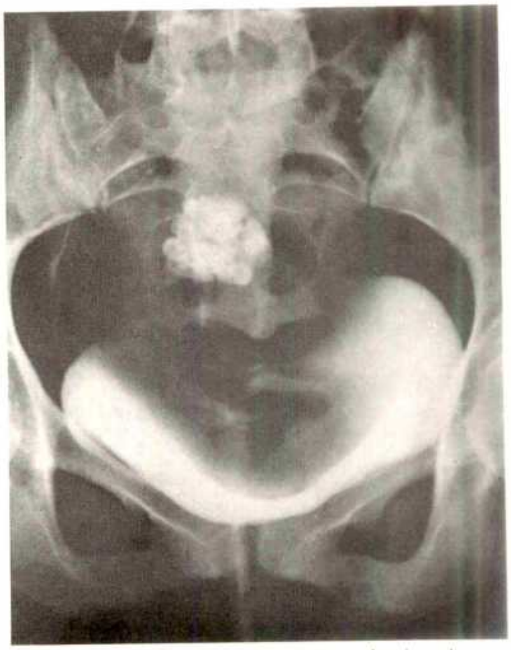

FIG. 3.—*Case* 2. Intravenous cystogram showing the cyst, containing teeth, indenting the bladder.

---

* Present address: Clinical Research Wing, Kings College Hospital, Denmark Hill, London SE5 8RX.

obtained. She remained trouble free for 2 years till 15 Nov., 1969, when she was readmitted with further retention of urine, on this occasion passing 930 ml. of urine after being given 0·25 mg. of intramuscular carbachol. She was again symptom free for 2 years until 2 Oct., 1971, when a 900-ml. retention of urine was similarly relieved. Urine cultures were negative on each occasion and it was felt that each episode of retention had been related to a stressful situation.

The patient was then referred to the Urological Department where intravenous pyelography showed her bladder to be considerably indented by a soft-tissue mass with opacities in its centre, suggesting the presence of teeth within a dermoid cyst (*Fig.* 3). Diagnostic ultrasound showed the presence of a large complex cystic mass rising out of the pelvis low down posteriorly with the bladder enlarging over and above it (*Fig.* 4). The appearance was consistent with the radiological diagnosis of an ovarian dermoid cyst.

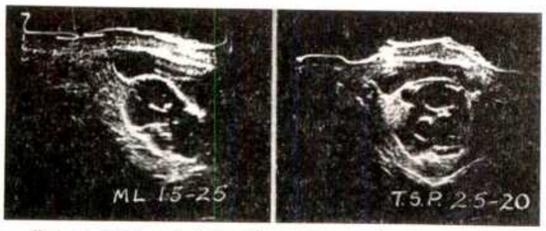

FIG. 4.—*Case* 2. Lateral ultrasonogram showing on the left the bladder flattened at its base by the impacted cyst. (*Reproduced by kind permission of the 'British Journal of Radiology', Vol.* 43, *p.* 611.)

Cystoscopy and an examination under anaesthetic were performed. The bladder mucosa and bladder neck were normal, but there was a midline bulge into the bladder base which was slow to fill out. On bimanual examination a ballotable cyst was felt in the posterior fornix.

At operation on 2 Nov. a large cyst arising from the left ovary filled the pelvis (*Fig.* 5). The left Fallopian tube was seen stretched out over its circumference and the bladder extruded above and in front of it. The uterus was squashed flat against the bladder neck by the tense, impacted, non-adherent cyst. The cyst was easily removed and macroscopic examination showed the 13-cm. thin-walled cyst to contain mucoid sebaceous material with several well-formed teeth and daughter cysts arising from a cartilaginous pedicle. Histology showed various tissues and epithelia but no evidence of malignancy.

Postoperatively the patient had a transient retention of urine until 12 hours after anaesthesia when this resolved spontaneously. Her subsequent progress was unremarkable.

DISCUSSION

The acute retention of urine in both the cases presented here appears to be the culmination of a chronic process.

Overflow incontinence from chronic retention in which an ovarian dermoid cyst perforated into the bladder has been reported (Wood, 1953). The retention in this case was thought to be due to severe cystitis and differs from that in the cases in the present report. Both cases had considerable extrinsic obstruction at the bladder neck. The mechanism must be similar to the retention produced by lower uterine fibroids, retroverted gravid uterus, pelvic abscess, or ovarian carcinoma. Talbot (1959) felt that progressive distortion stretches the bladder neck, disturbing the neuromuscular mechanism and leading to hypertrophy of the wall. This hypothesis is supported by the quick relief obtained by carbachol, the ease of catheterization, and the ultrasonic picture obtained in *Case* 2 (*Fig.* 4).

The single case reported from Poland was of an infected dermoid cyst incarcerated in the pelvis (Glinski, 1969). Catheterization produced 900 ml. of urine. That this was an acute or chronic episode is supported by the upper urinary-tract hydronephrosis and hydro-ureter seen preoperatively which had disappeared 40 days later.

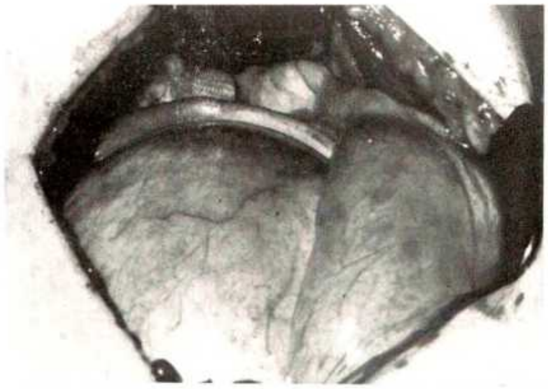

FIG. 5.—*Case* 2. Operative photograph, showing the bladder on the right with the more spherical cyst behind it, crossed by the left Fallopian tube.

The knowledge that girls may develop slowly growing ovarian or presacral dermoid cysts should remind the surgeon to exclude this possibility when examining a girl with an acute retention of urine.

Both the cases presented here illustrate the extremely valuable role of diagnostic ultrasound in the diagnosis of pelvic masses (Morley and Barnett, 1970). While still complementary to good radiographs, ultrasound has added a new dimension to the preoperative assessment of size, position, and content of dermoid cysts.

RUPTURED SPLEEN: A RADIOLOGICAL PITFALL AND A SUGGESTED MODIFICATION

By PETER G. A. LEIGH*

DEPARTMENT OF SURGERY, UNIVERSITY OF WITWATERSRAND AND GENERAL HOSPITAL, JOHANNESBURG

SUMMARY

The diagnosis of splenic injury may be obvious from the outset, or it may either be masked by other injuries or present much later in the phase of convalescence. Delayed rupture may occur as late as 1 month after injury, at which time it may be embarrassing for the doctor and dangerous for the patient. Any additional diagnostic measure is therefore considered appropriate in cases of abdominal trauma. Schorr and Danon (1967) described the value of a film taken in the left lateral decubitus position with barium in the stomach, and noted the significance of a distance of more than 3 cm. from the greater curvature of stomach to the lateral abdominal wall. A case is described in the present paper in which a false-positive result was obtained with the method of Schorr and Danon (1967) owing to interposition of a heavy mobile omentum. A right ateral decubitus film had been taken while the patient had a gas-filled stomach, and had revealed a distance of only 2·2 cm. between the greater curve and lateral abdominal wall. In this projection the mobile omentum had obviously fallen away, allowing the stomach to rise towards the left abdominal wall and thus demonstrating the absence of a fixed mass in this region.

Although it would appear that this technique is more useful in cases of delayed rupture than in acute cases, it is suggested that routine use be made of the right lateral decubitus film with a gas-filled stomach, prior to films being taken according to Schorr and Danon's (1967) method. This modification might also be useful in the diagnosis of diseases of the spleen, and in following the progress of patients after treatment.

TRAUMA to the spleen has assumed more significance recently owing to the increasing number of motor-car accidents and other forms of blunt abdominal injury. The typical case of acute splenic rupture usually does not present major difficulty in management, for even f the classic story of trauma followed by the development of signs of 'acute abdomen' and evidence of continuing internal bleeding does not pinpoint the exact pathology, it at least indicates the need for aparotomy, at which time the diagnosis will become apparent and correct treatment will be carried out. On the other hand, the clinical course of delayed or occult splenic rupture may entail some considerable embarrassment for the clinician and danger for the patient.

The following case reports are presented to show how a modification of a previously described radiological method for the diagnosis of splenic rupture may assist the surgeon, and to indicate one form of false-positive result that may be obtained with the unmodified method.

CASE REPORTS

Case 1.—A heavily built 47-year-old policeman was admitted to hospital following a motor-car accident. He had sustained a moderate concussion, a large right supra-orbital haematoma with laceration, and a simple posterior dislocation of the right hip. There was no chest or abdominal pain or tenderness, and the neurovascular supply of the right lower limb was intact. His laceration was sutured and the hip was relocated without difficulty under general anaesthesia.

His early postoperative course was uneventful and he remained apyrexial until the tenth post-injury day. At this stage a low-grade fever became evident but no obvious cause could be found. Three days later some deep-seated bruising appeared over his lower left costal margin and he complained of some pain in the left loin. The possibility of delayed splenic rupture was considered. Radiological examination of the chest was normal apart from a doubtful fracture line in the left ninth rib. Antero-posterior films of the abdomen revealed a gas-distended stomach in the normal situation (*Fig.* 1). A right lateral decubitus film (*Fig.* 2) showed the greater curve of the stomach to be lying approximately 2·2 cm. from the inner aspect of the left ninth rib. A left lateral decubitus film taken with barium in the stomach (*Fig.* 3) revealed the corresponding distance to be 11·3 cm. and in view of this gross increase it was decided to carry out laparotomy with the presumptive diagnosis of delayed splenic rupture and perisplenic haematoma.

At operation the greater omentum, which was heavily laden with fat, was interposed between the stomach and the inner aspect of the left lower costal margin in front of the spleen. Traction was required to dislodge the omentum from this position, after which it was noted that the spleen, although slightly enlarged and firmer than usual, was intact. There was no haemorrhage in the left subphrenic region. The liver was enlarged and firm with an appearance of active cirrhosis. A biopsy of the liver was taken and the operation was completed without incident. The post-operative course was uneventful.

Histological examination of the liver showed an active cirrhosis of the alcoholic type.

Case 2.—A 62-year-old female was admitted as an emergency after having fallen from a chair and sustained a blow to the lower left chest. Examination revealed localized tenderness over the costal margin anteriorly, but respiration was fairly adequate and the lung fields were clear. The abdomen was soft and non-tender to palpation. Radiographs did not reveal any fractures.

The patient was sent home, but she returned to hospital 2 weeks later complaining of exacerbation of pain in the left hypochondrium and persistent pain on breathing. Examination showed well-marked bruising in the left hypochondrium and a tender palpable mass projecting below the rib margin. A presumptive diagnosis of delayed splenic rupture and perisplenic haematoma was made and she was submitted to a radiographic study. The stomach was distended with gas by the ingestion of a teaspoonful of sodium bicarbonate with a quarter of a teaspoonful of tartaric acid. A right lateral decubitus film was taken and showed that the proximal end of the greater curve of the stomach closely approximated to the inner margin of the lower left ribs (parietal peritoneum), but that the distal border was indented and 'displaced' away from the lateral peritoneal line. It was thought that the gaseous distension might be inadequate, and therefore an additional amount of the gas-forming substance was administered. The subsequent film (*Fig.* 4) showed quite unequivocally that there was no space-occupying lesion in the splenic area. In fact, the excellent contrast provided by the air in the stomach enabled a very clear outline of the spleen to be seen. In view of this finding operation was withheld and subsequent examinations suggested that the mass was probably a haematoma attached to the anterior wall of the left hypochondrium. The patient has remained in good health.

---

*Formerly Department of Surgery, Kaplan Hospital, Rehovot, Israel.

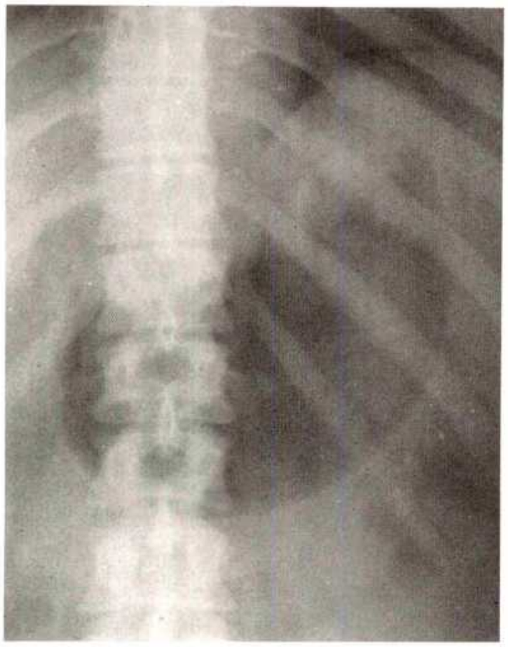

FIG. 1.—*Case* 1. Erect film of the abdomen, showing a gas-filled stomach in the normal undisplaced position.

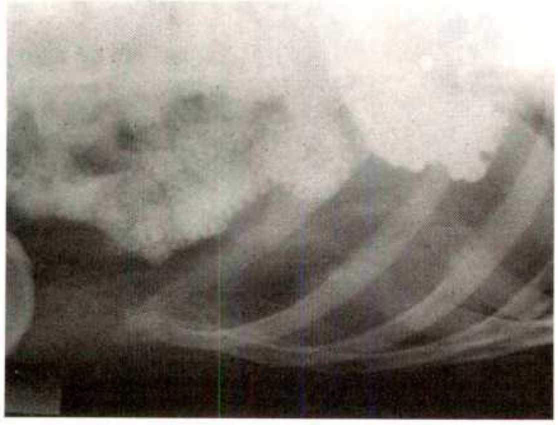

FIG. 3.—*Case* 1. Left lateral decubitus film of the barium-filled stomach, showing the greater curvature of the stomach displaced upwards away from the lateral peritoneal border (a positive result according to the criteria of Schorr and Danon, 1967).

Several young patients who had been involved in accidents and who were suspected of having a splenic or other visceral injury have also been subjected to this radiological procedure in the acute phase. In 1 male patient an exploratory laparotomy was postponed because of the normal 'ascent' of the greater curve with gas distension and his condition soon began to improve. He recovered without operation and with the retrospective diagnosis of retroperitoneal haematoma. Three other patients who were subjected to laparotomy and in whom the gas-filled stomach ascended to the peritoneal border were all found to have lesions away from the splenic area to account for their abdominal symptoms.

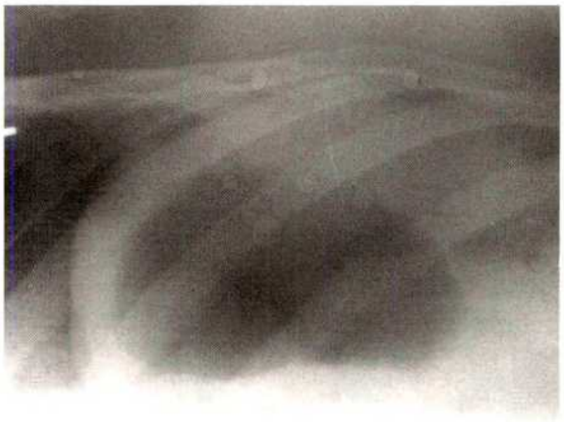

FIG. 2.—*Case* 1. Right lateral decubitus film, showing the greater curvature of the gas-filled stomach lying close to the lateral peritoneal border.

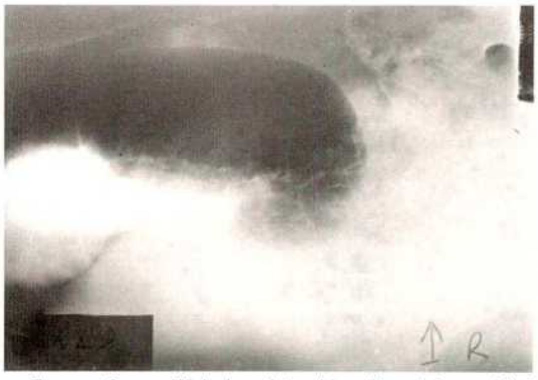

FIG. 4.—*Case* 2. Right lateral decubitus film of the gas-filled stomach with the greater curvature lying in the normal situation close to the lateral border of the peritoneum. Note that a clear outline of the normal-sized spleen can be seen.

DISCUSSION

It is not infrequent that a patient, having recently sustained multiple injuries, leaves hospital only to return within a short time with signs of 'acute abdomen'. The diagnosis of delayed splenic rupture is made and is usually verified by operation, but it can be wrong in a small number of cases. Sizer, Wayne, and Frederick (1966), in a review of the literature, reported that delayed rupture occurred more than 1 month after the initial injury in 10 per cent of cases, while Wilkinson (1968), in a review of 90 cases of splenic rupture seen at the Johannesburg Hospital, noted that 27·2 per cent of the cases of delayed rupture occurred later than 1 month after injury.

In view of the dangers inherent in delayed rupture of the spleen, any additional diagnostic measures which might lead to the earlier diagnosis of splenic injury should be considered. In 1967 Schorr and Danon described the method of radiographing the patient in the left lateral decubitus position after the oral administration of barium, and noting the position of this medium along the greater curvature of the stomach in relation to the lateral abdominal wall, as indicated by the inner margin of the lower ribs. They stated that the distance between these two points should not exceed 3 cm. and pointed out that values in excess of this figure indicate the presence of a space-occupying peri- or parasplenic mass. The reliability of this sign was noted to be positive in 71 per cent of the cases of Schorr and Danon (1967), while Wilkinson (1968) noted that it was positive in 87·5 per cent of cases in which it was used. Schorr and Danon (1967) stated that this method obviated the false-positive results which are obtained when the small intestine and colon interposed between the stomach and parietes. While this may be true for an empty bowel, it might well not apply to a fully loaded colon or fluid-distended loop of small intestine which may be as heavy as a barium-filled stomach. The present *Case* 1 demonstrated that Schorr and Danon's (1967) premiss does not apply when a heavy, bulky, and mobile omentum interposes itself between stomach and left lateral parietes.

Scant reference has been made to Schorr and Danon's (1967) technique in the recent literature. State, Getzen, and Laning (1969), in an analysis of 100 cases of splenic rupture, mentioned that they found 'no particular diagnostic examination to be of specific unequivocal benefit' in these cases, while Sargison, Cole, and Kyle (1968), in their series of 45 cases, used radiographs merely to confirm the presence of fractured ribs or other intrathoracic injuries.

The present *Case* 1 illustrates how the left lateral decubitus/barium method may give a positive result according to Shorr and Danon's criteria, but that the cause may not be related to splenic trauma. A mobile structure may certainly interpose itself between the barium-filled stomach and the parietes, but taking a radiograph of the gas-filled stomach in the right lateral decubitus position will allow the greater curvature to 'ascend' towards the left parietes as the mobile mass moves away by gravity. A fixed mass such as a perisplenic haematoma would not be expected to drop away. By this additional manœuvre, evidence may be forthcoming either in favour of or against the diagnosis of splenic injury.

The author suggests that this modification might also be used without the barium study in cases in whom it is deemed inadvisable to give barium by mouth.

GASTRODUODENOSCOPY USING AN IRRIGATING CYSTOSCOPE*

By R. M. KIRK

HAMPSTEAD GENERAL HOSPITAL AND WILLESDEN GENERAL HOSPITAL, LONDON

PERORAL fibre-optic gastroscopy is well established but duodenoscopy is less reliable (Morrissey, Tanaka, and Thorsen, 1967; Shearman, Warwick, Macleod, and Dean, 1971). It may be difficult to be sure that all the bulb has been examined, and in some patients the instrument may not pass through the pylorus. Kirk (1970) found at operation in 123 patients with duodenal ulcers or scars that the pyloroduodenal canal was less than 10 mm. in diameter in more than 40 per cent of the patients, yet the duodenoscope exceeds this diameter.

The surgeon may be faced with a difficult decision at operation, particularly in two circumstances. First, from time to time he is asked to explore the abdomen of a patient suffering from incapacitating dyspeptic pain in whom all the investigations have proved negative or only suggestive of peptic ulcer; he finds no abnormality in the abdomen and the duodenal bulb is unscarred. Secondly, he operates for the cure of a well-established duodenal ulcer, with typical features demonstrated on the barium-meal films; to his surprise he finds no evidence of duodenal ulcer or scarring.

It is not possible to exclude peptic ulcer or scar by examining the outside of the bowel. In 900 laparotomies 9 active ulcers (4 duodenal, 2 post-bulbar, and 3 gastric) were found when the bowel was opened that were completely undetectable from outside the bowel.

It is usual to perform gastroduodenotomy when seeking a peptic ulcer and to close this in the form of a Heineke-Mikulicz pyloroplasty. If the surgeon finds a duodenal ulcer he completes the procedure by performing a vagotomy. If he does not find an ulcer he has irrevocably damaged the antral pump and pylorus, possibly adding to the patient's disability. Even when an ulcer is found, many surgeons would prefer to leave the pylorus untouched and to carry out highly selective vagotomy as the elective procedure.

Various instruments have been tried in order to inspect the inside of the stomach and duodenum through a gastrotomy, including sigmoidoscopes, protoscopes, various specula, and retractors. These have all proved unreliable, especially for examining the duodenal bulb. The only dependable instrument that has been tried is the irrigating cystoscope.

TECHNIQUE

A gastrotomy, 0·5 cm. long, is made in the anterior gastric antral wall and encircled with a purse-string seromuscular suture. The gastric contents are aspirated. The cystoscope is inserted, the purse-string suture is tightened around it, clamped, and given to the care of an assistant. Non-crushing clamps are placed across the cardia of the stomach or lower oesophagus and the first loop of jejunum. The stomach and duodenum are filled with sterile water from a reservoir placed not more than 10 cm. higher than the stomach.

The whole stomach, duodenal bulb, and ampulla of Vater may be examined. If the duodenal loop is mobilized it is possible to see almost to the duodenojejunal junction.

When the examination is completed the cystoscope is withdrawn, and the stomach contents are aspirated. The purse-string suture is tightened, tied, and reinforced with further sutures. The clamps are removed from the upper stomach and jejunum.

ADVANTAGES

The cystoscope will pass through all but the narrowest pyloroduodenal canals. Because it is rigid it can be manœuvred easily and its position in the bowel can be checked by feel and by observing the light through the bowel wall. The optical system allows excellent views of the mucosa. All general surgeons have been well trained in handling the cystoscope.

Although peroral fibre-optic gastroscopy will normally have been carried out before operation for gastric ulcer, re-examination with a cystoscope can be done at operation. If the small biopsy specimen removed through the peroral instrument leaves doubt about the nature of the ulcer, Lowsley's forceps may be inserted to take a larger specimen. Diathermization of bleeding points could be performed; Youmans, Patterson, McDonald, and Derrick (1970) reported the diathermization of bleeding lesions in the stomach using a resectoscope inserted through a gastrostomy.

It is as a duodenoscope that the cystoscope is most valuable. A duodenal ulcer or scar has been confidently confirmed or excluded on 16 occasions. Biopsy specimens could be removed, avoiding the need for duodenotomy. The ampulla of Vater can be seen and biopsy specimens can be removed, avoiding the need for duodenotomy. The ampulla could potentially be cannulated using a cystoscope fitted with an Albarran lever. The duodenum may be inspected without the need to damage the pyloroduodenal canal.

concerned about sutures?

Do you feel sure that the sutures that you are using
are the best available, both for the job and the patient?
The simplest way to choose the best is to go to the manufacturer
who makes the finest sutures in the widest range of materials –
• each most suitable for its specific purpose
• every one made to the same high standards

Silk
for silicone impregnated smoothness and high tensile strength and no capillary action.

Ti·cron*
braided polyester fibre, silicone impregnated smoothness (no capillary action) with long flex life, Ti·cron* gives the inert security essential for cardio-vascular work.

Dacron*
the long flex life of braided polyester fibre, inertness and high tensile strength make this suture especially suitable for cardio-vascular work.

Dermalon*
smooth monofilament nylon.

Flexon*
The twisted, stainless steel suture that handles like silk.

Dermalene*
polyethylene monofilament with the best handling properties and, of course, no capillary action.

Catgut (plain and chromic)
precision diameter sutures with uniform strength of strands.

Dexon*
the near-perfect absorbable suture that supersedes catgut

The finest sutures on the finest needles

why not prove them for yourself

REGENERATION OF PARIETAL AND VISCERAL PERITONEUM

A LIGHT MICROSCOPICAL STUDY

By A. T. RAFTERY

DEPARTMENT OF ANATOMY, SCHOOL OF MEDICINE, UNIVERSITY OF LEEDS

SUMMARY

1. The healing of visceral and parietal peritoneum has been investigated using conventional light microscopy, Häutchen preparations, and by using 1 μ sections of epoxy-resin-embedded material to follow the activity of peritoneal macrophages labelled with polystyrene spheres (0·79 μ in diameter).

2. Healing has been found to occur rapidly and for the most part without adhesion formation. Parietal peritoneum and caecum are covered by a new mesothelial membrane in 8 days, while the liver is covered in 7 days.

3. It has not been possible to support the theory that peritoneal macrophages are transformed into mesothelial cells via fibroblasts. The results obtained in the present investigation suggest that the new mesothelial layer is derived directly from the subperitoneal fibroblast.

CONFLICTING opinions still exist with regard to the precise nature of peritoneal regeneration. Hertzler (1919) showed that when a defect was made in the parietal peritoneum of an animal 'the entire surface becomes endothelialized simultaneously and not gradually from the borders as in epidermitization of skin wounds'. This finding has been confirmed by others (Robbins, Brunschwig, and Foote, 1949; Johnson and Whitting, 1962; Ellis, Harrison, and Hugh, 1965; Eskeland, 1966a; Hubbard, Khan, Carag, Albites, and Hricko, 1967). However, disagreement exists among these workers with regard to the origin of the cells which form the new mesothelial lining. Some workers (Robbins and others, 1949; Williams, 1955; Ellis and others, 1965; Hubbard and others, 1967) consider that regeneration of the mesothelial lining takes place by metaplasia of the subperitoneal fibroblasts, while others (Cameron, Hassan, and De, 1957; Johnson and Whitting, 1962; Bridges and Whitting, 1964) consider that mesothelial cells are detached from the adjacent intact peritoneum and become implanted on the wound surface where they proliferate and eventually give rise to a continuous sheet of mesothelial cells. Johnson and Whitting (1962) also suggest that monocytes and macrophages present in the wound exudate can become transformed into mesothelial cells—a suggestion which has received support from Eskeland (1966a, b) and Eskeland and Kjaerheim (1966a, b). Much of the difficulty in the study of peritoneal regeneration arises in the problem of identifying mesothelial cells in histological sections cut perpendicular to the wound surface, but this can be overcome by using Häutchen preparations which permit inspection of the surface cells *en face*. The present study was undertaken in an attempt to clarify the problem of which type of cell is responsible for the new mesothelium, and also, in view of the fact that little attention has been given to the healing of visceral peritoneum, to compare the healing of defects of visceral peritoneum with that of defects of parietal peritoneum using Häutchen preparations.

MATERIALS AND METHODS

A total of 100 adult male Sprague-Dawley rats, weighing 220–250 g., were used in this investigation. The rats were anaesthetized with ether. The abdominal cavity was opened by a 5-cm. midline incision. Wounds approximately 1 mm. deep and either ½ cm. or 1 cm. square were made in the liver capsule by a tangential cut with a scalpel blade. A wound was also made on each side of the midline in the parietal peritoneum, that on the left side being 2 cm. square and that on the right side 1 cm. square. The peritoneum together with the underlying layer of muscle was removed within this area. In other animals the caecum was delivered through the wound and the peritoneum was stripped from the antimesenteric border over areas of about 1 × 1 cm. or 1 × 2 cm. Haemostasis was obtained by applying pressure from a gauze swab. The abdominal incision was closed in two layers, catgut sutures being placed through the musculoperitoneal layer and silk sutures through the skin. Animals were killed by exsanguination under ether anaesthesia at intervals of 12 hours up to 3 days, then at daily intervals up to 8 days, and at 10 and 14 days after operation.

The liver was removed, rinsed briefly in 5 per cent glucose, immersed in 0·25 per cent silver nitrate for 30 seconds, rinsed again in 5 per cent glucose, and then fixed in 10 per cent formol–saline for 8–12 hours. The wounds in the parietal peritoneum were removed together with a wide margin of normal peritoneum, pinned flat on cork, and treated in the same manner as the liver. A ligature was placed around the ileocaecal junction and the ascending colon, and the distended caecum was removed *in toto*. It was then treated as described above. Häutchen preparations of the wounds were subsequently made, as described by Eskeland (1966a), and stained with haematoxylin. In other animals the wounds were excised, fixed in formol–sublimate or Bouin's fluid, dehydrated, and embedded in paraffin wax. Serial sections were cut perpendicular to the wound surface at 6 μ. These sections were stained with haematoxylin and eosin, and either by the picro-Gomori method or Ledrum's stain (Humason, 1962) for fibrin and collagen. Smears of peritoneal fluid were obtained at each stage, and were either air-dried and stained with Wright's blood-stain or fixed in equal parts of ether and absolute alcohol and stained by the method of Papanicolaou.

Specimens of parietal peritoneum, liver, and caecum were also fixed in 2·5 per cent glutaraldehyde in 0·1 *M* cacodylate buffer, post-fixed in 1 per cent osmium tetroxide in 0·1 *M* phosphate buffer, dehydrated in graded solutions of ethanol, and embedded in Araldite. Sections 1 μ thick were cut on an ultramicrotome and stained with methylene blue–Azure II (Richardson, Jarett, and Finke, 1960).

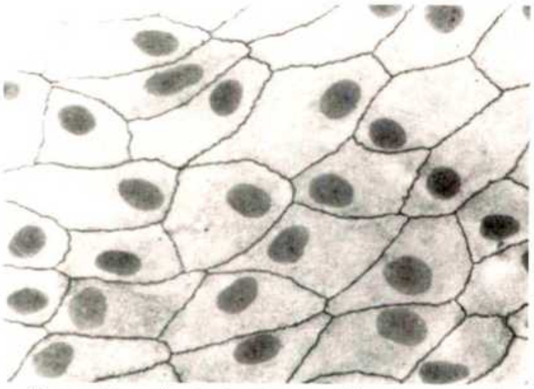

FIG. 1.—Normal parietal peritoneum. Häutchen. (× 222.)

In order to label the peritoneal macrophages some animals were given an intraperitoneal injection of 2·5 ml. of a 0·2 per cent suspension of polystyrene spheres (0·79 μ diameter Dow–Latex; Serva, Feinbiochemica, Heidelberg) in 0·9 per cent saline at the time of operation. Specimens from these animals were processed for Häutchen preparations in order to check if the inflammatory reaction caused by the polystyrene spheres had had any effect on the nature of healing. Some specimens were fixed in 2·5 per cent glutaraldehyde, processed as described above, sectioned at 1 μ, and stained with methylene blue–Azure II. Smears of peritoneal fluid from these animals were fixed in equal parts of ether and absolute alcohol and stained by the method of Papanicolaou. Some non-operated animals were given an intraperitoneal injection of 2·5 ml. of a 0·2 per cent suspension of polystyrene spheres. Specimens of both visceral and parietal peritoneum were fixed in 2·5 per cent glutaraldehyde and processed as described above. Smears of peritoneal fluid from these animals were stained by the method of Papanicolaou.

RESULTS

1. Macroscopic.—Adhesions to the wounds were found in only 6 animals and in each case the liver wound was adherent to the midline wound. During the first 2 days the wounds were uneven and haemorrhagic; thereafter the wounds became paler and by 5 days were usually smooth and glistening. In particular the wounds in the liver capsule were easily seen up to 10 days when they appeared as shiny, greyish-white, puckered areas. In the case of parietal peritoneum it was difficult to distinguish the wound from the surrounding peritoneum after 7 days After 5 days it was difficult to see the wound in th caecum.

2. Microscopic.—

a. Peritoneal Fluid.—Normal peritoneal fluid wa found to contain macrophages, monocytes, lympho cytes, eosinophils, mast cells, and a small number o large cells with a pale, occasionally fragmented nucleus and indistinct cell boundary. The peritonea fluid of operated animals contained the same types of cell except that the macrophages were larger and contained phagocytosed material; in addition, polymorphonuclear leucocytes were present but decreased in number after the third day. In specimens from animals injected with polystyrene spheres the large cells with fragmented nuclei and indistinct cel boundaries were found to contain polystyrene spheres. These cells are most likely either dead macrophages or macrophages which had been damaged when the smears were made. No cells which resembled mesothelial cells were seen in the smears of either normal or operated animals.

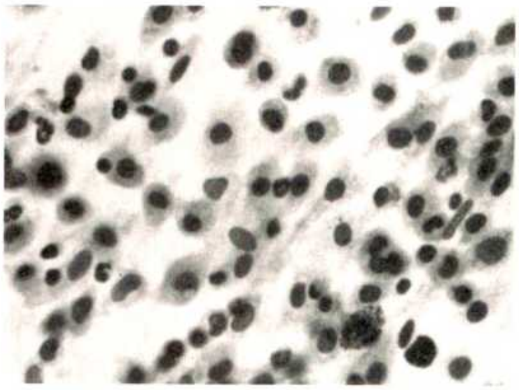

FIG. 2.—Parietal peritoneum at 1 day. Macrophages, monocytes, polymorphs, eosinophils, lymphocytes, and the occasional mast cell are seen on the wound surface. The majority of cells are of the monocyte/macrophage type. Häutchen. (× 222.)

b. Parietal Peritoneum.—Normal parietal peritoneum as seen in a Häutchen preparation is shown in *Fig.* 1. At 12 and 24 hours after injury the surface of the wound was covered by a fibrinous exudate containing red blood-corpuscles and nucleated cells Most of the latter cells resembled peritoneal macrophages and monocytes although polymorphs, eosinophils, lymphocytes, and mast cells were also present (*Fig.* 2).

At 2 days the appearance of the wound surface resembled that at 1 day. During the first 48 hours changes were seen in the mesothelial cells adjacent to the wound. These changes were characterized by widening and loss of definition of the silver lines in Häutchen preparations, pronounced cytoplasmic basophilia in the perinuclear region, and the appearance of two or more prominent nucleoli within the nucleus (*Fig.* 3). By the second day occasiona mitotic figures were seen in the adjacent peritoneum

At 3 days there were marked changes on the wound surface (*Fig.* 4). Polymorphs, lymphocytes, eosinophils, and mast cells were no longer seen and the only cells of the initial inflammatory reaction which remained were round cells with a dark-staining, eccentric kidney-shaped nucleus which were identified as monocytes or macrophages.

A further type of cell was seen at this stage which had a poorly defined cell boundary, was larger than the monocyte, possessed a large, round, or oval nucleus containing one or more prominent nucleoli, and was occasionally multinucleate. In addition, some had pronounced basophilic cytoplasm and resembled the cells seen on the surface of the adjacent peritoneum during the first 48 hours. In some areas of the wound surface these cells were numerous while in others cells of the monocyte/macrophage type were predominant. At this stage silver lines were present around cells in some areas but were wide and often ill defined. Mitotic figures were seen on the wound surface at this stage and were numerous in the mesothelial cells adjacent to the wound.

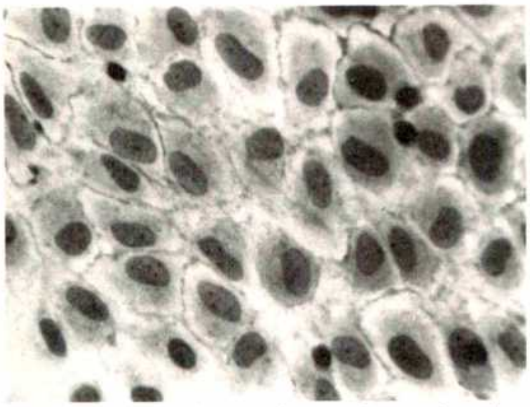

FIG. 3.—Parietal peritoneum adjacent to the wound at 2 days. Note the indistinct silver lines, pronounced cytoplasmic basophilia, and the prominent nucleoli. Häutchen. (× 222.)

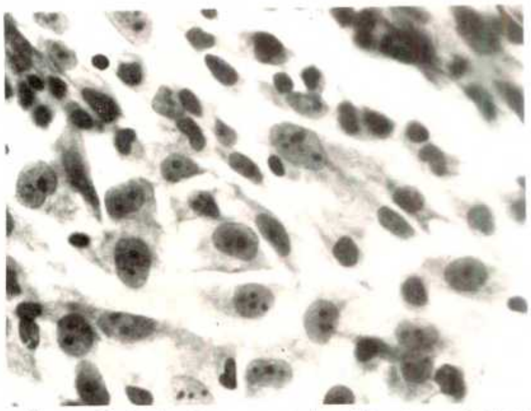

FIG. 4.—Parietal peritoneum at 3 days. Two types of cell are seen on the wound surface, one resembling a monocyte, the other a large cell with indistinct boundary and many prominent nucleoli. Häutchen. (× 222.)

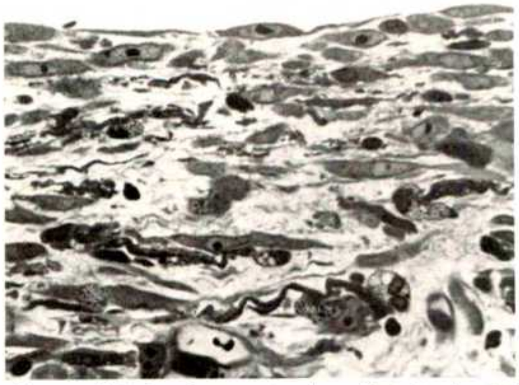

FIG. 5.—Parietal peritoneum at 4 days. Note the elongated flattened cells on the wound surface. They resemble the fibroblasts in the deeper part of the wound except that the cells on the wound surface possess a brush border. Methylene blue–Azure II. (× 222.)

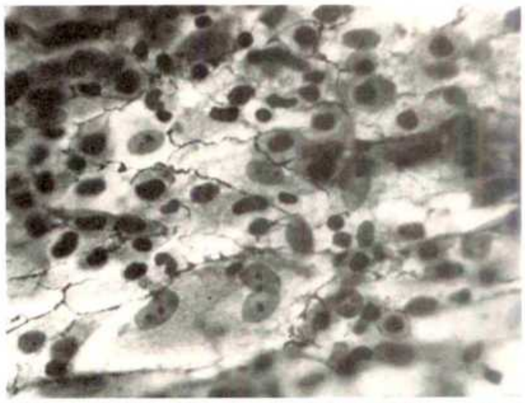

FIG. 6.—Parietal peritoneum at 5 days. Two types of cell are still present on the wound surface but silver lines are seen around the larger cells in some areas. A multinucleate cell is seen on the lower left-hand side. Häutchen. (× 222.)

The appearances on the wound surface were similar at 4 days. In sections cut perpendicular to the surface marked fibroblast proliferation was seen in the base of the wound and occasional strands of fibrin were present in the more superficial parts of the wound. On some areas of the wound surface cells which resembled fibroblasts were seen; they were elongated and flattened and had an oval nucleus with a thin, regular rim of chromatin and a prominent nucleolus (*Fig.* 5). They were considered to be identical with the large cells with prominent nucleoli and pronounced cytoplasmic basophilia seen in the Häutchen preparations. Other cells seen on the surface at 3 and 4 days were round, with a kidney-shaped nucleus with denser chromatin and were identified as cells of the monocyte/macrophage type.

At 5 days the appearance of the wound surface varied from one specimen to another and also in different areas of the same Häutchen preparation. In some areas the surface resembled that of normal peritoneum in that the silver lines were narrow and more regular, although they were less distinct than in normal peritoneum (*Fig.* 6). The cytoplasm still showed marked basophilia and multinucleate cells were seen. In other areas (*Fig.* 7) cells with indistinct boundaries and large nuclei with several prominent nucleoli were present. Scattered between these cells were small cells resembling monocytes. Mitoses were seen on both the wound surface and in the adjacent mesothelium. Sections cut perpendicular to the surface showed flattening of the surface cells in some areas giving the appearance of a continuous layer of mesothelium (*Fig.* 8), while in other areas breaks were seen in the surface layer and cells resembling monocytes were present (*Fig.* 9). Fibroblasts in the base of the wound were now alined parallel to the surface and bundles of collagen were present.

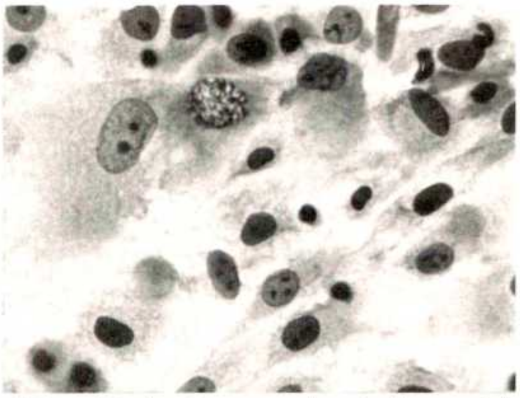

FIG. 7.—Parietal peritoneum at 5 days. Another area of the same preparation as *Fig.* 6. Two types of cell are present but the large cells with prominent nucleoli do not have distinct boundaries. Häutchen. (× 222.)

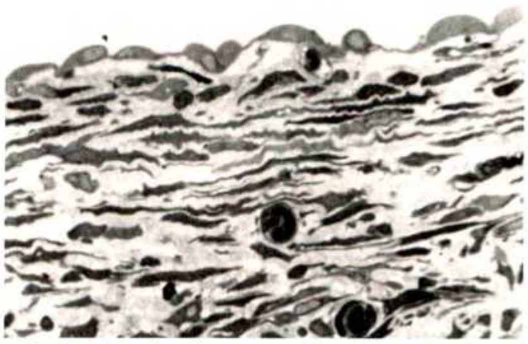

FIG. 8.—Parietal peritoneum at 5 days. The surface layer of cells is beginning to flatten, giving the appearance of a continuous layer of mesothelium. Methylene blue–Azure II. (× 222.)

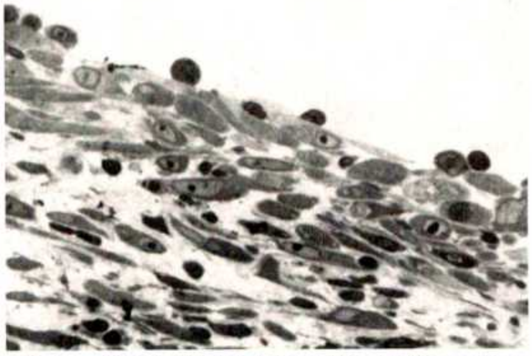

FIG. 9.—Parietal peritoneum at 5 days. Healing is not as advanced as that shown in *Fig.* 8. Small monocyte-like cells are present on the wound surface. Methylene blue–Azure II. (× 222.)

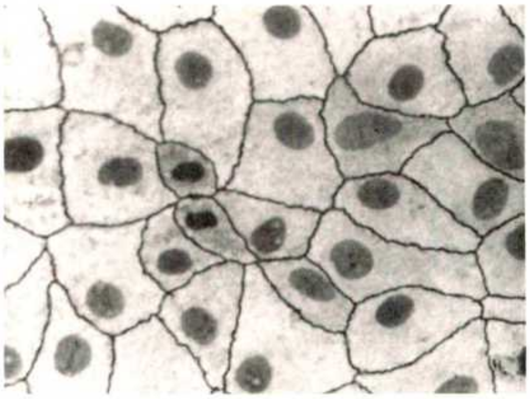

FIG. 10.—Parietal peritoneum at 8 days. There is complete healing of the mesothelial layer. A mitotic figure is seen at the centre of the field. Häutchen. (× 222.)

At 6 days the silver lines between most cells were regular and complete although sometimes they were broader than in normal mesothelium. Cells with prominent nucleoli were often seen. In some areas cells resembling monocytes were still present and occasional multinucleate cells remained on the wound surface.

At 8 days no cells resembling monocytes were seen on the wound surface. The surface was lined with a continuous layer of flattened cells which resembled normal mesothelium except that a few mitotic figures were seen. The prominent cytoplasmic basophilia had disappeared, nucleoli were not as prominent within the nucleus, and the silver lines between cells were sharp and regular (*Fig.* 10). The surrounding mesothelium had also reverted to its normal appearance. Thick bundles of collagen now occupied the base of the wound. At 2 weeks no distinction could be made in Häutchen preparations between the wound surface and normal peritoneum. A thin layer of fibrous tissue covered by a continuous layer of mesothelium occupied the site of the original defect.

There was no difference in the time or nature of healing between wounds 1 cm. and 2 cm. square.

c. Visceral Peritoneum.—

i. *Liver*: Healing of the wounds in the liver capsule resembled the healing of parietal peritoneum for the most part. At 24 and 48 hours appearances were identical with those of the parietal peritoneum both in the wound area and in the adjacent peritoneum.

Two types of cell were seen at 3 days: the small cell of the monocyte/macrophage type and the larger cell with indistinct boundaries and a large nucleus with prominent nucleoli. Again, as in parietal peritoneum, many of the latter types of cell were very large and multinucleate. Some areas showed quite advanced healing at this time when compared with parietal peritoneum. Silver lines occupied many areas although they were broad and incomplete. The exudate around and between monocyte-like cells was impregnated with silver. Mitotic figures were seen in the adjacent mesothelium at this stage.

At 5 days the majority of the cells on the wound surface were large and contained a large nucleus with prominent nucleoli. There was marked cytoplasmic basophilia.

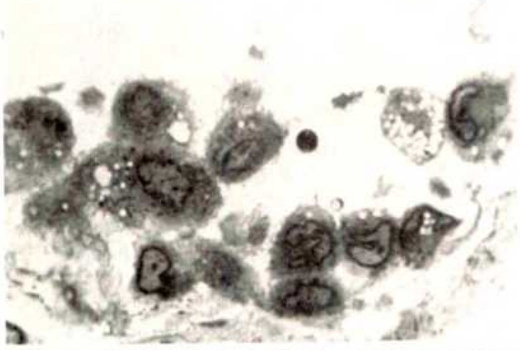

FIG. 11.—Parietal peritoneum at 2 days. Polystyrene spheres, which appear as white dots in the dark cytoplasm, are seen within the macrophages on the wound surface. In some cells the polystyrene spheres are aggregated and appear as white patches within the cytoplasm. Methylene blue–Azure II. (×900.)

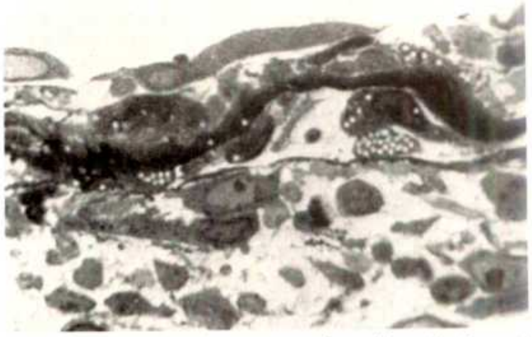

FIG. 12.—Parietal peritoneum at 4 days. Note the flattened surface cell with a brush border. No polystyrene spheres are seen in this type of cell although they may still be seen in the macrophages. Methylene blue–Azure II. (×900.)

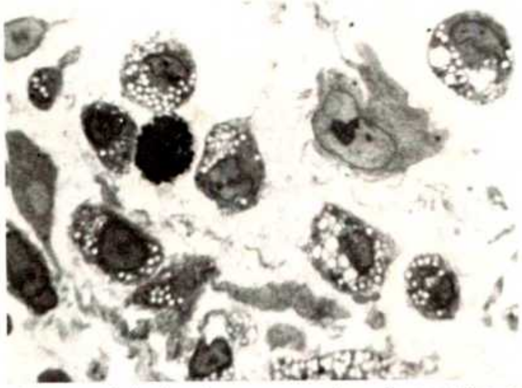

FIG. 13.—Parietal peritoneum at 4 days. Same section as shown in *Fig.* 12, but a deeper part of the wound. Note the large number of polystyrene spheres in the macrophages, while none is seen in the fibroblasts. Methylene blue–Azure II. (×900.)

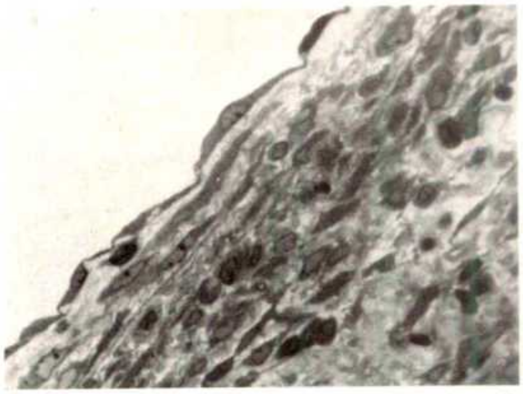

FIG. 14.—Parietal peritoneum at 6 days. The surface cells resemble the underlying fibroblasts. No polystyrene spheres are seen in these cells. Methylene blue–Azure II. (×222.)

At 6 days the silver lines were complete although in some areas wider than normal, the cytoplasm remained basophilic, but monocyte-like cells were not seen. Mitoses were seen on the wound surface. Healing appeared more advanced when compared with parietal peritoneum in that no multinucleate cells or monocyte-like cells were seen on the wound surface.

At 7 days the surface layer could not be distinguished from normal mesothelium. The larger wounds were found to heal as rapidly as the smaller ones.

ii. *Caecum*: This closely resembled the healing of parietal peritoneum. After an initial inflammatory response, the surface at 3 days showed the same two types of cell seen on the surface of the liver and parietal peritoneum. At 5 days silver lines were seen but these were wide and irregular. The majority of cells at this time were large with marked cytoplasmic basophilia and large nuclei with prominent nucleoli. Some multinucleate cells and also monocyte-like cells were seen at this stage. At 8 days healing was complete. Large wounds healed as rapidly as smaller ones.

d. Healing following Intraperitoneal Injection of Polystyrene Spheres.—Following intraperitoneal injection of a suspension of polystyrene spheres an inflammatory reaction was produced within the peritoneal cavity. Polystyrene spheres were seen within peritoneal macrophages, polymorphs, and monocytes. No polystyrene spheres were seen in mesothelial cells or subperitoneal fibroblasts.

Intraperitoneal injection of polystyrene spheres at the time of operation had no effect on the time or nature of healing in the case of either parietal or visceral mesothelium.

At 1 and 2 days polystyrene spheres were seen in cells on the surface of the wound (*Fig.* 11). These cells, which were round with an irregular or kidney-shaped nucleus with a thick irregular rim of chromatin and a 'ruffled' cell membrane, were macrophages. At 3 and 4 days two types of cell were seen on the wound surface. One contained polystyrene spheres and was identical with the macrophage described above; the other was flattened and elongated, and had an oval nucleus with a thin, regular rim of chromatin and a prominent nucleolus. Some of these cells had a brush border (*Fig.* 12). Apart from the brush border they resembled fibroblasts. Polystyrene spheres were never seen in these cells nor in subperitoneal fibroblasts even when macrophages in the base of the wound were filled with polystyrene spheres (*Fig.* 13). Once the cells of the monocyte/macrophage type had left the wound surface no polystyrene spheres were seen in the cells of the surface layer. As healing progressed the cells in the surface layer appeared to come into close contact with one another and eventually formed a continuous sheet of cells. The cells which ultimately formed the new mesothelial layer resembled the subperitoneal fibroblasts (*Fig.* 14). No polystyrene spheres were seen in the new mesothelial cells although they often remained in peritoneal macrophages for up to 2 weeks.

DISCUSSION

When conventional histological sections, cut perpendicular to the wound surface, are examined it is easy to see how investigators using this method alone have formed the opinion that mesothelial regeneration has occurred when the surface cells become flattened. However, when Häutchen preparations (viewed *en face*) are examined the absence or incompleteness of silver lines shows that these flattened cells are not in contact with one another as in normal mesothelium. Only when the silver lines are regular and complete, as in normal mesothelium, can regeneration be considered to have finished and this does not occur until some time after the surface cells become flattened. Therefore the appearance of a layer of flattened cells on the wound surface as seen in sections cut perpendicular to the wound surface is not an adequate criterion for assessing the completeness of mesothelial regeneration. Eskeland (1966a) pointed out that Häutchen preparations have certain drawbacks. Certainly it is difficult to obtain optimal photomicrographs since cells embedded in the celloidin do not always lie in the same plane; also more than one layer of cells may adhere to the celloidin in the early stages of wound healing. It is, however, difficult to agree with Eskeland that the method is time consuming. It is quicker than serially sectioning the wound perpendicular to the surface and much more can be learned in a shorter time from a single Häutchen preparation than from numerous serial sections.

The findings in the present investigation differ from those of Eskeland (1966a) on certain points. At 3 days Eskeland's preparations showed only one type of cell, which had a pale-staining oval or reniform nucleus with conspicuous chromatin, pale cytoplasm, and an indistinct cell border. In the present investigation two well-defined types of cell were present at this stage: a small round cell with a dark-staining, eccentric, kidney-shaped nucleus, which was identified as a cell of the monocyte/macrophage type, and a large cell with an ill-defined boundary, having a large, round, or oval nucleus containing one or more prominent nucleoli and with pronounced cytoplasmic basophilia. These cells resembled fibroblasts. Many of the latter type of cell were multinucleate in the early stages of healing. The number of monocyte-like cells on the wound surface gradually decreased and eventually only the larger type of cell remained. These cells came into contact with one another, as shown by complete silver lines in Häutchen preparations, and reconstituted the new mesothelium.

This study has thrown some light on the type of cell responsible for the new mesothelium. At the end of 48 hours the majority of cells on the wound surface were of the monocyte/macrophage type and some of these cells persisted until the sixth day. Eskeland and Kjaerheim (1966a) claimed that these macrophages became transformed into fibroblasts and that the cells in the most superficial layer gradually attained the characteristics of mesothelial cells. It has not been possible to substantiate this theory in the present investigation. Using polystyrene spheres to label peritoneal macrophages, it has been shown that no polystyrene spheres were seen in fibroblasts, nor were they seen in the flattened cells on the surface of the wound at 3 days which resembled fibroblasts and which ultimately formed the new mesothelium. If macrophages gradually became transformed into fibroblasts it is likely that at some stage polystyrene spheres would be seen in fibroblasts and also in the flattened cells of the superficial layer. At a time when macrophages were filled with polystyrene spheres none was seen in the flattened cells of the superficial layer and none in the reconstituted mesothelium. These findings do not support the theory that macrophages may be converted to mesothelial cells by way of fibroblasts. Further, Ellis and others (1965) have shown that while macrophages which had been labelled with trypan blue were present during the first 48 hours, trypan blue could not be identified in the surface cells at 3 days. Also at this time there was marked proliferation in the underlying fibroblasts. They concluded that these appearances suggested a two-stage process: an initial wave of phagocytic cells responsible for clearing cell debris, followed by a second wave of fibroblasts responsible for the healing of the defects and differentiation of the new mesothelium. The present investigation supports the findings of Ellis and others (1965) in this respect. However, Eskeland (1966b) and Eskeland and Kjaerheim (1966b) have grown autologous peritoneal fluid cells in Millipore diffusion chambers implanted within the peritoneal cavity and have obtained fibroblasts and cells resembling mesothelial cells within the chamber. Since no cells resembling mesothelial cells were seen in sample smears of the peritoneal fluid of these animals they concluded that the most likely source of the mesothelial cells was from transformation of the peritoneal macrophages, either directly or via fibroblasts. Two main criticisms may be levelled at this work. First, if mesothelial cells become detached and float in the peritoneal fluid they would almost certainly lose their characteristic shape and it would be difficult to recognize them in smears of peritoneal fluid stained by routine methods. Secondly, it is likely that the peritoneal fluid could be contaminated with fibroblasts. Again, these may not be recognizable in smears stained by routine methods. Ross and

Lillywhite (1965) culturing buffy coat cells of blood in subcutaneous diffusion chambers have shown that 91 per cent of chambers containing blood obtained by cardiac puncture contained connective-tissue-forming cells and collagen, whereas only 6 per cent of chambers containing blood obtained by cannulation of the carotid artery did so. They explained this by contamination of the blood by connective-tissue cells picked up during puncture of the thick wall of the heart. Surely if this could occur in cardiac puncture it is even more likely that the peritoneal fluid would be contaminated with fibroblasts after a laparotomy wound. Also, although it has been claimed (Allgower and Hulliger, 1960; Ross and Benditt, 1961; Kouri and Ancheta, 1972) that macrophages and monocytes are capable of transformation into fibroblasts there is a body of evidence to refute this claim (Grillo, 1963; Ross and Odland, 1968; Ross, Everett, and Tyler, 1970). Ross and others (1970) have clearly shown in experiments on skin wounds in parabiotic animals that fibroblasts do not arise from haematogenous precursors and therefore must arise from connective-tissue cells adjacent to the wound. It seems unlikely if transformation of monocytes and macrophages to fibroblasts cannot take place in skin wounds that it would occur in peritoneal wounds since the source of peritoneal macrophages and monocytes is from haematogenous precursors (Volkman, 1966), which is the same as the source of these cells in skin wounds.

The healing of visceral peritoneum has been found to differ little from the healing of parietal peritoneum. The one difference is that wounds of the liver capsule appear to heal more rapidly than either caecum or parietal peritoneum. There are two possible reasons for this: first, the liver provides a fairly firm substrate for healing while the peritoneum of the anterior abdominal wall and, more so, the caecum are subject to distension. Secondly, and less likely, there is the possibility that the caecum and parietal peritoneum may be damaged by stretching when they are removed and pinned out after fixing.

Some discrepancy exists between the various authors on the time taken for regeneration of the mesothelial layer. Ellis and others (1965) and Hubbard and others (1967) have shown that healing occurs in 5–6 days in the case of parietal peritoneum, and Glucksman (1966) has shown that the visceral mesothelium covering the terminal ileum heals in 5 days, while Eskeland (1966a) has demonstrated that regeneration of the mesothelial layer of parietal peritoneum is not complete until 8 days. With the exception of Eskeland these investigators have used flattening of the surface layer of cells as a criterion for mesothelial regeneration, whereas Eskeland has used Häutchen preparations. Using Häutchen preparations it has been shown that when the surface cells become flattened, cell-to-cell contact, as shown by silver lines, has not necessarily occurred. The present study has confirmed the findings of Eskeland (1966a) that the parietal peritoneum of the rat is healed within 8 days, and also that while multiplication and migration of mesothelial cells from the margin of the wound may play a small part in the regenerative process it cannot play a major part, since new mesothelium develops in the centre of a large wound at the same time as it develops in the centre of a smaller one. It has not been possible to confirm the finding of Eskeland (1966a) and Eskeland and Kjaerheim (1966a) that macrophages are transformed into mesothelial cells by way of fibroblasts. The present study suggests that mesothelium is reconstituted by differentiation of subperitoneal fibroblasts. This problem is being investigated further with the electron microscope in this laboratory at the present time.

Acknowledgements.—I wish to thank Professor R. L. Holmes for his helpful criticism, Messrs. R. K. Adkin, R. H. Nettleton, P. McPhie, and V. C. Menys for technical assistance, and Mrs. Sandra Brougham for typing the manuscript.

MAXIMAL GASTRIC SECRETION IN PATIENTS WITH CHRONIC AIRWAY OBSTRUCTION[*]

By M. A. HASSAN[†] and M. HOBSLEY[‡]
DEPARTMENT OF SURGICAL STUDIES, THE MIDDLESEX HOSPITAL, LONDON

SUMMARY

It has been suggested that patients with chronic obstructive chest disease have greater maximal gastric secretion than normal subjects. This problem was studied in 30 subjects using the histamine infusion test with phenol red as a marker to correct for pyloric loss. Clinical, radiological, and physiological criteria were used to define two groups: (1) 13 subjects with normal chests; (2) 14 subjects with unequivocal chronic airway obstruction.

The two groups did not differ significantly in maximal gastric secretion, and this conclusion was not altered by taking stature into account because stature was statistically comparable in the two groups. However, age was significantly different and correction of the secretory data for the diminution of maximal secretion with age improved the correspondence between the groups.

The failure to take stature and age into account may be responsible for conflicting evidence in the past.

THERE is a clinical association between chronic respiratory disease and peptic ulceration. First, there is an increased incidence of chronic obstructive airway disease in patients with peptic ulcer (Hirvonen and Perttila, 1951; Weber and Gregg, 1955). Secondly, peptic ulceration is a frequent, and often unexpected, finding at the post-mortem examination of patients dying from severe pulmonary emphysema (Fulton, 1933; Green and Dundee, 1952; Plotkin, 1957; Flint and Warrack, 1958). Thirdly, there are reports of an increased incidence of peptic ulceration during life in patients with chronic obstructive airway disease (Glick and Kern, 1964).

A possible connecting link between peptic ulceration and chest disease might be gastric hypersecretion of acid, which occurs commonly in patients with duodenal ulcer and has also been reported to occur in patients with chronic airway obstruction (Kramer and Markarian, 1960; Passi and Vasko, 1969). Evidence has recently been produced confirming that gastric acid output is correlated significantly with body stature (Baron, 1969; Hassan and Hobsley, 1969) and age (Hassan and Hobsley, 1971). The present paper reports the results of a study of maximal gastric secretion in patients with obstructive chest disease, taking age and lean body mass into account.

CLINICAL MATERIAL AND METHODS

Thirty volunteers including 14 subjects from the Chest Out-patients' Clinic at the Middlesex Hospital were investigated. None of these subjects had any clinical evidence to suggest the presence of gastroduodenal ulceration.

Assessment of Pulmonary Function.—This assessment was made in each subject clinically, radiologically, and by performing pulmonary-function studies. Using a closed-circuit double spirometer (Goodart Pulmotest), the following pulmonary-function studies were performed in each of the 30 subjects: forced vital capacity (F.V.C), forced expiratory volume in 1 second ($F.E.V._1$), functional residual capacity (F.R.C.), residual volume (R.V.), total lung capacity (T.L.C.), and transport factor (pulmonary diffusing capacity) using carbon monoxide ($T._LCO$). Conversion factors were used to correct gas volumes to standard conditions (B.T.P.S.) for a body temperature of 37° C. Predicted values according to the age, sex, and indices of body build of the subject were determined from nomograms. The final verdict as to whether the subject had a normal respiratory system or not was made by a neutral observer from the Respiratory Function Laboratory.

Calculated Lean Body Mass (L.B.M.).—This was calculated from the height (*H*) and weight (*W*) of each subject using the formulae described by Hume (1966):—

$$\text{For males, L.B.M.} = 0{\cdot}3281W + 0{\cdot}3392H - 29{\cdot}533.$$

$$\text{For females, L.B.M.} = 0{\cdot}29569W + 0{\cdot}4181H - 43{\cdot}2933.$$

Gastric Secretion Test.—The histamine-infusion test (Lawrie, Smith, and Forrest, 1964) was performed on each subject using histamine acid phosphate, 0·04 mg. per kg. per hour by continuous intravenous infusion. All the other technical details, including the use of phenol red as an inert marker to correct for pyloric loss, were as described by Hobsley and Silen (1969).

Phenol red was measured spectrophotometrically, correcting for contamination with bile and blood (Crawford and Hobsley, 1968) in each sample. The percentage recovery of phenol red was used to calculate the true total volume of gastric secretion corrected for pyloric loss.

RESULTS

As a result of assessing the respiratory system in each subject, two groups emerged (*Table I*). First, there was a group of 13 subjects with no evidence of respiratory abnormality. Of these, subjects Nos. 19

---

and 31 had abnormal values of R.V./T.L.C., being 43 and 41 per cent respectively. Nevertheless, as these findings were the only ones not in line with the clinical, radiological, and other pulmonary-function studies, these 2 subjects were considered to have normal chests. This group will be referred to as control subjects with normal chests. The second group consisted of 14 subjects with evidence of chronic airway obstruction. The remaining 3 subjects gave equivocal results and were, therefore, excluded.

Table II.—COMPARISON BETWEEN SUBJECTS WITH CHRONIC AIRWAY OBSTRUCTION AND THOSE WITH NORMAL CHESTS

	AGE (yr.)	CALCULATED L.B.M. (kg.)	WEIGHT (kg.)	HEIGHT (cm.)	SURFACE AREA (m.^{2})
Mean ± S.E.M. for 13 control subjects with normal chests	38·5 ± 4·0	49·9 ± 2·5	68·4 ± 4·0	171·6 ± 3·5	1·80 ± 0·067
Mean ± S.E.M. for 14 subjects with chronic airway obstruction	51·6 ± 3·3	47·8 ± 2·0	64·8 ± 2·9	168·2 ± 2·9	1·73 ± 0·058
Student's *t* test *P*	2·502 < 0·02	0·66 > 0·5	0·72 > 0·4	0·74 > 0·4	0·71 > 0·4

Table II compares the vital statistics in the two groups. Application of Student's *t* test demonstrated that there was no significant difference in the calculated lean body mass, weight, height, and surface area between the two groups. However, the control subjects with normal chests were significantly younger than those with chronic airway obstruction ($P < 0{\cdot}02$).

Comparison of maximal gastric secretion in the two groups showed that there was no significant difference in their secretory rate or acid output, even when corrected for pyloric loss (*Table III*). For the secretory rate the corrected figures were 75·7 (S.E.M. 6·9) ml. per 15 minutes for the control group, and 66·6 (S.E.M. 6·6) ml. per 15 minutes for those with chronic airway obstruction. While this difference was not statistically significant ($P > 0{\cdot}3$), a trend towards a *reduced* secretion in the group with abnormal chests might have been suspected.

However, the average ages of our two groups were significantly different, and there is quantitative confirmation that gastric secretion diminishes in a linear fashion with age (Hassan and Hobsley, 1971). Using the regression equation of Hassan and Hobsley (1971), the secretory rates of the present data, already corrected for pyloric loss, were standardized for differences in age by the formula:—

Standardized secretory rate (ml. per 15 min.)
= Phenol-red corrected secretory rate (ml. per 15 min.) − 34·1 + (0·75 × age in years).

The results of this calculation showed that the average standardized secretory rates were 71·0 ml. per 15 minutes for the control group and 71·6 ml. per 15 minutes for the group with chronic airway obstruction.

DISCUSSION

There is convincing evidence in the literature that patients with chronic chest disease suffer from peptic ulceration more frequently than subjects with normal chests. The aetiological factors responsible for this increased incidence are not understood clearly. Various suggestions have been advanced, such as increased corticosteroid activity (as a result of chronic stress), the injurious effect of hypoxia upon the gastric and duodenal mucosa (Passi and Vasko, 1969), and the possibility that endogenous histamine production may be increased as a result of cell damage. In this last respect, Eiseman (quoted by Passi and Vasko, 1969) believes that inactivation of histamine in these patients is reduced by the acidosis. Yet another suggested mechanism, applicable only to *gastric* ulcers, involves the competence of the pylorus: there is an association between gastric ulcer and duodenal regurgitation (reviewed by Delaney, Cheng, Butler, and Ritchie, 1970), and Beeley and Grech (1971) have reported a higher incidence of duodenal

Table III.—COMPARISON OF MAXIMAL GASTRIC SECRETION BETWEEN SUBJECTS WITH CHRONIC AIRWAY OBSTRUCTION AND THOSE WITH NORMAL CHESTS

	SECRETORY RATE (ml. per 15 min.)		ACID OUTPUT (mEq. per 15 min.)	
	Un-corrected	Corrected for Pyloric Loss	Un-corrected	Corrected for Pyloric Loss

regurgitation into the stomach in patients with chronic non-specific lung disease than in normal control subjects. The unquestionable association between gastric acid hypersecretion and duodenal ulceration has encouraged the study of gastric secretion in patients with obstructive chest disease. Up to now the evidence, though not unanimous, has suggested that patients with chronic chest disease secrete more gastric acid in response to a given stimulus than do subjects with normal chests (Kramer and Markarian, 1960).

In producing this evidence, however, stature and age were not considered, and therefore the hypersecretion of acid described in patients with obstructive chest disease might have been due to differences in stature and/or age.

In the present study indices of stature in the two groups were comparable. The maximal gastric secretion in these two groups was not statistically significantly different. Any difference might have been masked by the fact that the mean age of the control subjects with normal chests was considerably less than that of the other group. However, age correction of the maximal gastric secretion did not alter this finding, but made the already non-significant difference in maximal gastric secretion even less conspicuous.

It can be concluded that chronic airway obstruction does not significantly influence maximal gastric secretion. This conclusion is confined to maximal gastric secretion and there remains the possibility that if basal or submaximal gastric secretion is studied in these two groups of subjects, a significant difference may emerge.

Acknowledgements.—We are grateful to Dr. F. H. Scadding for allowing us to study his patients and to Dr. Gabriel Laszlo for being our neutral observer. We also wish to thank the staff of the Respiratory Function Laboratory, the Middlesex Hospital, and Miss S. Godfrey for technical assistance.

THE ASSOCIATION OF PEPTIC ULCER AND ABDOMINAL AORTIC ANEURYSM AND ITS SIGNIFICANCE

BY J. BOUHOUTSOS, A. BARABAS, AND PETER MARTIN*
HAMMERSMITH HOSPITAL AND ROYAL POSTGRADUATE MEDICAL SCHOOL, LONDON

SUMMARY

Twelve out of 51 consecutive patients who were operated on for unruptured abdominal aortic aneurysm were found to have, in addition, a peptic ulcer. Of these 12 patients, 7 developed complications (haemorrhage or perforation) in the immediate post-operative period. Eight of the 51 patients died following operation and the commonest cause of death (5 out of 8 patients) was either haemorrhage or perforation of a peptic ulcer.

On the basis of these observations it is suggested that in patients with both an aortic aneurysm and a peptic ulcer vagotomy and pyloroplasty with gastrostomy should be carried out at the same time as aortic reconstruction.

IN a study of 7044 necropsies Jones, Kirk, and Bloor (1970) found that of 99 subjects with an abdominal aortic aneurysm, 22 (22·2 per cent) also had a peptic ulcer, whereas in the series as a whole the incidence of peptic ulceration in a comparable age-group was 7·2 per cent.

A clinical study of patients presenting with the stenotic type of arteriosclerosis of the aorto-iliac segment revealed that 24 per cent of 300 consecutive patients had peptic ulceration (Bouhoutsos, Barabas, and Martin, 1972). These patients suffered an eventual amputation of one limb more than twice as often, and of both limbs four times as often, as those without an ulcer, although there was no difference in the distribution of disease, in the surgical management, or in the early results of the operation. In the same study, of 100 consecutive patients with an abdominal aortic aneurysm, an incidence of peptic ulcer similar to that found by Jones and others (1970) was recorded. It is with this group that this paper is concerned.

MATERIAL AND RESULTS

A retrospective study of 100 consecutive patients operated on before 1971 for abdominal aortic

aneurysm at Hammersmith and Chelmsford District Hospitals revealed a peptic ulcer in 24 of the patients. There were 90 male and 10 female patients with an average age of 70 and 67 years respectively. Of the ulcers, 20 were duodenal and 4 were gastric. Twelve of the 24 patients had been operated on for ulcer before, mostly by vagotomy and pyloroplasty. The remaining 12 patients, in whom the diagnosis of ulcer had been made previously or at the time of operation on the aneurysm or at post-mortem examination, had received no surgical treatment for the ulcer at the time of the aortic reconstruction. Of these 12 patients, 8 suffered haemorrhage or perforation in the immediate postoperative period (*Table I*).

Fifty-one patients were operated on for uncomplicated aortic aneurysm and 7 of these developed ulcer complications shortly after operation. Five of the patients with ulcer complications died. Two others died from renal failure and 1 from graft leakage. The mortality of the group was thus 8 (15·6 per cent).

Forty-nine patients were operated on for ruptured aneurysm and in these it is almost certain that some peptic ulcers were undiagnosed because of the urgent clinical condition presenting on the patient's admission. Furthermore, complications of an associated peptic ulcer might well be forestalled by the death of the patient, and in only 1 patient in this group did ulcer complications occur after operation. Unfortunately an autopsy was not performed on all those dying after the operation. Because of these indeterminate factors the incidence of peptic ulcer and the complication rate after operation for a ruptured aneurysm were not estimated. It is difficult to imagine that the incidence of peptic ulcer in association with abdominal aortic aneurysm would be less in patients with a ruptured aneurysm than in those with an uncomplicated aneurysm.

Table I.—COMPLICATIONS OF PEPTIC ULCER AFTER RESECTION OF AN ABDOMINAL AORTIC ANEURYSM IN A SERIES OF 100 PATIENTS

CASE	AGE AND SEX	RESECTION	PEPTIC ULCER COMPLICATION	DAY AFTER OPERATION THAT COMPLICATION OCCURRED	OUTCOME
1	60 M.	Elective	Perforation of duodenal ulcer	2	Died
2	62 M.	Elective	Perforation of gastric ulcer	10	Died
3	63 M.	Elective	Haematemesis from duodenal ulcer	38	Died
4	57 M.	Elective	Haematemesis from duodenal ulcer	2	Died
5	58 M.	Elective	Haematemesis from duodenal ulcer	7	Died
6	73 M.	Elective	Haematemesis from duodenal ulcer	2	Successful conservative treatment
7	65 M.	Elective	Haematemesis and melaena from duodenal ulcer	5	Successful emergency gastrectomy
8	73 F.	Emergency for ruptured aneurysm	Melaena from duodenal ulcer	7	Successful conservative treatment

DISCUSSION

Schatz, Fairbairn, and Juergens (1962) reported the fate of a selected series of 139 patients with abdominal aortic aneurysm who were managed conservatively; 18 died of rupture of the aneurysm and 2 from bleeding duodenal ulcer. They did not report the total number of patients with peptic ulcer in this group nor did they make mention of patients who may have recovered after a haemorrhage or perforation and, of course, no patient was subjected to the stress of aortic replacement. In the necropsy study of Jones and others (1970) 22 of 99 subjects with abdominal aortic aneurysms also had a peptic ulcer. Of these 22 patients, 9 died as a result of the aneurysm, 6 of the peptic ulcer, and 7 from unrelated causes.

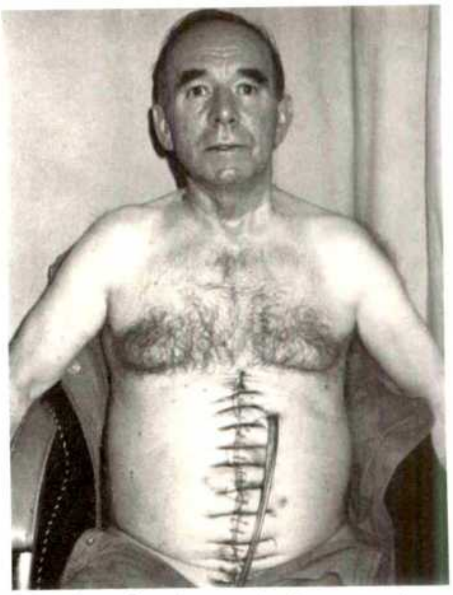

FIG. 1.—Patient 3 days after operation for a ruptured aneurysm. Note the distended abdomen and the gastrostomy drainage.

From our experience of ulcer complications in the immediate postoperative period after reconstruction of the aorta for aneurysm, the stress of such surgery is a very significant factor in the aggravation of the ulcer with consequent haemorrhage or perforation. Elective resection of an aortic aneurysm in a patient with a peptic ulcer is therefore hazardous, and ulcer complications were in fact the major cause of postoperative death. If this cause could have been excluded the mortality in our series after operation would have been reduced from 15·6 per cent to 5·9 per cent.

The high mortality of ulcer complications at this time may be due to a number of factors. First, diagnosis of some complications may be delayed, or even not made at all, because symptoms and signs are masked by the postoperative state and the ileus which is common after aortic surgery. Secondly, at the time that complications occur the patient is in a poor state to withstand further major surgery. Thirdly, if a pernasal intragastric tube has been used there is probably retention of secretions in the bronchi.

To prevent this prohibitively high complication rate all patients with abdominal aneurysm should be investigated for the presence of a peptic ulcer, and if an ulcer is found there appear to be two possibilities regarding management. Either the ulcer is dealt with first, in most cases by vagotomy and drainage, and the aorta resected at a later date, or both conditions are treated at the same time. If the first alternative is preferred then an often elderly patient is subjected to two major operations with the cumulative risk of each. In addition, the aneurysm may rupture in the waiting period. If the second alternative is adopted the magnitude of the operation is increased and the risk of sepsis possibly increased. As to the danger of sepsis, it has certainly been our practice that surgery of the colon or small intestine should never be undertaken when an aortic graft is to be used, and indeed we would abandon the operation if this part of the intestine were accidentally injured during exposure. When concerned with a duodenal ulcer, however, it seems to us safe to do a vagotomy and pyloroplasty at the time of operation on the aorta, particularly as such leakage as occurs from the pyloroplasty is probably not infective. We have in fact for some years been doing a gastrostomy in every patient after transperitoneal, aortic, or aorto-iliac surgery to avoid the use of a nasogastric tube and have had no cause to regret this measure (*Fig.* 1). In one instance some years ago we did a gastrectomy without complication, and recently in 3 patients with an aortic aneurysm and a duodenal ulcer, after completing the aortic reconstruction, we have carefully replaced the apron of the stomach, colon, and omentum to cover the operation field and have then done a vagotomy and pyloroplasty together with a gastrostomy using a balloon catheter. In these 3 patients convalescence was smooth. We admit that sometimes, because of difficulties during the aortic reconstruction, the surgeon may feel that the added risk of vagotomy and pyloroplasty would outweigh the risk of complication of the ulcer in the early period after operation, when he will act accordingly.

It is interesting that of the 300 operations for arteriosclerotic aorto-iliac stenosis which we have previously reported (Bouhoutsos and others, 1972), there were only 2 fatal complications from peptic ulcer, though the incidence of ulcer is the same in this group as it is in the aneurysm group. This may be because operations for stenosis are usually of a lesser magnitude than those for aneurysm, and indeed many are done by a retroperitoneal approach with little disturbance to the patient.

We believe, therefore, that it is necessary, and is at present our practice, to treat a patient with such dual pathology by vagotomy and pyloroplasty and a gastrostomy at the same operation as that for the aortic reconstruction, though we are hesitant in advising a gastrectomy in such circumstances.

GENTICIN

INJECTABLE

gives more bactericidal cover than any other antibiotic

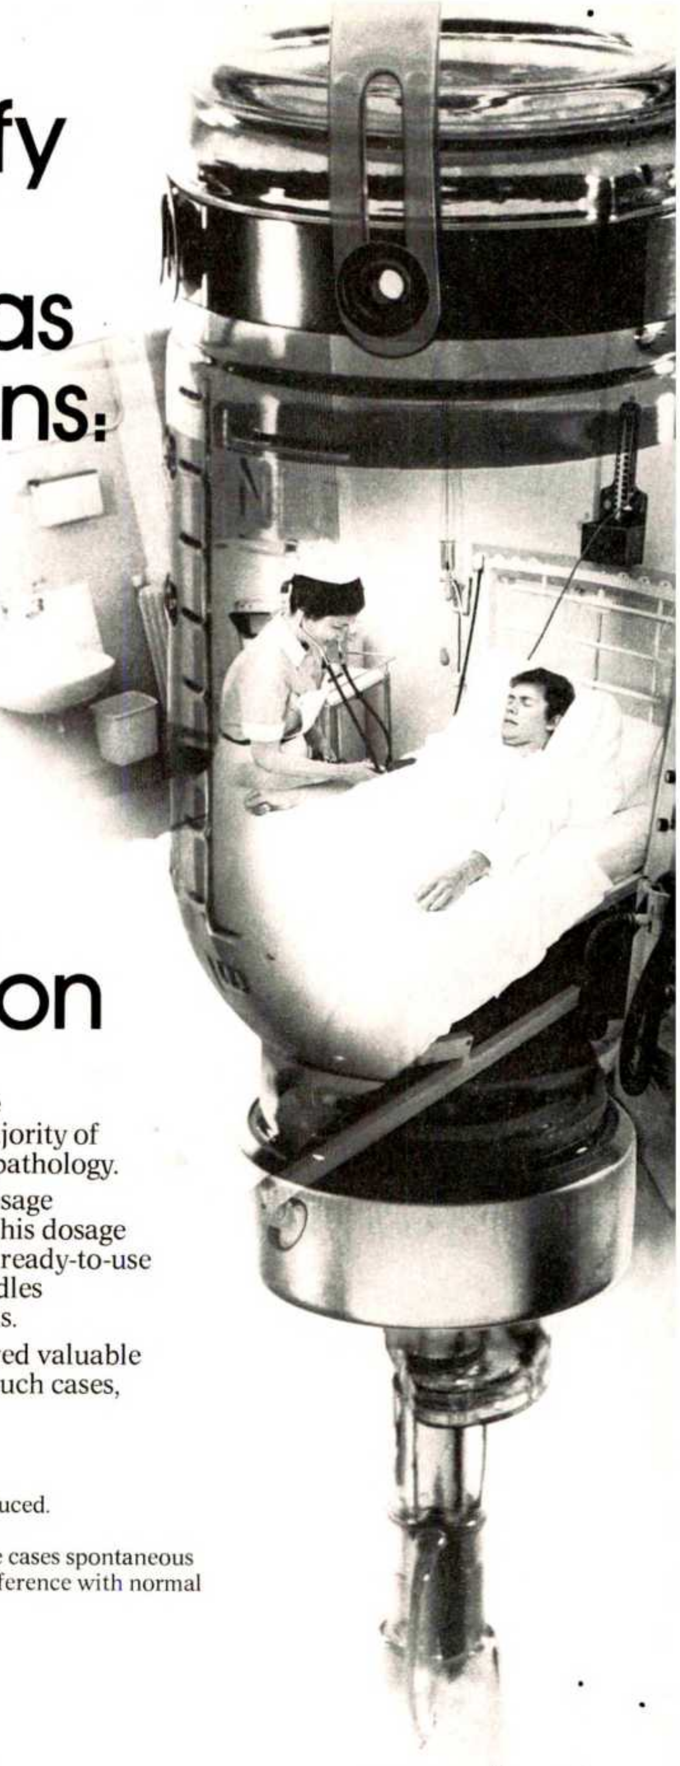
Genticin Injectable is available in 2 ml multidose vials. Each 2 ml contains 80 mg gentamicin as gentamicin sulphate.

Further details are available on request from:
Genticin Technical Service,
Slough 23971
Nicholas Laboratories Limited
British Schering Limited
Slough Buckinghamshire

Genticin is a registered trade mark.

1898

Now, to simplify treatment of pseudomonas chest infections:



Pyopen infusion

In the published papers, Pyopen's success rate in chest infections is 65% even though the majority of the patients described had severe underlying pathology.

The best results have been achieved with a dosage of 20-30G. I.V. daily. Pyopen infusion makes this dosage simpler to administer by providing Pyopen in ready-to-use infusion bottles with diluent and transfer needles for the easier preparation of infusion solutions.

Pyopen is, of course, a penicillin, and has proved valuable in patients with known renal impairment: in such cases, however, dosage should be reduced.

Adult dosage: 20-30G. I.V. daily.
In patients with renal impairment dosage should be reduced.
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by

SURGICAL RESEARCH SOCIETY

A meeting of the Surgical Research Society was held in the University College Hospital Medical School, London, on 5 and 6 January, 1973, with Professor L. P. LeQuesne (President of the Surgical Research Society) in the Chair. The following papers were presented:—

1. Effect of Aortocoronary By-pass Graft on Graded Anginal Symptoms, Exercise Performance, and Left Ventricular Function:

S. E. P. MILLER and W. D. JOHNSON (P. R. F. Bell), Medical College of Wisconsin, Milwaukee, and Western Infirmary, Glasgow.

Myocardial revascularization by reversed saphenous vein by-pass graft (R.S.V.B.G.) between the aorta and coronary arteries distal to atheromatous obstruction is reported to alleviate symptoms of angina pectoris. This study attempts to correlate changes in exercise performance, ventricular function, and graft patency with symptomatic improvement following surgery.

Seventy-eight patients with graded anginal symptoms were assessed pre- and postoperatively and symptomatic change was correlated with vein patency. Twenty-five of these patients were further studied by bicycle ergometry and left-heart catheterization, and assessed as to exercise performance and ventricular function.

Following R.S.V.B.G. 56 of the 78 patients (72 per cent) became asymptomatic and 21 improved. All the grafts were patent in 52 cases (67 per cent), all were closed in 6 (7·7 per cent), and in 20 patients (23·3 per cent) one or more but not all the grafts were closed. Of the 25 patients who were studied further, all showed increased exercise performance postoperatively. This was less pronounced in those with closed grafts, where angina was improved but fatigue and dyspnoea were marked.

The cardiac index (C.I.) increased at rest in some patients and with exercise in others, but no distinct pattern emerged. The left ventricular end-diastolic pressure (L.V.E.D.P.) which had been abnormally elevated in 6 patients at rest preoperatively returned to normal in 5 cases. With exercise, 23 patients had had an elevated L.V.E.D.P. which was reduced significantly in all cases. Systolic ejection fraction (S.E.F.) was significantly increased in 17 patients (68 per cent) postoperatively and reduced in 4 (16 per cent), all of whom had closed grafts.

2. Aberrant Positions of Central Venous Catheters:

A. O. B. JOHNSTON and R. G. CLARK, Department of Surgery, University of Sheffield.

Central venous catheters are used increasingly for monitoring central venous pressure and administering hypertonic nutritional solutions. It is known that incorrectly positioned catheter tips can cause serious complications—perforation of the myocardium (Brandt et al., 1970) and extensive thrombophlebitis. Langston (1971) stated that the catheter tip should be positioned in the superior vena cava or innominate veins if complications are to be minimized. All other positions are considered incorrect.

This study reports the radiological position of the catheter tip following 75 consecutive catheterizations performed by one operator under standard conditions. A radio-opaque 61-cm. Bardic Intracath was inserted via the cubital fossa. When the catheter was assessed clinically to be positioned correctly a radiograph was taken. In 39 patients the tip was found to be in the superior vena cava, and in the innominate vein in 8. Aberrant positions included 10 in the atrium, 12 in the internal jugular vein, and 4 in the subclavian vein. All the catheters found to be in an aberrant position were immediately repositioned. In this series no complication resulted from the catheter initially being positioned incorrectly.

It is concluded that radiographic control is essential for accurate positioning.

3. A Healing Bond between Tissues and a Smooth Synthetic Polymer:

M. E. B. JONES and DAVID ANNIS, University of Liverpool Medical School, Liverpool.

Since the normal process of healing does not result in the bonding of surrounding tissue to an implanted, smooth, synthetic surface the permanent location of internal prosthetic devices is dependent upon tissue ingrowth into porous or woven structures on the surface of the device. The object of this investigation was to look for surface factors of synthetic materials which could influence tissue bonding to smooth surfaces.

Contact-angle measurements on collagenous tissues, taken from various locations in a number of animals, showed that their surface energies (Y_s) differed in three important respects from the surface energies of conventional plastic materials used for the construction of implants:—

1. Tissue-surface energy is significantly higher.
2. The contribution of the two components of surface energy (Y_s^h and Y_s^d) is inverted, i.e., $Y_s^h > Y_s^d$ for collagenous tissues, and $Y_s^h < Y_s^d$ for most synthetic polymers.
3. Dehydration lowers the surface energy of these tissues.

A range of three copolymers was prepared from poly-(ethylene glycol) and poly(ethylene terephthalate) and the composition adjusted until the surface energy matched that of collagenous tissue. Across this range the effect of progressive changes in the surface energy of these copolymers on the healing/bonding process was examined by subcutaneous implants in rats. These showed that limited bonding occurred above a certain surface energy and that bond strength increased as it approached that of collagenous tissue.

The bond of living tissue directly to a synthetic polymer opens up many applications in prosthetic surgery.

4. A Clinical Trial of Treatment in Early Breast Cancer:

M. MAUREEN ROBERTS, MARION DAVIES, M. HENK, A. P. M. FORREST, L. H. BLUMGART, E. N. GLEAVE, C. W. JAMIESON, M. HULBERT, and H. CAMPBELL, Welsh National School of Medicine and St. Mary's Hospital, London.

Since 1967 a controlled, randomized clinical trial has been carried out to compare a conservative with a radical policy of treatment in early breast cancer.

Patients selected for conservative treatment underwent simple mastectomy with removal of the axillary tail of the breast and its associated pectoral nodes, but the contents of the axilla were left undisturbed. If the nodes did not contain tumour no further treatment was given. Those selected for radical treatment underwent mastectomy and axillary clearance, with radiotherapy when there was histological evidence of spread to the axillary nodes.

To date, 116 patients have been treated by the conservative method and 111 by the radical policy. Over the period of follow-up no differences have emerged between the treatment groups in terms of death or recurrence rates. Axillary recurrence was found in 5 of the 71 patients treated by simple mastectomy alone, giving a false-negative histological stage I of 5 per cent. This compares favourably with our clinical staging error of 40 per cent.

The low rate of recurrence together with the significantly decreased morbidity of conservative as compared with radical treatment already reported indicate that simple mastectomy alone is an adequate form of treatment for breast cancer when the tumour is known to be limited to the breast. We emphasize the need for histological proof of the state of the axillary nodes, as disease, if present, should be treated.

5. 'Early' Breast Cancer, Bone Scanning, and the Urinary Excretion of Hydroxyproline: D. S. Sumner, M. Baum, V. Parsons, and M. H. Edwards, Department of Surgery, King's College Hospital Medical School, London.

Galasko (1969) showed that many patients with apparently localized cancer of the breast had widespread unsuspected bony metastases which could be detected by scintiscanning of the skeleton. The technique unfortunately requires expensive equipment and is not universally available. A cheaper and simpler way to select these patients with disseminated disease and to save them from extensive radical treatment was suggested by Cuschieri and Felgate (1972). They found that urinary hydroxyproline was increased in some patients with breast cancer 2 years before metastases became apparent.

We have investigated bone scanning and its relationship to urinary hydroxyproline excretion in 112 patients. The patients were grouped as follows:—

Group I: 37 patients with benign breast disease.

Group II: 45 patients with early breast cancer and a normal scan.

Group III: 17 patients with early breast cancer and an abnormal scan.

Group IV: 11 patients with widespread disease.

The results were:—

Group	Total Hydroxyproline (mg. per 24 hr. ± S.D.)	Significance to Group above
I	22·4 ± 9·5	
II	20·8 ± 8·4	$P > 0·05$
III	32·3 ± 9·2	$P < 0·001$
IV	47·9 ± 12·6	$P < 0·001$

The urinary hydroxyproline level is elevated significantly when bony metastases are present.

Galasko, C. S. B. (1969), *Br. J. Surg.*, **56**, 757.

6. The Relationship between Leg-vein Thrombosis and Pulmonary Emboli at Autopsy: M. Tessa Morrell, Nuffield Department of Surgery, Radcliffe Infirmary, Oxford.

Ignorance of the actual risk of pulmonary embolism in patients with venous thrombosis has resulted in some uncertainty in the need for treatment in every case.

The statistical relationship between thrombosis and embolism was studied at autopsy. The right lung and soft tissues of both legs were removed from each of 52 patients; the leg tissues were fixed in formol–saline, the lung was distended with and fixed in formol–saline, and both were sliced transversely at 1-cm. intervals. Suspected thrombi were examined histologically.

Of 33 patients with venous thrombi, 22 (66 per cent) had pulmonary emboli; 8 died of the emboli, 6 having had a good original prognosis. The incidence of embolism was greatest (18 in 23) when the longitudinal leg veins were thrombosed and least (4 in 10) when thrombi were confined to the calf tributaries. Death from embolism occurred in 6 out of 12 patients with femoro-iliac vein thrombosis but in none with only distal vein involvement. The relationship between thrombosis and embolism was independent of age and type of operation.

It is concluded that every patient with a diagnosis of thrombosis should be treated, as involvement of the longitudinal leg veins carries a high risk of pulmonary embolism.

7. The Action of Gastro-intestinal Polypeptide Hormones on the Isolated Perfused Gastro-oesophageal Sphincter: P. A. Thomas, and R. J. Earlam, Surgical Unit, the London Hospital.

An isolated preparation of the canine stomach and oesophagus perfused with autologous blood under controlled physiological conditions (Thomas and Earlam, 1972) has been used to study the direct effects of polypeptide gastro-intestinal hormones on the gastro-oesophageal sphincter. The hormones tested were gastrin I and II, cholecystokinin (CCK), caerulein, secretin, and glucagon. In the human, gastrin has already been shown to increase sphincter pressure and secretin to reduce it (Cohen and Lipshutz, 1971). The hormones were administered into an artery either as a bolus dose or as a continuous infusion. Bolus doses of gastrin I and II (1 μg.), CCK (10 Ivy units), and caerulein (12·5 μg.) all produced a rise in sphincter pressure as did a continuous intra-arterial infusion. These responses were abolished by atropine. Bolus doses of secretin (5 units) and glucagon (25 μg.) produced a fall in sphincter pressure. Continuous intra-arterial infusion had a similar effect. These results demonstrate that in this preparation the polypeptide gastro-intestinal hormones can be divided into two groups on the basis of their pharmacological action. The C-terminal related hormones produced a rise in sphincter pressure but secretin and glucagon reduced the pressure.

8. The Bacterial Flora of the Upper Gastro-intestinal Tract in Relation to Gastric Secretion and to Bowel Habit following Vagotomy and Pyloroplasty: S. T. D. McKelvey, W. P. Ferguson and T. L. Kennedy, Department of Surgery Queen's University of Belfast.

Diarrhoea following vagotomy has been attributed to loss of the gastric acid trap, thus allowing passage of infective material into the intestine (Dragstedt, 1966) This paper reports quantitative bacterial counts of the gastric, duodenal, and jejunal juice following vagotomy.

Thirty-four patients were studied more than 1 year following vagotomy and pyloroplasty. Seventeen of these patients were undergoing investigation for episodic postvagotomy diarrhoea. The control group consisted of 17 patients with satisfactory bowel habit since vagotomy and pyloroplasty.

The resting juice in the stomach and duodenum wa cultured after aspiration through a double-lumen tub which had been positioned under fluoroscopic control. At the same intubation an insulin study was performed and analysed by the criteria of Hollander. On a separate occasion the resting juice in the upper jejunum was sampled using a specially devised capsule (Shiner, 1963).

The resting gastric juice contained heavy counts of nasopharyngeal organisms but colonic-type organisms were found infrequently. A similar pattern was found in duodenal and jejunal juice. Asymptomatic patients did not differ from those with diarrhoea. Colonization of the gut was heavier if the vagotomy was complete.

Vagotomy leads to colonization of the upper gastro-intestinal tract but this is not causally related to the occurrence of postvagotomy diarrhoea.

Shiner, M. (1963), *Lancet*, **1**, 532.

9. Effects of Varying the Extent of Vagotomy on the Myoelectrical and Motor Activity of the Stomach in Man:

C. J. Stoddard, B. H. Brown, G. E. Whittaker, W. E. Waterfall, and H. L. Duthie, Medical Physics and Surgery Departments, University of Sheffield.

Transthoracic vagotomy in dogs is followed by temporary disorganization of the electrical activity in the stomach (Kelly and Code, 1969). The aim of this study was to assess the changes in electrical activity and gastric motility in man following truncal (T.V.), selective (S.V.), or highly selective vagotomy (H.S.V.) for the treatment of duodenal ulcer.

Nineteen conscious patients were studied 5 days post-operatively using electrodes mounted on a gastric tube and sucked on to the mucosa of the gastric antrum. Motility was measured via an open-tipped tube and gastric secretion was aspirated continuously. In 12 patients, after a control period of 1 hour, insulin, 0·2 U. per kg., was given intravenously. All the patients had a negative gastric secretory response to insulin.

The regular 3-per-minute rhythm of the electrical activity was maintained after H.S.V. with a normal peaked wave-form. After T.V. the rhythm was disorganized with occasional periods of 2–15 minutes of regular 3-per-minute activity with a sinusoidal wave-form. Patients after S.V. showed intermediate findings. Insulin hypoglycaemia did not alter these patterns except to increase the amplitude of the electrical waves and the incidence of action potentials. The disorganization of the electrical activity of the gastric antrum is related to the extent of vagal denervation.

Kelly, K. A., and Code, C. F. (1969), *Gastroenterology*, **57**, 51.

10. An Assessment of Clinical Tests of Gastric Emptying before and after Operation:

I. F. Gunn, K. D. Harding, Anne Brown, and J. Alexander Williams, The General Hospital, Birmingham.

In previous studies a correlation has been shown between dumping after vagotomy with pyloroplasty and rapid initial emptying from the stomach of a 10 per cent dextrose solution (Clarke and Williams, 1972). As the use of a fluid meal can be criticized in that it is unphysiological we have compared the emptying of a fluid meal with scintiscanning of a solid meal labelled with indium 113m (Harvey et al., 1970). Patients have been studied by both methods before and after different operations for duodenal ulcer.

Preoperatively the liquid meal had emptied more rapidly than the solid meal at 10 minutes ($P<0·01$) but by 20 minutes the emptying patterns were not significantly different. The regression line between the 50 per cent emptying times of the two methods shows good correlation ($r = 0·572$, $P<0·05$). Application of the paired *t*-test to 50 per cent emptying times shows there is no significant difference ($P>0·2$) between values for the two methods. After operation the rapid initial emptying found with a liquid meal is not reflected in the solid-meal patterns.

Although emptying of a solid meal after gastric operation is the more physiological, the fluid-meal test is better able to demonstrate differences between operations and may correlate better with the clinical symptoms of dumping.

Clarke, R. J., and Williams, J. A. (1972), *Br. J. Surg.*, **59**, 903.

11. Gastric Emptying of a Solid Meal after Long and Short Pyloroplasties:

W. D. George, C. R. Royston, D. J. Cowley, and J. Spencer, Department of Surgery, Royal Postgraduate Medical School, London.

Symptoms of delayed gastric emptying commonly follow vagotomy and pyloroplasty, possibly owing to pyloric narrowing. Gastric emptying of solid meals has been studied in a randomized controlled clinical trial of selective or truncal vagotomy with either a short Heineke-Mikulicz pyloroplasty or a long Finney pyloroplasty, and compared with a control group of 17 patients with no gastro-intestinal disease. Emptying was measured by the modified gamma-camera technique (Cowley et al., 1972) and the results were expressed in half-emptying times ($T_{\frac{1}{2}}$).

The control group (17) had a mean $T_{\frac{1}{2}}$ of 85 ± 7·1 minutes.

Thirty-seven patients were studied; in 26 emptying times were measured 10–22 days after operation (mean 14 days), and in 24 at 4–6 months (mean 5·3 months). At 10–22 days after operation the mean $T_{\frac{1}{2}}$ was 364 ± 34 minutes in 15 patients with a Finney pyloroplasty and 332 ± 47 minutes in 11 patients with a Heineke-Mikulicz pyloroplasty. At 4–6 months postoperatively the mean $T_{\frac{1}{2}}$ was 146 ± 54 minutes in 13 patients with a Finney pyloroplasty and 150 ± 24 minutes in 11 patients with a Heineke-Mikulicz pyloroplasty. No difference in emptying was found between truncal or selective vagotomy. There was no relationship between the incidence of diarrhoea and abnormalities in gastric emptying. The slowing of gastric emptying was identical after long and short pyloroplasties.

Cowley, D. J., Vernon, P., Jones, T., Glass, H. I., and Cox, A. G. (1972), *Gut*, **13**, 176.

12. A Study of the Relationship between the Rate of Gastric Emptying and the Dumping Syndrome in Patients after Vagotomy and Drainage:

S. Haynes, J. P. S. Thomson, N. Brown, and D. H. Keeling (L. P. Le Quesne), The Department of Surgical Studies and Institute of Nuclear Medicine, The Middlesex Hospital Medical School, London.

Whilst it is widely accepted that the dumping syndrome is associated with rapid gastric emptying this relationship has not been clearly established. An investigation has been performed to determine the relationship between the rate of gastric emptying, the occurrence of dumping symptoms, and the changes in plasma volume following a hypertonic glucose meal (200 ml. of a 50 per cent solution). Gastric emptying was measured isotopically by labelling the meal with Indium 113m (1 m.c.) and using a gamma camera. The symptoms occurring during the test were noted and changes in plasma volume were indicated by serial measurements of the haematocrit.

Fourteen patients with duodenal ulcer were studied preoperatively and 29 after vagotomy (selective 16, truncal 13) and drainage (Heineke-Mikulicz pyloroplasty 14, gastroduodenal 5, gastrojejunal 10). The average initial (2–10 minutes) rate of gastric emptying in preoperative patients (0·8 per cent per minute) was not significantly different to that in 12 postoperative patients *without* dumping symptoms (1·2 per cent per minute), whereas the rate in 17 patients *with* dumping symptoms (5·2 per cent per minute) was significantly faster ($P < 0\cdot001$).

In the postoperative patients there was a significant correlation between the rates of initial gastric emptying and of plasma-volume fall ($r = 0\cdot67$, $P < 0\cdot001$).

13. Plasma Enteroglucagon and Plasma-volume Changes after Oral Hypertonic Glucose—Their Relationship to the Dumping Syndrome: J. P. S. Thomson, S. R. Bloom, S. Haynes, and O. Ogawa (L. P. Le Quesne), Department of Surgical Studies and Institute of Clinical Research, The Middlesex Hospital Medical School, London.

After partial gastrectomy (Marco et al., 1972) or vagotomy and drainage (Bloom et al., 1972) oral hypertonic glucose provokes a greater rise in plasma enteroglucagon than preoperatively. The magnitude of the rise is related to dumping symptoms (Bloom et al., 1972). To study these relationships further a hypertonic glucose meal (200 ml. of a 50 per cent solution) was administered and the plasma enteroglucagon was measured by radioimmunoassay and the plasma-volume changes were calculated from serial haematocrit estimations.

The mean rate of rise of plasma enteroglucagon in 14 duodenal ulcer patients preoperatively was 1·6 femtomole per ml. per minute. In studies in 42 postoperative patients (partial gastrectomy 13, vagotomy and drainage 29) the glucose provoked dumping symptoms in 26, the mean rate of fall in plasma volume in these patients (0·43 per cent per minute) being significantly greater than that in 16 patients without such symptoms (0·17 per cent per minute) ($t = 6\cdot76$, $P < 0\cdot001$). In the patients *without* dumping symptoms the rate of rise of plasma enteroglucagon (4·15 femtomole per ml. per minute) was significantly faster than in preoperative patients ($t = 2\cdot69$, $P < 0\cdot02$), while in patients *with* dumping symptoms the rate of rise (13·83 femtomole per ml. per minute) was significantly faster than in those without such symptoms ($t = 7\cdot21$, $P < 0\cdot001$).

In all the patients the rates of plasma-enteroglucagon rise and of plasma-volume fall correlated closely ($r = 0\cdot86$, $P < 0\cdot001$).

14. Mechanism of Raised Serum Alkaline Phosphatase in Some Liver Disorders in the Baboon: J. Jersky (D. J. du Plessis), Department of Surgery, University of the Witwatersrand, Johannesburg, South Africa.

Liver extracts were assayed for alkaline phosphatase (Engstrom, 1964). In orthotopic liver transplants an increase (from 4 to 20 King-Armstrong units per g. of liver tissue) in liver-type isoenzyme accompanied rejection and in auxiliary liver transplants similar increases were seen in both the donor and recipient livers when the former was rejected. As the rise in alkaline phosphatase in the recipient liver could be explained either by increased local production or by accumulation from the donor liver the following experiment was performed.

An auxiliary liver was removed 5 days after insertion, by which time it was being rejected. Radioactive leucine was then injected into the animal, which was killed 24 hours later. Using a specific antibody, alkaline phosphatase was extracted from the recipient liver; a fourfold increase in radioactivity confirmed increased local production.

In separate experiments a single hepatic duct of a normal liver was ligated. Both the obstructed and unobstructed lobes produced an excess of alkaline phosphatase.

Thus, in these two situations the increased serum alkaline phosphatase of liver disease is due to increased hepatic production of the enzyme and not to failure of excretion. A humoral stimulator seems to play a role in this phenomenon.

Engstrom, L. (1964), *Biochim. Biophys. Acta*, **92**, 71.

15. Rate of Blood-loss estimated by an Isotope-dilution Method: J. M. T. Griffiths, W. B. Clark, and A. N. Smith, Department of Clinical Surgery, University of Edinburgh, and Edinburgh Northern Hospital Group.

Serial blood-volume estimations using standard isotope-dilution methods are highly inaccurate in haemorrhage. Important factors are the loss of isotope, its sequestration in the circulatory bed, and its artificial dilution by simultaneous replacement therapy; repeated doses of isotope cause high background radiation which progressively increases the error. An equation was derived to overcome these difficulties, integrating mathematically the apparent blood-volume, for the theoretical measurement of the amount and rate of haemorrhage from a concealed source using a single dose of isotope:—

$$Vc = I_t \frac{1}{Vb/Va - 1},$$

where Vc = initial blood-volume minus the amount of blood loss in time t, Va the initial blood-volume, and Vb the apparent blood-volume after time t; I = infusion volume (ml.) in time t.

The validity of the method has been examined in two groups of experiments as follows:—

1. Using a model, a measured 'blood loss' was compared with a computed one; in 8 experiments, with initial 'blood-volumes' varying from 2·0 to 5·5 litres, the results verified the equation.
2. The method was applied to 6 female baboons under phencyclidine anaesthesia. Controlled measured haemorrhages were produced from the femoral artery. The error in the computed blood-volume (Vc) varied from 0 to 17·6 per cent with a mean overestimation of the initial volume remaining of 4·4 per cent.

16. A Circulating Myocardial Depressant Factor after Shock: W. D. Fisher, C. S. McArdle, M. Maddern, and I. McA. Ledingham, University Departments of Surgery and Orthopaedics, Western Infirmary, Glasgow.

A myocardial depressant factor has been demonstrated in the plasma of animals and patients following experimental and clinical shock respectively (Lefer, 1970; Lovett et al., 1971). The present study is an attempt to confirm this important observation using a modified assay with guinea-pig atrium.

Two groups of 6 greyhounds were subjected to haemorrhagic hypotension for 1 and 3½ hours. Plasma ultrafiltrates were prepared and were found to depress contractions of guinea-pig atrium from 15 ± 2 per cent preshock to 45 ± 4 per cent after 1 hour of hypotension ($P < 0\cdot001$). Following 3½ hours of hypotension significantly more depression was shown (73 ± 4 per cent; $P < 0\cdot005$), corresponding to the appearance of impaired cardiac function in the dogs. Further purification of plasma ultrafiltrates on gel chromatographic columns demonstrated the appearance of a peak of molecular weight 500–700 which appeared to contain most of the depressant activity.

The ultrafiltrates of plasma from 12 patients suffering from haemorrhagic endotoxic and cardiogenic shock were also assayed. Significantly greater depression ($P < 0\cdot05$) occurred in 7 patients dying from heart failure (56 ± 6 per cent) than in the 5 patients who survived (31 ± 11 per cent). These results support the view that a low-molecular-weight compound with cardiotoxic effects appears in the circulation after shock.

17. Urinary Losses of Intravenous Nutrients:

A. E. B. GIDDINGS, A. O. B. JOHNSTON, and R. G. CLARK, Department of Surgery, University of Sheffield.

Urinary losses of carbohydrate and amino acids were measured in 40 patients receiving parenteral nutrition during 4 postoperative days. In 20 patients (trial I) sorbitol and a *d*/*l*-amino-acid mixture (Trophysan Conc. 10) were given, while the other 20 patients received (trial II) sorbitol, fructose, and an *l*-amino-acid mixture (Vamin). A range of caloric intake from 12 to 51 Cal. per kg. per day was used within each trial. Nitrogen, fluid, and electrolyte intakes were related to body-weight.

Up to 8–13 per cent of infused sorbitol and 1–3 per cent of fructose were lost in the urine. Increased osmolar loading with sorbitol did not alter total urine osmolar output or volume. There was no change in sodium or potassium balance at higher osmolar intakes.

In trial I amino-acid losses were 7–12 per cent, and in trial II 2–6 per cent of the amount given was lost ($P < 0\cdot001$). In both groups the amounts lost were greater than those in control patients, who showed a small postoperative increase. Increased losses of infused amino-acids occurred in patients receiving the *d*/*l* mixture. The capacity of glycine to interfere with tubular reabsorption (Handler et al., 1949) may account for these higher losses.

Urinary losses reduced effective daily intake in a 70-kg. man by 210 Cal. and 2 g. of nitrogen per day.

HANDLER, P., KAMIN, H., and HARRIS, J. S. (1949), *J. biol. Chem.*, **179**, 283.

18. Insulin Secretion and Glucose Tolerance during and after Surgical Operation:

P. D. WRIGHT and I. D. A. JOHNSTON, Department of Surgery, University of Newcastle upon Tyne.

Glucose utilization becomes less efficient and plasma-insulin levels rise in the postoperative period or after injury (Bernard, 1877; Allison et al., 1969). A study was planned to examine the time of onset of these changes during surgery of varying degrees of severity. Plasma-glucose, insulin, and cortisol levels were measured in three groups of 6 patients undergoing (1) inguinal herniorrhaphy, (2) vagotomy and pyloroplasty, and (3) aortofemoral by-pass grafting.

Intravenous glucose-tolerance tests (25 g.) were performed before operation, during operation, and on four occasions in the first 8 postoperative days. Glucose-utilization coefficients (K values) were calculated and showed significant depression of glucose tolerance during the time of operation ($P < 0\cdot005$). Normal levels were restored by the eighth day. The depression of glucose tolerance was greatest on the third postoperative day in the major surgery group compared with the minor surgery groups ($P < 0\cdot025$). Insulin secretion was significantly depressed in all the groups during operation ($P < 0\cdot01$). Following operation secretion was enhanced ($P < 0\cdot025$), indicating insulin resistance.

Glucose tolerance is depressed following surgery, the degree of depression varying with severity of operation. Insulin secretion is suppressed during surgery and is later enhanced, suggesting later insulin antagonism.

19. The Effect of Thyroid Status on Nitrogen Balance and the Rate of Wound Healing after Injury in Rats:

J. LENNOX and I. D. A. JOHNSTON, Department of Surgery, University of Newcastle upon Tyne.

The relationship between post-traumatic changes in thyroid activity, the metabolic response (Harland et al., 1972), and wound healing is uncertain. Wound healing rates (Cuthbertson et al., 1941) and the tensile strength of wounds using Sandblom and Peterson's tensiometer were measured in rats with varying levels of thyroid activity.

Three groups of 10 rats were used. After total thyroidectomy one group was given thyroxine in high dosage; the second group received nothing and were hypothyroid. The third group underwent sham surgery and were used as controls.

Wound healing was accelerated by a mean of 2·5 days ($P < 0\cdot001$) in the hyperthyroid group and delayed by a mean of 2·0 days ($P < 0\cdot001$) in the hypothyroid group with reference to the control groups. The tensile strength of linear wounds was significantly greater at 10 days in the hyperthyroid group. The mean basal nitrogen turnover was 99·3 ± 8·9 mg. nitrogen per 100 g. rat in the hypothyroid group, 105·9 ± 4·4 mg. nitrogen in the control group, and 155·6 ± 8·8 mg. nitrogen in the hyperthyroid group. Following trauma the increase in nitrogen excretion was less in the hypothyroid group and greater in the hyperthyroid group compared with the control group.

There is a significant correlation between tensile strength of wounds and basal nitrogen turnover which may be related to thyroxine activity.

20. Coronary Vein Perfusion as an Alternative Method for ameliorating Ischaemic Changes in Experimental Animals:

I. A. SALLAM, W. H. BAIN, and W. J. KOLFF, Division of Artificial Organs, University of Utah, Salt Lake City, United States.

The possible augmentation of obstructed coronary blood-flow by utilizing the coronary vein instead of the artery was investigated. Studies were made in 10 anaesthetized animals. Myocardial ischaemia was established by ligating the left anterior descending coronary artery. In 8 animals ischaemic changes were evident electrocardiographically. Retrograde perfusion of the coronary vein with the internal mammary artery was accomplished either by direct end-to-side anastomosis or by the interposition of a Teflon cannula. The vein was ligated proximally. When perfusion of the coronary vein was begun signs of ischaemia disappeared over a period of 12–25 minutes but could be reproduced by clamping the internal mammary artery.

Previous attempts to utilize the coronary vein have been described by Beck in 1948, where a vein-graft was placed between the aorta and coronary sinus as a first stage, followed a month later by a second-stage operation in which the coronary sinus was removed. The high mortality-rate made such procedures unacceptable. The present approach differs in that it only utilizes the part of the vein involved in the ischaemic area and it establishes a retrograde perfusion. This may offer new prospects in patients in whom neither available surgical nor medical treatment proves to be of value and includes patients in whom the coronary artery is not suitable for coronary by-pass grafts owing to extensive diffuse narrowing or those patients presenting with cardiogenic shock after myocardial infarction.

Beck, C. S. (1948), *J. Am. med. Ass.*, **137**, 436.

21. Observer Variation in Clinical Diagnosis: Its Magnitude and Importance in Patients with Acute Abdominal Pain:

F. T. de Dombal, P. W. Gill, D. J. Leaper, Jane C. Horrocks, J. R. Staniland, and P. J. Guillou, University Department of Surgery, University of Leeds.

This report describes an evaluation of 'observer variation' in history taking and examination of patients with abdominal pain. Initial studies confirmed previous gloomy predictions. When 3 observers recorded data from a (fourth) clinician's patient interview there was a 20 per cent disagreement amongst them as to whether individual questions had been asked or not, and an 18 per cent disagreement as to whether the patient's response indicated any abnormality.

Following this initial experience a system of 'agreed definitions' was produced. Further studies using this system showed a rapid and considerable fall in the degree of observer variation between the data recorded by the same 3 observers, from just under 20 per cent to around 4 per cent in a series of 10 cases. Moreover, a fourth observer in a further series of cases rapidly achieved comparable levels of agreement with the original team. Finally, experience with a computer-aided diagnostic system using the same 'agreed definitions' scheme for entering data into the computer showed the rate of diagnostic error due to inadequate data acquisition to be low (4·8 per cent in a series of 500 cases).

It is suggested that observer variation in recording data from patients with acute abdominal pain is considerable, but that by using a system of carefully agreed definitions, 'faulty' data acquisition need not be the prime cause of errors in diagnosis.

22. Abnormal Detrusor Function in Asymptomatic Diabetes:

A. C. Buck, C. U. McRae, and P. I. Reed (G. D. Chisholm), Urological Unit, Department of Surgery, Hammersmith Hospital and Royal Postgraduate Medical School, London.

Abnormalities of bladder function in diabetes are considered to be a late manifestation of diabetic neuropathy. In a review of 3000 diabetic patients the incidence of neuropathy was 7 per cent, of which 25·6 per cent exhibited bladder dysfunction (Rundles, 1945). A higher incidence of bladder dysfunction is now recognized and in a selected group of asymptomatic juvenile diabetics the incidence was 87 per cent (Faerman et al., 1971).

In this study 25 diabetic patients who were free of urinary symptoms were studied by urodynamic techniques. The following measurements were made: (1) urinary flow rate, (2) residual urine volume, (3) cystometry, and (4) bladder capacity. Bladder sensation in relation to bladder capacity was recorded.

The results showed that 24 patients (90 per cent) had normal flow rates and residual urine volumes, but 17 patients (68 per cent) had atonic bladders with a low pressure curve and absence of detrusor contractions. Grossly abnormal bladder capacities (mean 817 ml.) were recorded. In addition, bladder sensation was diminished in 75 per cent of these patients, while in 6 patients there was complete loss of bladder sensation. There was a positive correlation between the severity of diabetes and bladder abnormalities ($P < 0{\cdot}04$).

The incidence of abnormal bladder function in asymptc matic diabetes is higher than suspected previously.

23. Neural Elements in the Medulla activate via C-fibres in Abdominothoracic Vagal Trunk

I. V. F. Fussey, J. F. B. Morrison, and H. I Duthie, Department of Surgery, University c Sheffield, and Department of Physiology, Universit of Leeds.

Using micro-electrodes, the spike activities of singl neural elements in the dorsal motor vagal nucleu (D.M.V.N.) have been recorded in 10 anaesthetized dog The units showed a characteristic low-frequency irregula discharge when spontaneously active and a single evoke spike when an electrical stimulus was applied to a vag trunk at the level of the diaphragm. The recording site were shown to be in the D.M.V.N. by examination c serial sections of each medulla.

The distribution of some of the fibres which activate D.M.V.N. units was demonstrated by electricall stimulating points along the nerve of Latarjet and vag branches which were followed to the wall of the stomacl The units were activated via vagal C-fibres as indicated b the high-stimulus intensities at threshold (6–10 V.) an the conduction velocities (0·95–1·50 m. per sec.) calculate from latency and approximate vagal conduction distanc Some units were shown to be efferent neurons by demor strating the abolition of the evoked spike during the tim that a spontaneous spike was passing in the opposi direction.

These results are the first direct evidence of effere gastric innervation from the D.M.V.N. and are consiste with the suggestion by Kerr and Preshaw (1969) that th nucleus mediates hypoglycaemia-induced acid secretion.

Kerr, F. W. L., and Preshaw, R. N. (1969), *J. Physiol Lond.*, **205**, 405.

24. Further Studies on the Response t Insulin after Three Types of Vagotomy in Mar

P. J. Lyndon, D. Johnston, R. B. Smith, C. S Humphrey, M. C. Mason, and J. C. Goligher University Department of Surgery, The Gener Infirmary, Leeds.

The vagotomies were truncal (T.V.), selective (S.V. and highly selective (H.S.V.). Studies were carried o before operation ($n = 30$), 1 week after operation (T.V 515; S.V., 150; H.S.V., 150), and more than 1 year aft operation (T.V., 35; S.V., 27; H.S.V., 56). Patien studied more than 1 year after operation were in goo health. The dose of insulin used was 0·2 U. per kg.

The incidence of incomplete vagotomy at 1 week w 16 per cent for T.V., 13 per cent for S.V., and 4 per ce for H.S.V., but after 1 year it was more than 50 per ce for each type of vagotomy. However, mean peak ac output to insulin (P.A.O.$^{\text{I}}$) at more than 1 year aft operation was only 3·0 mEq. per hour for T.V., 5·0 mE per hour for S.V., and 4·4 mEq. per hour for H.S.V preoperatively. Six serial studies of P.A.O.$^{\text{I}}$ in H.S. patients for up to 3 years suggest that P.A.O.$^{\text{I}}$ does n increase after 1 year.

After H.S.V. the vagotomy can be incomplete only (on the oesophagus or (*b*) at the antral end of the stomac It is shown, first, that incompleteness is usually on t oesophagus and not distally and, secondly, that incon pleteness distally is usually detectable at the early pos operative test.

Complete vagotomy of the parietal cell mass is obtai able in 96 per cent of patients by the use of H.S.V., and t P.A.O.$^{\text{I}}$ does not increase significantly 1 year after H.S.

25. An Assessment of the Insulin Test by Graded Vagotomy in the Dog: S. NUNDY and J. H. BARON, Department of Surgery, Royal Postgraduate Medical School, London.

Hollander postulated that the insulin test was qualitative, the rise in acidity affording no indication of the number of intact vagal fibres. The insulin test has therefore been assessed by graded vagotomy in the dog.

Three dogs with a chronic gastric fistula had four operations each. Approximately half the acid-secreting area was denervated by cutting nerves in the lesser omentum from the antral border to 1 cm. of the oesophagogastric junction, and this partial vagotomy was then followed by conventional proximal gastric vagotomy, selective vagotomy, and truncal vagotomy. Each dog had 8 insulin tests 3 weeks after each operation, the doses ranging from 0·125 to 1·0 U. per kg.

Although the mean rises in acidity after presumed total parietal-cell denervation were less than 20 mEq./l. (a Hollander-negative result), about 20 per cent of the results of individual tests were Hollander positive. Before vagotomy the highest rises in acidity occurred between 30 and 60 minutes after insulin injection. After partial vagotomy this rise occurred significantly later, between 45 and 90 minutes. The rise in acid output differentiated more completely between innervated and denervated stomachs and was more repeatable than the rise in acidity.

Our findings support the contention that the results of the insulin test should be reported in terms of the rise in acid output.

26. Effect of Proximal Gastric Vagotomy on Plasma-gastrin Response to Meat Extract in Duodenal Ulcer Subjects: J. H. WYLLIE, B. H. STAGG, M. R. LEWIN, and C. G. CLARK, Department of Surgery, University College Hospital Medical School, London.

In 16 patients treated by proximal gastric vagotomy the postoperative insulin test was positive in 8. Using a radio-immunoassay the ability of the antrum to release gastrin into the circulation in response to meat extract (Oxo) was studied before and 10 days after operation in all patients. The mean fasting plasma-gastrin level preoperatively was 92 pg. per ml., and was not significantly altered after vagotomy, when it was 77 pg. per ml. In the insulin-negative cases the plasma-gastrin response to meat extract was reduced postoperatively, being absent in 4 cases, so that the mean peak plasma-gastrin level fell from 237 to 135 pg. per ml. In contrast, mean plasma-gastrin responses were unchanged in patients with a positive insulin test.

This unexpected relationship between the vagus nerve and the release of antral gastrin by meat extract may be explained if preservation of the antral nerves is essential for gastrin release by Oxo. If so, it appears that a positive insulin test may be the result of residual antral rather than fundic innervation. This means that insulin tests after proximal gastric vagotomy may have less significance than positive tests in other types of vagotomy.

27. Gastric Secretory Response to Continuous Insulin Infusion in the Dog: R. R. DOZOIS, D. C. CARTER, and J. R. KIRKPATRICK, Department of Clinical Surgery, University of Edinburgh.

The gastric secretory response to a continuous insulin infusion was studied in 4 dogs which were each provided with a gastric fistula.

Following collection of two 15-minute samples of basal secretion, soluble insulin (0·025, 0·05, 0·15, and 0·30 U. per kg. per hour) was delivered intravenously for 3 hours by a slow-injection pump. Samples of gastric juice were collected every 15 minutes and samples of venous blood were drawn every 30 minutes after the start of the infusion. Volume, acid concentration, and acid output were measured and blood-glucose levels were determined.

Graded doses of insulin produced graded levels of hypoglycaemia and a graded acid response. The highest peak acid output (P.A.O.) and the highest total acid output were achieved with a dose of insulin of 0·15 U. per kg. per hour. No initial inhibitory phase of gastric acid secretion was seen, but a dose-related delay in the onset of the acid response was noted. A linear correlation between the P.A.O. and the lowest blood-glucose, the plateau blood-glucose, and the maximum fall of blood-glucose (Baron, 1970) was observed.

Our results further substantiate the recent hypothesis (Baron, 1970; Spencer and Grossman, 1971) that insulin provides a graded glycopenic stimulus producing a graded acid response.

BARON, J. H. (1970), *Gut*, **11**, 826.
SPENCER, J., and GROSSMAN, M. I. (1971), *Ibid.*, **12**, 891.

28. Gastric Secretion and Serum Gastrin after Intravenous Infusions of Insulin in Man: D. P. GIRVAN, J. H. BARON, J. SPENCER, and J. HANSKY, Department of Surgery, Royal Postgraduate Medical School, London, and Department of Medicine, Monash University, Melbourne, Australia.

Intravenous infusion of insulin produces plateau acid secretion with minimal side-effects (Carter et al., 1972). This infusion test has been compared with bolus injections of insulin and the relationships of hypoglycaemia, acid, and serum gastrin have been explored.

An insulin infusion of 0·04 U. per kg. per hour produced a mean lowest blood-glucose of 23·5 ± 9·2 mg. per 100 ml., which is significantly higher than the 16·1 ± 6·4 mg. per 100 ml. produced after a bolus injection dose of 0·2 U. per kg. The peak acid output and mean rise in acidity were comparable in the two procedures, and the Hollander status after vagotomy was identical. Unpleasant side-effects were fewer and milder in the patients undergoing infusion.

Serum gastrin (Hansky and Cain, 1969) was increased during infusion of insulin and inversely correlated with blood-glucose. The mean rise of serum gastrin in 6 unoperated patients with duodenal ulcer was 46·7 pg. per ml., which is almost identical with the mean rise of 48·7 pg. per ml. in 6 patients with positive Hollander tests after vagotomy.

The insulin-infusion test uses less insulin, avoids severe hypoglycaemia, has milder side-effects, and provides comparable acidities to the conventional insulin test. Measurements of serum gastrin after insulin infusion, as after single injections, gave no additional information of value in assessing vagotomy.

29. Turbulence in the Classification of Varicose Veins: J. SOMERVILLE, P. BYRNE, and D. KING (W. G. Fegan), Department of Clinical Research, Sir Patrick Dun's Hospital, Dublin.

It has been suggested that turbulent retrograde flow is important in the production of superficial varicose veins (Kline and Byrne, 1972). To investigate the significance of turbulence 38 female patients were selected and tape recordings were made of the audio output of a Parks 806 Directional Doppler during retrograde flow in the long saphenous vein. The recordings were analysed using a Kay Sona spectrograph and the patterns were compared with those of known turbulent and laminar flows in *in vivo* and *in vitro* models. Retrograde flow was produced by having an upright person stand on her toes. Five of the patients investigated had medial malleolar ulcers.

Ten of the patients exhibited turbulence. Of these, none had ulcers but 2 (12·5 per cent) showed mild signs of calf-muscle-pump failure (oedema, pigmentation). Thirteen patients (81 per cent) showed gross varicosity. Of the 22 patients who did not show turbulence, 7 (31·4 per cent) showed signs of calf-pump failure. The remaining 15 patients (68 6 per cent) had no signs of calf-pump failure, had minimal symptoms and varices, and had only a short history.

These results show three distinct groups: (1) a group exhibiting turbulence, largely asymptomatic with gross varicosities, (2) an asymptomatic non-turbulent group with a short history, and (3) a symptomatic non-turbulent group showing evidence of calf-pump dysfunction.

KLINE, A. L., and BYRNE, P. (1972), *Br. J. Surg.*, **59**, 915.

30. The Use of Venous Pressure Measurements and Directional Doppler Recordings in Distinguishing between Superficial and Deep Valvular Incompetence in Patients with Deep Venous Insufficiency: J. D. LEWIS, D. C. S. PARSONS, T. N. NEEDHAM, J. N. DOUGLAS, J. LAWSON, J. T. HOBBS, and A. N. NICOLAIDES, Surgical Unit, St. Mary's Hospital, London.

It has been suggested recently that cinephlebography will distinguish between superficial and deep valvular incompetence in patients with venous insufficiency (Field et al., 1972). In the present study a simple technique based on the reduction of venous pressure during exercise has been developed which can also achieve this.

The pressure in a superficial vein on the foot was recorded with the patient standing still and walking. The measurements were repeated after occluding the superficial veins only, with a 5-cm. wide pneumatic cuff on the ankle.

Fifty patients (80 limbs) have been studied. In 27 clinically normal limbs pressure measurements were normal. Of the 53 clinically abnormal limbs, 6 had normal pressures and in these lymphoedema was confirmed by lymphangiography, 16 had abnormal pressures on walking which became normal when the ankle cuff was inflated ('superficial insufficiency only'), and 31 had abnormal pressures on walking whether the cuff was inflated or not ('deep venous insufficiency').

Ascending phlebography was performed on all the patients. The state of the valves in the deep veins was assessed by recording the effect of respiration and the Valsalva manœuvre on the blood velocity using a directional Doppler. This confirmed the presence of reflux in the popliteal vein in all 31 limbs with 'deep venous insufficiency'. With the exception of 2 limbs no reflux was detected in the remaining limbs.

FIELD, E. S., KAKKAR, V. V., STEPHENSON, G., and NICOLAIDES, A. N. (1972), *Br. J. Surg.*, **59**, 304.

31. The Influence of a Temporary Arteriovenous Fistula in maintaining the Patency of Venous Replacements by Autografts, Allografts, and Dacron Prostheses in the Dog: D. C. S. PARSONS and J. T. HOBBS, St. Mary's Hospital, London.

Venous replacement distal to the diaphragm has not been successful. The problems are the replacement of occluded proximal veins and the insertion of valves to correct valvular insufficiency in the deep veins.

The effect of a temporary distal arteriovenous fistula on the patency rate of grafts placed in canine iliac veins was investigated. Bryant et al. (1958) suggested the use of a fistula during venous replacement.

In 13 dogs 1½-cm. segments of knitted Dacron tu were inserted into both common iliac veins, and a femor arteriovenous fistula was constructed on one side. T fistula was later closed and the dogs were observed 10 months. Patency of the grafts was monitored venography. On the side with the arteriovenous fistu 10 of the 13 grafts were patent, as compared with t contralateral side with no fistula where 10 grafts we occluded and 3 stenosed. The fate of the graft w related to the volume flow and the diameter.

In a further series of 9 dogs 2½-cm. allografts a autografts which contained a patent valve and we vitally preserved were inserted in the iliac veins. temporary arteriovenous fistula was again constructed one side. The patency rate was shown to be more th 90 per cent at 7 months. Valvular function was present 4 of the 9 autografts; no valve function was seen in t allograft veins.

BRYANT, M. F., LAZENBY, W. D., and HOWARD, J. (1958), *Archs Surg., Chicago*, **76**, 289.

32. The Risk of Deep-vein Thrombosis Surgical Patients: A. NICOLAIDES, D. IRVIN M. PRETZELL, P. DUPONT, J. LEWIS, S. DESAI, J. DOUGLAS, V. V. KAKKAR, and E. S. FIELD, Surgi Unit and Department of Epidemiology, St. Mar Hospital, and Department of Surgery, Kin College Hospital, London.

Factors such as age, severity of operation, previo history of deep-vein thrombosis (D.V.T.), obesi malignancy, varicose veins, and infection may be associat with a high incidence of D.V.T. (Kakkar et al., 197 Nicolaides et al., 1972).

In a prospective series of 390 general surgical patie factors believed to predispose to D.V.T. have be studied by linear logistic analysis. The patients had be screened with the ^{125}I-fibrinogen test in two differe hospitals using the same criteria for diagnosing D.V. The two groups of patients were comparable with resp to the incidence of the various factors studied.

A standard computer program was used to obtain t maximum-likelihood estimates of the coefficients for t various factors studied. The most important fac appeared to be the hospital ($P<0{\cdot}001$). Severity operation, infection, previous history of D.V.T., and a were also important ($P<0{\cdot}01$); malignancy and p medication with opiates were the least important of t significant factors ($P<0{\cdot}05$).

Using the coefficients for the significant factors equation was obtained of the form:—

$$\begin{aligned} y = -0{\cdot}28 &- (0{\cdot}92 \times \text{hospital}) \\ &+ (0{\cdot}72 \times \text{severity of operation}) \\ &+ (0{\cdot}70 \times \text{previous history of D.V.T.}) \\ &+ (0\ 60 \times \text{infection}) \\ &+ (0{\cdot}024 \times \text{age}) + (0{\cdot}38 \times \text{malignancy}) \\ &+ (0{\cdot}38 \times \text{premedication with opiates}). \end{aligned}$$

The value of factors other than age was 0 or 1. For a patient y can be expressed as a percentage risk of devel ing D.V.T. and is useful in determining which patie will need preventive measures.

33. The Effect of Dextran 40 on Venous Fl Changes in the Leg induced by Abdomi Operations: D. H. LEWIS and H. JANSEN (Matheson), Department of Surgery I, University Gothenburg, Gothenburg, Sweden.

In 34 patients the venous flow pattern of the leg was investigated immediately before and after abdominal operations. All the patients were operated upon under general anaesthesia and with muscle relaxation. Isotope injections were made via a short plastic cannula in the dorsal vein of the great toe. Time-concentration curves were registered with a scintillation detector over the groin and, in several cases, simultaneously over the calf. Twenty-two patients received glucose only during operation (control group) and 12 received 500 ml. of 10 per cent dextran 40 (Rheomacrodex). The patients in the dextran group were operated upon for gall-stones and were compared with 12 in the control group undergoing the same operation. In the control group the time of appearance of the isotope at the groin was *shorter* after operation than before. Preoperatively the curve rose slowly to a broad, low peak and declined slowly. Postoperatively the curve rose quickly to a peak of short duration. The difference between the pre- and postoperative curves was most marked over the calf. In the dextran group the pre- and postoperative curves were identical both with regard to appearance time and pattern.

It is suggested that the changes in the curves in the control group are due to a decrease in the vessel volume available for venous return from the leg, especially in the calf. This is prevented by the administration of 500 ml. of dextran 40 during operation. These observations could account, at least in part, for the anti-thrombotic action of a single infusion of dextran 40 during operation.

34. An Improved Electrical Impedance Technique for the Detection of Deep-vein Thrombosis: K. W. Johnston, V. V. Kakkar, T. P. Corrigan, D. P. Fossard, and J. J. Spindler, Department of Surgery, University of Toronto, and Department of Surgery, King's College Hospital Medical School, London.

Several studies have recently confirmed the inadequacy of clinical examination in diagnosing deep-vein thrombosis (D.V.T.) in the legs. In addition, the ^{125}I-fibrinogen test and the Doppler ultrasound technique have limitations. In this paper a simple non-invasive method is described which can be used to detect clinically significant thrombi.

The technique is based on the measurement of the change in calf electrical impedance following deep inspiration. Wheeler et al. (1972) first applied this method to the diagnosis of D.V.T. In the present study 100 limbs with suspected D.V.T. were examined by Wheeler's technique and also by ascending venography. Thirty per cent of the patients studied were unable to co-operate sufficiently to allow the measurement of electrical impedance changes. Also, 50 per cent of the thrombi in the popliteal and femoral veins were missed.

Wheeler's technique has been improved by using a thigh pressure cuff instead of relying on deep inspiration to produce calf-impedance changes. Fifty patients with suspected D.V.T. were studied. In contrast to Wheeler's method it was possible to use this new technique in all patients and it clearly delineated between those with and those without clinically significant D.V.T., and may prove a simple, safe, and non-invasive method for detecting significant thrombi.

35. Isografts and Allografts of Pancreatic Islets in Rats: W. F. Ballinger, P. E. Lacy, D. W. Scharp, C. B. Kemp, and M. Knight (A. W. Kay), Departments of Surgery and Pathology, Washington University School of Medicine, St. Louis, United States.

Viable islets of Langerhans can be transplanted in rats as isografts (inbred Lewis strain) and allografts (Wistar to Lewis). The need for the development of such techniques is indicated by the discouraging results of whole-organ pancreatic transplantation in humans.

Streptozotocin-induced diabetic rats lose weight and die in 4–8 weeks; they secrete, on average, 130 ml. of urine containing approximately 14 g. of glucose per day and have blood-sugars over 400 mg. per 100 ml. Diabetic rats receiving approximately 600 islets of Langerhans intraperitoneally or into a muscle pouch in the thigh gain weight, produce 50–60 ml. of urine containing 6–8 g. of glucose per day, and their hyperglycaemia is reduced to approximately 200 mg. per 100 ml. Allografted rats receiving azathioprine are remarkably similar to the isograft series.

Preliminary studies indicate: (1) dialysed, layered Ficoll solutions permit rapid separation of islets, (2) preparations containing acini as well as islets do not survive when transplanted, (3) intact rat islet preparations can be successfully stored for at least 24 hours at 4° C. with evidence of continued viability, (4) tissue-culture techniques may permit long-term survival of islet cells, and (5) human islets have been prepared as in rats with preservation of synthesis and production of insulin.

36. Transplantation of Interstitial Cells of the Testis: Pauline F. Boyle and M. Fox, Department of Urology, Royal Hospital, Sheffield.

The first successful testicular transplant showing vascularization of the graft and subsequent changes of secondary sexual development was reported by Berthold in 1849. The testis has usually been transplanted as a whole and major problems were associated with vascular supply and allograft rejection.

Experiments were designed to investigate the effect of transplantation of homogenates of the testis under conditions in which the allograft response could not occur. The fate of the transplanted cells was followed histologically and effects on secondary sexual development were observed.

Bilateral orchidectomy was performed in groups of F 1 mice (CBA/T6XC57BL) at the age of 3 weeks and 3 months, and the testes were cut up finely with scissors and transplanted into ear pinnae, under the skin of the snout and back, and under the parietal peritoneum. The animals were weighed at regular intervals and killed after 3 months. The grafts were removed and examined histologically, and the seminal vesicles and penises were weighed and also examined.

Castrated mice gained weight more slowly than control and transplanted animals. Weight-gain was similar in transplanted and control animals. Cells indistinguishable from interstitial cells were found in ear pinnae and under the peritoneum at 3 months. After orchidectomy the seminal vesicles and penis atrophied in adult mice and did not develop in adolescent animals. Following transplantation nearly normal results were obtained.

Berthold (1849), *Arch. Anat. Phys. Wiss. Med., Berlin*, 42.

37. The Early Diagnosis of Rejection by the Leucocyte Migration Test in Cadaveric Renal Transplantation: R. J. Williams, H. McFarlane, N. P. Mallick, G. Taylor, and W. McN. Orr, Renal Transplantation Unit, Manchester Royal Infirmary and University of Manchester.

Experience of the leucocyte migration test as a means of providing an early diagnosis of rejection in cadaveric renal transplantation has been reported (Williams et al., 1971). The method has now been evaluated in an additional 22 patients using whole foetal kidney and glomerular basement membrane from homologous kidney as sources of antigen.

A high degree of reproducibility of migration indices (Mx/M_0) was obtained using these antigens in 50 normal subjects (range 0·80–1·10; mean 0·93; S.D. 0·075).

In the transplanted patients 33 episodes of inhibition of migration (M.I. < 0·75), with or without initial stimulation (M.I. < 1·15), were observed and were followed in 25 instances by clinical and biochemical evidence of rejection within 2–5 days. Antirejection doses of prednisolone were already being given in 6 of the 8 instances where inhibition of migration was not followed by evidence of rejection.

38. Measurement of Lymphocyte Activity in Response to a Renal Allograft: R. W. BLAMEY, RITA NICOL, and THELMA BAXTER, St. Vincent's Hospital, University of Melbourne.

Measurement of immune activity against a renal transplant would be of use in the management of antirejection therapy. Synthesis of DNA (measured by the uptake of ^{3}H-thymidine) and of RNA (^{3}H-uridine) by lymphocytes of recipients of renal allografts has been measured in 2-hour cultures at intervals after transplantation.

Two rat transplant systems have been studied in 39 DALF$_1$ to MAB grafts, and 23 transplants within the MAB (closed) strain; the former gives consistent acute rejection, the latter variable rejection. ^{3}H-thymidine uptake to recipient lymphocytes is significantly raised at 4 days when there is little evidence of rejection and at 7 days when rejection occurs in the former system. Rise in uptake is proportional to the histological degree of rejection in the latter system. Recipient lymphocyte ^{3}H-uridine incorporation is not raised at the time of rejection.

In 15 patients following transplantation a fivefold increase in thymidine uptake accompanied 6 out of 7 definite rejection episodes. However, uptakes of these levels have also occurred on 10 other occasions, some being associated with infection. Acute tubular necrosis and problems from urinary obstruction did not give raised thymidine uptakes. Uridine uptake did not correlate with rejection.

Incorporation of ^{3}H-thymidine to recipient lymphocytes offers some measure of the immune activity against an allograft.

39. The Mechanism of Enhancement of Rat Renal Allografts. The Nature of Enhancing Antibody: S. DESAI and M. RUSZKIEWICZ (C. W. Jamieson), St. Mary's Hospital, London.

The rejection of rat renal allografts between Lewis × Brown Norway F$_1$ hybrid to Lewis across a strong histocompatible barrier can be markedly delayed by prior intravenous administration of donor-strain bone-marrow cells to the recipients; this delay is due to immunological enhancement rather than to tolerance. This study has now been extended by attempting to reproduce the delay in rejection by passive transfer of allo-antiserum, by demonstrating cytotoxic effects *in vitro* of the active serum on donor-strain lymphocytes by a modification of the cytotoxic test using ^{51}Cr (Lance et al., 1968), and by identification of the types of antibodies involved by a modification of the method described by Deutsch and Morton (1957).

These studies show that passive transfer of allo-antiserum produces delay in rejection similar to that in animals treated with bone-marrow. The degree of abrogation of rejection is related to the levels of cytotoxic allo-antibody; the cytotoxic antibodies have been identified as belonging to 19S(IgM) and 7S(IgG) classes of immunoglobulins.

40. Antibody-induced Enhancement of Cardiac Allografts in Mice: R. A. SELLS and J. BRADLEY, Departments of Surgery and Haematology, University of Liverpool.

Hearts were removed from HALB/C mouse foetuses and transplanted to pockets created beneath the dorsal ear skin of adult CBA mice. Using a modification of the technique of Judd and Trentin (1971) initial failure of grafts was 12 per cent. Graft function was evaluated using E.C.G. electrodes implanted on either side of the graft, with an indifferent electrode placed in a hind-limb muscle.

Recipients and grafts were treated with antibodies prepared in CBA mice by injecting donor thymocytes and spleen cells with adjuvant (group III) and by two donor skin-grafts (group IV). The cytotoxic titres of both groups of sera were similar.

In group I (isografts; $n = 28$) 80 per cent of the grafts survived beyond day 90. In group II (control allografts; $n = 36$) 50 per cent of the grafts ceased to function by day 7 (range 5–11 days). In group III (allografts + adjuvant-induced antibodies; $n = 16$) 50 per cent of the grafts ceased to function by day 10·5 (range 8–13 days). In group IV (allografts + skin-graft induced antibodies; $n = 20$) 50 per cent of the grafts ceased to function by day 25 (range 11–70 + days).

Prolongation of mouse foetal heart allograft survival may be produced by using antibodies directed at the donor antigens. The ability to prolong graft survival does not appear to be related to the titre of the cytotoxic antibodies.

JUDD, K. P., and TRENTIN, J. J. (1971), *Transplantation*, **11**, 298.

41. The Character of Effector Cells and the Accumulation of Macrophages in rejecting Heart Allografts in the Rat: N. L. TILNEY (P. R. F. Bell), Sir William Dunn School of Pathology, University of Oxford.

The morphologic simplicity of the myocardium makes the heterotopic cardiac transplant in the inbred rat an attractive model for defining events and patterns of cellular rejection. The rapid destruction of allografts transplanted between animals of major genetic differences was studied.

Cells in normal hearts and in isografts and effector cells infiltrating allografts were harvested. Grafts were removed serially from groups of recipients. Pieces of myocardium were digested enzymatically, the cell infiltrate was removed, and total counts and differential counts were performed. Cell populations and their varying rates of accumulation were compared and related to histological and autoradiographical observations. Increasing cell numbers were correlated with weight-gain of the heart grafts which were being rejected.

Macrophages may destroy allografts following specific activation by host lymphocytes (Mackaness, 1969). Following intravenous administration, particles of colloidal carbon were noted to adhere selectively to the vascular endothelium of transplanted hearts. Circulating macrophages phagocytoze these particles upon entering the myocardium. The distribution and rate of accumulation of the labelled cells were documented.

Small lymphocytes which rapidly infiltrate allografts undergoing acute rejection are followed by increasing numbers of macrophages. Primitive cell forms are present. Few cells enter isografts, and those which do are predominantly medium and large mononuclear cells.

MACKANESS, G. B. (1969), *J. exp. Med.*, **129**, 973.

42. The Immunosuppressive Effect of Surgery—A Possible Mechanism: J. BANCEWICZ, AILEEN C. GRAY, and G. LINDOP (P. R. F. Bell), University Department of Surgery and Pathology, Western Infirmary, Glasgow.

Lymphocyte responsiveness to mitogens is decreased following operation (Riddle and Berenbaum, 1967; Park et al., 1971). The leucocyte-migration-inhibition test, which is a good *in vitro* correlate of cell-mediated immunity *in vivo*, was used to demonstrate a period of postoperative immune depression.

The reactivity of 9 patients to tuberculoprotein (PPD) was studied. All the tests were positive preoperatively and became negative postoperatively. In 2 patients recovery of the response occurred within 10 days, but in the others recovery was slower.

In the morphological studies the size of the lymphocytes appeared to increase postoperatively. A sevenfold increase in the spontaneous uptake of ^{14}C-labelled thymidine which was maximal on the fifth postoperative day was also found. This observation indicates an increased synthesis of DNA following surgery. Similar changes were seen in 1 patient who suffered trauma but did not undergo anaesthesia.

The increase in DNA synthesis plus the observed increase in lymphocyte size may indicate an activation of lymphocytes following trauma which renders them unresponsive to further immune stimulation.

43. **Properties of Somatosensory Cells in the Human Thalamus:** J. Hankinson and P. Wilson (I. D. A. Johnston), Regional Neurological Centre, Newcastle upon Tyne, and the University of Newcastle upon Tyne.

Following the studies of Guiot et al. (1962) thalamic recording is regarded as the most precise localizing technique available for stereotaxic operations within the thalamus, but there is little quantitative information concerning the properties of human thalamic somatosensory cells.

One hundred and ninety-three somatosensory cells were studied in 80 patients, most of whom suffered from Parkinson's disease. The majority of these cells probably lay within the ventrocaudalis and ventro-intermedius nuclei. One hundred and thirty-seven of the cells responded to cutaneous stimulation of either the contralateral hand or face. Most of the receptive fields on the face were situated near the mouth and nose, and the tips of the digits were usually represented. Cells giving non-adapting discharges usually had larger fields than those giving rapidly adapting responses. For the former the mean areas of receptive fields were $5{\cdot}0 \pm 0{\cdot}9$ cm.^{2} on the face and $3{\cdot}9 \pm 0{\cdot}8$ cm.^{2} on the hand. For the latter the corresponding values were $0{\cdot}8 \pm 0{\cdot}1$ cm.^{2} on both the face and hand. Forty-four cells responded only to either flexion or extension of single joints in the contralateral hand. Following electrical stimulation of the median nerve, somatosensory cells discharged with latencies between 13 and 19 mseconds.

44. **Effect of Carotid Ligation on Cerebral Blood-flow in the Baboon:** D. Sengupta, A. M. Harper, and W. B. Jennett, Wellcome Surgical Research Institute, University of Glasgow, and Institute of Neurological Sciences, Southern General Hospital, Glasgow.

Following carotid ligation there is a risk of ischaemia of the cerebral hemisphere during or after the operation. Experiments were made on anaesthetized baboons to test the effects of ipsilateral carotid ligation on cerebral blood-flow (C.B.F.) and on the normal physiological responses of cerebral circulation to hypercapnia, hypoxia, and hypotension. The C.B.F. was measured following intracarotid injection of ^{133}Xe and calculated from the height/area equation (Høedt-Rasmussen et al., 1966).

The results showed that, at steady state, C.B.F. did not alter following ipsilateral carotid ligation. Before carotid ligation there was a 123 per cent rise in the C.B.F. at hypercapnia, and an 81 per cent rise at hypoxia. C.B.F. was maintained until the mean blood-pressure fell below 70 per cent of the normal value (autoregulation). Following ipsilateral carotid ligation there was only a 41 per cent rise in the C.B.F. at hypercapnia, a 20 per cent rise at hypoxia, and the C.B.F. fell steadily with a fall in the blood-pressure (autoregulation impaired).

It is inferred that although C.B.F. may be normal following carotid ligation, it is likely that the circulatory reserve of the brain is insufficient to meet physiological challenges such as hypercapnia, hypoxia, or hypotension and that this may be the reason for the development of delayed neurological complications.

Høedt-Rasmussen, K., Sveinsdottir, E., and Lassen, N. A. (1966), *Circulation Res.*, **18**, 237.

45. **Ventilatory and Intracranial Pressure Responses to CO_2 Stimulation:** M. Briggs and A. P. Adams (W. B. Jennett), Radcliffe Infirmary, Oxford.

An attempt has been made to analyse some aspects of the relationship between intracranial pressure (I.C.P.) and respiration in man. The I.C.P. end tidal CO_2 and ventilation were monitored continuously in 14 patients during a CO_2 challenge, using a rebreathing circuit adapted from Clark et al. (1966).

Within the P_{CO_2} range studied (40–60 mm. Hg) the relationship between I.C.P. and P_{CO_2} was always linear in one group of 5 patients and was always alinear in a second group of 6 patients. No common factors have been found linking the patients in these groups. The rate of pressure change observed with increasing P_{CO_2} was not significantly related to the mean resting I.C.P.

Regression slopes for ventilation versus P_{CO_2} revealed, as expected, a wide variation between patients (Bulow, 1963) which was unrelated to the resting I.C.P. One patient, however, who was tested before surgery, when the mean I.C.P. was 13 mm. Hg, and after the insertion of a ventriculo-atrial shunt (with a valve opening pressure of 5·3 mm. Hg) showed an increased respiratory responsiveness to CO_2 postoperatively, the slope improving from 1·62 to 2·91 litres per mm. Hg increase.

The results establish base-line patterns of responses to CO_2 stimulation, and those observed in 1 patient indicate that respiratory sensitivity may be depressed by levels of I.C.P. not previously considered to be pathological.

46. **Measurements of Breathing in Brain-damaged Patients:** J. B. North and Sheila Jennett (W. B. Jennett), Institute of Neurological Sciences, Glasgow, and Departments of Neurosurgery and Physiology, University of Glasgow.

Recent reports of abnormal breathing in brain-damaged patients indicate an area for study. Hyperventilation is associated with a poor prognosis after head injury (Vapalahti and Troupp, 1971); different abnormal respiratory patterns may be of localizing value in brain damage; hypoxaemia without obvious lung pathology is common after head injuries.

A system has been developed for detecting abnormal breathing in neurosurgical patients using impedance pneumography (North and Jennett, 1972). Of the first

150 patients who were screened, 86 showed some abnormality, but no close association was found between particular disorders and sites of lesions.

Patients with abnormal breathing patterns were studied quantitatively, measuring ventilation volume and frequency by pneumotachygraphy, together with arterial blood-gases and end tidal CO_2, during breathing of air, 100 per cent oxygen, and CO_2. This provided information about pulmonary gas exchange and respiratory centre chemosensitivity. More than 25 per cent of the patients studied showed an abnormal ventilatory response to CO_2; hyperventilation was not uncommon, but was often associated with hypoxaemia.

47. A Clinical Study of Intracranial Volume/Pressure Relationships:

J. D. MILLER, J. GARIBI, and J. D. PICKARD, University Department of Neurosurgery, Institute of Neurological Sciences, Glasgow.

In experimental animals inflation of an intracranial balloon causes little increase in intracranial pressure (I.C.P.) at first, but eventually uniform increases in volume cause progressively greater increases in I.C.P.; there is thus an exponential relationship between balloon volume and I.C.P. (Langfitt et al., 1965). The purpose of this study was to test whether the same relationship was valid for changes in C.S.F. volume in patients with increased I.C.P.

In 20 patients, during continuous monitoring of the I.C.P., a constant volume of 1 ml. was withdrawn from or injected into the lateral ventricles, and the resulting change in I.C.P. was measured. This was repeated at different times and at differing levels of resting I.C.P., so that 371 observations were made.

There was a positive correlation between the resting I.C.P. and the increase in I.C.P. produced by the injection of fluid ($r = 0{\cdot}41$; $P < 0{\cdot}001$), and between the resting I.C.P. and the reduction in I.C.P. produced by withdrawal of fluid ($r = 0{\cdot}45$; $P < 0{\cdot}001$). The results support the concept of an exponential intracranial volume/pressure relationship in patients with several different causes for increased I.C.P. Induction of small changes in C.S.F. volume gave useful information in individual patients concerning the compensatory capacity available in the presence of intracranial space-occupying lesions.

48. Early Intracranial Pressure and Blood-flow Measurements in Cerebral Gunshot Wounds:

H. A. CROCKARD and D. S. GORDON (H. W. Rodgers), Department of Neurosurgery, Royal Victoria Hospital, Belfast.

Studies of intracranial pressure (I.C.P.), blood-pressure, cerebral blood-flow by radiocirculography, and blood-gas analysis have been used in the management of bullet wounds of the brain in 24 patients within 1 hour of injury.

Intracranial Pressure.—Three groups were recognized.

1. Low intracranial pressure (0–10 mm. Hg): These patients had a very low I.C.P. associated with low blood-pressure. After massive transfusions the blood-pressure and I.C.P. rose. In 2 cases with severe brain damage the I.C.P. reached very high levels before death.

2. High intracranial pressure (60–80 mm. Hg): This response occurred with 'through-and-through' high-velocity injuries. The blood-pressure was also high and the patients required little resuscitation.

3. Moderate intracranial pressure (20–30 mm. H Two groups displayed moderate hypertension: (low-velocity missile injuries usually affecting one hem sphere and (*b*) tangential impacts with high-veloc missiles.

Routine controlled ventilation (I.P.P.V.) controlled t intracranial pressure. Inattention to the state of the airw caused an irrevocable increase in the I.C.P.

Cerebral Blood-flow.—Estimations of the cerebral bloo flow within the first hour after injury helped the progno and confirmed animal experiments (Grauber and Mood 1971). Patients with a blood-flow reduction of over 40 p cent of normal within the first hour died.

GRAUBER, S. E., and MOODY, D. (1971), *J. Neurosurg.*, 568.

49. A New Approach to the Treatment Brain Oedema: Mineralocorticoids:

SCHMIEDEK, W. OETTINGER, A. BAETHMANN, and ENZENBACH, Institute for Surgical Research, Depar ments of Surgery and Neurosurgery, University Munich, West Germany.

The use of adrenal steroids for the prevention reduction of brain oedema is confined to glucosteroi However, from previous studies (Koczorek et al., 196 mineralocorticoids may also exert a beneficial effect brain oedema. The results from neurosurgical patien treated with high doses of aldosterone are reported.

In 20 patients with brain tumours aldosterone w given pre- and postoperatively for several days in a dose 5–10 mg. per day. During the operation samples fro perifocal brain tissue, including cortex and subcortic white matter, were obtained and analysed for: (*a*) wat content and tissue electrolytes (Na, K), (*b*) tissue enzym (GAPDH, CE, IDH, MDH, GLDH, GOT), and (labile metabolites (CP, ATP, ADP, AMP, Pyr., Lact When compared with 20 unpretreated patients, tiss analysis revealed: (1) a significant reduction of wat content in both the cortex and white matter ($P < 0{\cdot}002$ (2) a concomitant decrease of Na ($P < 0{\cdot}005$) and a slig increase in K, (3) little but insignificant changes of tiss enzymes, and (4) an almost identical pattern of lab metabolites in the two groups. Aldosterone medicati was well tolerated in all the patients without any sid effects.

KOCZOREK, KH. R., ANGSTWURM, A., BAETHMANN, ENGELHARDT, D., REULEN, H. J., SCHMIEDEK, VOGT, W., SIMON, B., FRICK, E., and BRENDEL, (1968), in *Postoperative Störungen des Elektrolyt- u Wasserhaushaltes* (ed. BÜCHERL, E. S.). Stuttga Schattauer.

50. A Chronic Experimental Model for t Production of Subarachnoid Haemorrhag

E. W. PETERSON, R. SEARLE, F. MANDY, R. LEBLAN and MIRIELLE BOSC (W. G. Waddell), Departme of Neurosurgery, Faculty of Medicine, University Ottawa, Canada.

A Rickham reservoir was implanted subcutaneously the neck of macaque Rhesus monkeys and connected by catheter to the subarachnoid space anterior to the brai stem. Several days after recovery the animals we anaesthetized and control angiograms of the carotic vertebral circulation were performed by the transbrach route. Subarachnoid haemorrhage was induced injecting 2·5 ml. of the animal's blood by transcutaneo puncture of the reservoir. Repeat angiography demo strated marked arterial spasm of the intracerebral vesse Reversal of this vasospasm was accomplished by injecti the reservoir with theophylline and/or dibutyryl cyc AMP. Serial post-treatment angiograms showed prolonged drug reversal effect. Radiographic subtracti technique applied to the angiograms accentuated the appearance of the vasospasm and of the vasodilatation as a result of treatment (Rickham, 1964).

The experimental model permits long-term survival and repeated production of subarachnoid haemorrhage. The tolerance to drug modification of vascular tone suggests that this may have clinical application in the control of cerebral vasospasm, and in the prevention of ischaemic sequelae following subarachnoid haemorrhage.

51. The Effect of Ovariectomy on Experimental Mammary Carcinoma in the Rat with Portacaval Shunt: J. F. O'GRADY, MARGOT GRUENSTEIN, and F. A. REICHLE (P. Fitzgerald), Department of Surgery, University College, Dublin, and Temple University Hospital, Philadelphia, United States.

End-to-side portacaval shunt (P.C.S.) significantly reduces the incidence of experimental mammary carcinoma in the rat (Reichle et al., 1969). The mechanism of this inhibition is unknown. The major circulatory, metabolic, and hormonal changes which occur after portasystemic by-pass may be related to this tumour inhibition (Reichle et al., 1972).

Ten mg. of 7,12-dimethylbenz-(α)-anthracene (DMBA) were given in a single intragastric instillation to 105 Holtzman rats (150 g.). After 2 weeks P.C.S. (77 rats) and sham operations (28 rats) were performed. When palpable mammary tumours had developed bilateral ovariectomy was performed. A total of 19 rats (10 with shunts, 9 having had sham operations) with breast tumours underwent bilateral ovariectomy and survived long enough for adequate follow-up. Average increase in tumour size at death or 1 year after DMBA was $2\cdot48 \pm 0\cdot57$ cm. in sham-operated rats and $0\cdot82 \pm 0\cdot39$ cm. in rats with shunts ($P < 0\cdot05$). The average time of death after ovariectomy was $85\cdot7 \pm 11\cdot8$ days in sham-operated rats and $92\cdot7 \pm 18\cdot2$ days in rats with shunts (not significant). Approximately equal weight-gain following the sham or shunt operation was observed in both groups.

Following bilateral ovariectomy the suppression of DMBA-produced carcinoma growth is significantly greater in animals with a portasystemic by-pass. This may be due either to an altered hormonal response of the tumours in the shunted animals or to an effect of the P.C.S. on the hormonal changes associated with ovariectomy.

52. *In vivo* Binding of Tritiated Oestradiol in Benign and Malignant Lesions of the Human Breast: N. O'HIGGINS, N. DESHPANDE, and J. I. BURN, Breast Unit, Department of Surgery, Royal Postgraduate Medical School, London, and the Imperial Cancer Research Fund.

Previous workers have examined the uptake of tritium-labelled hormones by mammary cancers (Braunsberg et al., 1967). The capacity to bind tritiated oestradiol-17 *in vivo* was determined in 8 benign and 13 malignant mammary cancers. Uptake was measured in whole-tissue slices and nuclear preparations.

A loading dose of 9 μc. of tritiated oestradiol was given intravenously. This was followed by a continuous slow infusion of 64μc. of tritiated oestradiol, which was started at least 3 hours before operation and continued until the lesion had been removed. Serial venous blood samples were examined to confirm that a steady state of oestradiol had been achieved. Radioactivity levels in the excised specimens were measured in a well counter.

The uptake in the benign lesions ranged between 808 and 2530 disintegrations per minute (d.p.m.) per mg. of wet tissue (mean 1229 d.p.m.). Levels in the malignant cancers ranged between 1456 and 12,563 d.p.m. (mean 2196 d.p.m.). There was a complete separation between postmenopausal patients with benign and malignant disease.

BRAUNSBERG, H., IRVINE, W. T., and JAMES, V. H. T. (1967), *Br. J. Cancer*, **21**, 714.

53. Macrophage Activity and Hormonal Responsiveness in Mammary Cancer: W. D. GEORGE, WENDY PARTRIDGE, and J. I. BURN, Breast Unit, Department of Surgery, Royal Postgraduate Medical School, London.

Changes in reticulo-endothelial macrophage activity occur in patients with cancer and may reflect the host's resistance to the disease (Old et al., 1961). Hormone therapy in advanced breast cancer should theoretically stimulate macrophage activity. Hepatic macrophage activity was studied serially in 14 patients with advanced mammary cancers before and after endocrine therapy. Activity was measured by the rate of clearance of radio-iodine labelled micro-aggregates of albumin given intravenously (Ilio and Wagner, 1963).

Seven patients received oestrogen therapy. Four responded successfully to treatment and all showed an increase in macrophage activity as therapy continued. Of 3 patients who failed to respond to oestrogens, 2 showed a decrease in macrophage activity whilst the third showed no change.

Seven patients underwent major endocrine ablations. Two responded successfully and both showed increase in macrophage activity. Of the 5 non-responders, macrophage activity decreased in 4 and remained unchanged in the other patient.

These results suggest that in patients with advanced mammary cancer successful endocrine therapy is related to the stimulation of reticulo-endothelial macrophage activity.

54. A New Method of determining the Hormone Dependence of Human Breast Cancer: H. FLAX (H. Ellis), Tumour Biology Group, Westminster Hospital, London.

A new technique has been developed to determine the hormone dependence of individual breast cancers (Salih et al., 1972) involving the 24-hour maintenance at 37° C. of tumour slices in Trowell's T8 medium with two near-physiological concentrations each of 17-β-oestradiol, testosterone, and prolactin. The technique has been successful for soft-tissue metastases as well as for the primary tumour. Results are determined by a histochemical reaction demonstrating the total dehydrogenase activity of the pentose shunt (Chayen et al., 1970) as well as by conventional haematoxylin and eosin staining (which showed 96 per cent correlation on independent histopathological assessment). The tumour is classed as dependent if it appears more active with a particular hormone or hormones than both the initial untreated biopsy and the medium control.

In the 100 patients studied so far, dependences have been as follows: prolactin only, 14 per cent; prolactin and oestradiol, 10 per cent; testosterone only, 12 per cent; prolactin and testosterone, 8 per cent; oestradiol only, 8 per cent. Where appropriate, endocrine-ablative surgery was advised for the dependent cases. In the 48 per cent of cases that were independent the results, by indicating whether any particular hormone was strikingly inhibitory to the tumour, were helpful for selecting hormones for administration. Correlation with the clinical progress of these patients (only at 9 months so far) has been encouraging.

55. The Effect of Vagotomy on the Exocrine Pancreatic Secretory Response to Pentagastrin and to a 400-g. Meat Meal in Dogs: M. Davis, Saroj Gupta, and J. B. Elder, University Department of Surgery, Royal Infirmary, Manchester.

It has been stated that the pancreas becomes more sensitive to humoral stimulation after truncal vagotomy but the evidence is controversial (Konturek et al., 1971; Moreland and Johnson, 1971). The effect of truncal vagotomy on the exocrine secretory response to a 400-g. meat meal and to intravenous pentagastrin infusion at a dose maximal for acid secretion before and after vagotomy in 2 dogs with chronic pancreatic and gastric fistula (G.F.) has been studied.

With the G.F. closed the mean bicarbonate output after pentagastrin (8 μg. per kg. per hour) increased from 22·98 ± 1·1 mEq. to 33·1 ± 4·6 mEq. ($P < 0·05$) after vagotomy; protein output to pentagastrin increased from 1898 ± 422 mg. to 3520 ± 342 mg. ($P < 0·01$) after vagotomy. Bicarbonate output to the meat meal decreased significantly ($P < 0·001$) after vagotomy but protein output was not significantly altered ($P < 0·4$).

These results may be explained on the basis of an increased sensitivity of the pancreas to hormonal stimulation after vagotomy.

56. Does the Vagal Nerve-supply to the Pancreas matter in Man? R. B. Smith, J. P. Edwards, and D. Johnston, University Department of Surgery, The General Infirmary, Leeds.

Reports on the function of the pancreas after severance of its parasympathetic nerve-supply in man (as in truncal vagotomy (T.V.)) are conflicting. These nerves are preserved in highly selective vagotomy (H.S.V.). The pancreatic response to insulin (0·2 U. per kg.) has been studied in 9 preoperative patients with duodenal ulcer (D.U.), and in patients more than 1 year after T.V. (6 patients) or H.S.V. (12 patients). The three groups of patients were matched for age and weight. Gastric acid was aspirated continuously and the duodenal *p*H remained greater than 7.

Outputs of amylase were found to increase significantly after insulin in D.U. and H.S.V. patients (from a mean of 9·1 to 20·5 kilo units in D.U. patients and from 6·0 to 16·5 kilo units in H.S.V. patients), whereas no significant increase was found in patients after T.V. (3·8 to 4·5 kilo units). Similarly, outputs of trypsin increased significantly in D.U. patients (from 16·0 to 31·1 I.U.) and in patients after H.S.V. (from 14·1 to 27·6 I.U.), whereas no such increase was observed after truncal vagotomy.

These results are in agreement with previous reports of impaired (Pfeffer et al., 1952) or absent (Dreiling et al., 1952) pancreatic response to insulin after T.V. in man. After H.S.V. significant increases in enzyme output still occurred in response to vagal stimulation.

57. Disappearance of Acid from the Duodenum: N. J. Dorricott and W. Silen (G. Slaney), Department of Surgery, Queen Elizabeth Hospital, Birmingham, and Harvard Medical School, Beth Israel Hospital, Boston, United States.

Experiments were carried out to investigate the poorly understood mechanism by which the duodenal mucosa contributes to the disappearance of hydrogen ions in the duodenum in the absence of pancreatic juice and bile.

In 7 standing awake dogs distal duodenal pouches were perfused by a constant-circulation technique with isotonic solutions ranging from 60 to 120 m*M* HCl (Dorricott and Silen, 1972). Fluxes of H^+, Na^+, K^+, and Cl^- were related to the initial concentration of H^+ and Na^+ and load of H^+ exposed to the duodenal mucosa per unit of time.

In all the experiments there was a loss of H^+ from the perfusate and a gain of Na^+, K^+, and Cl^-. A higher initial concentration of H^+ was associated with a greater rate of disappearance of H^+, e.g., 667 ± 70 μEq. per 30 minutes from 120 m*M* HCl and 312 ± 30 μEq. per 30 minutes from 60 m*M* HCl ($P < 0·001$). Alteration of load of H^+ and initial concentration of Na^+ did not produce significant change in the rate of disappearance of H^+. An excess of cations over measurable anions, closely related to H^+ loss, entered the pouch, which can best be explained by a process of bicarbonate neutralization.

These experiments show a relationship between disposal of H^+ by the duodenal mucosa and intraluminal H^+ concentration, and not load of H^+ as found by Meyer et al. (1970).

58. Human Duodenal Electrical Activity: W. Waterfall, B. Brown, and H. L. Duthie, University Department of Surgery, Royal Infirmary, Sheffield.

Stainless-steel electrodes (0·25 mm. in diameter) were mounted on a gastric tube and attached to the mucosa of the second part of the duodenum by suction in 16 subjects. Unipolar records of the electrical activity of the duodenum were obtained with the subjects in the resting state and also during intravenous infusion of pentagastrin (1·0 and 6·0 μg. per kg. per hour in 8 tests) and of secretin (0·25 and 2·0 U. per kg. per hour in 6 tests).

In the fasting subject a regular waveform of 11–12 cycles per minute was present all the time (pacesetter potential; basal electrical activity) with an amplitude of 0·2–1·6 mV. When motor waves were present (16 per cent of the time) they were accompanied by bursts of action potentials superimposed on the pacesetter potentials which then had their maximal amplitude. The frequency of the pacesetter potential was not affected by the infusion of pentagastrin or secretin. Action potentials and motor activity were increased significantly with pentagastrin and decreased with secretin. The contrasting actions of these hormones on the motor action of the duodenum have been confirmed and their effects on the electrical activity displayed.

59. *Ex vivo* Perfusion of Canine Jejunal Loop: Electrical and Mechanical Activities: C. Mendel, D. Jaeck, J. C. Schang, J. Kachelhoffer, M. R. Eloy, and J. F. Grenier (H. L. Duthie), Service d'Investigations Chirurgicales et Unité de Recherches de Biophysiopathologie Digestive de l'I.N.S.E.R.M. Pavillon Chirurgical B, Hôpital Civil de Strasbourg.

Controversy remains concerning bioelectrical potentials and motility of intestinal smooth muscle (Hiatt and Goodman, 1971). Using extracorporeal perfusion with pulsatile blood-flow, bioelectrical activity and motility were studied simultaneously in isolated loops of dog jejunum. Twenty experiments have been performed. Six silver electrodes were spaced 2·0 cm. apart on the antimesenteric border of the intestine. In each dog serial bioelectric and motility recordings were obtained from the intact loop *in vivo*, then from the isolated loop *in vivo*, and finally from the perfused isolated loop.

Electro-enterographic tracings demonstrate similar bioelectric activity *in vivo* and under *ex vivo* perfusion. Independent slow wave activity was initiated at all recording sites on the jejunum and propagation occurred regardless of a duodenal pacemaker. Immediate and consistent intestinal contraction occurred with each slow-wave electrical potential. Such contractions persisted despite the absence of spike activity. Augmented amplitude of contraction was associated with increased frequency of spike activity.

Thus, for the first time correlation between the mechanical and bioelectrical activities of the jejunum has been determined under *ex vivo* conditions in the absence of extrinsic nervous control and the duodenal pacemaker.

HIATT, R., and GOODMAN, I. (1971), *J. surg. Res.*, **11**, 454.

60. Is there Impaired Immunity in Patients with Crohn's Disease?

P. M. BOLTON, S. L. JAMES, and L. E. HUGHES, University Department of Surgery, Welsh National School of Medicine, Cardiff.

One of the popular theories of the aetiology of Crohn's disease is that there is an abnormal immune response to either intestinal contents or components of the gut wall. Evidence for this concept has been produced by the demonstration of impairment of cellular immunity in Crohn's disease (Parent et al., 1971). Contrary results have also been reported (Röpke, 1972), and the immunological competence of Crohn's patients remains undecided. In order to investigate this question, immunological profiles (lymphocyte count, immunoglobulin level, DNCB response, Mantoux test and lymphocyte transformation to phytohaemagglutinin) have been measured in patients with Crohn's disease and compared with those of control subjects, matched for degree of illness.

The patients with Crohn's disease were studied in two groups, 21 being ill and 15 in remission. Ill patients with Crohn's disease had significantly elevated IgG and IgA levels and an increased rate of Mantoux negativity. The immunoglobulin changes were probably non-specific and the Mantoux responses were related to steroid therapy. Other parameters were similar in the ill patients and the control subjects. There was no significant difference between the patients with Crohn's disease in remission and the control subjects in any parameter.

The results do not confirm an immunological abnormality associated with Crohn's disease.

PARENT, K., BARRETT, J., and DODD WILSON, I. (1971), *Gastroenterology*, **61**, 431.

61. A Study of Lymphocyte Function in Crohn's Disease using the Mitotic Index:

D. CAVE and B. N. BROOKE, Professorial Surgical Unit, St. George's Hospital, London.

When studying cellular immunity in Crohn's disease, it has been found that lymphocyte transformation, though widely accepted as an indication of cell-mediated immunity, presents problems as regards quantification owing to difficulty of recognizing transformed cells. Mitosis is an easily recognized event to which transformation proceeds. Mitotic lymphocytes are accumulated using colchicine. By recording the percentage of lymphocytes in mitosis a mitotic index is obtained.

Ten consecutive patients with Crohn's disease of the large and/or small intestines, unselected for age or sex, were used in the study. The mitotic index for this group was highly significantly lower ($P < 0{\cdot}001$) than for a control group (mean mitotic index for Crohn's group 4·8, control group 15·8).

Doubt still remains regarding the immunological abnormality contributing to Crohn's disease (Brooke, 1972). The evidence regarding cellular immunity is equivocal using both lymphocyte migration and lymphocyte transformation.

The present results lend support to the evidence that the ability of lymphocytes to transform is reduced in Crohn's disease, which may therefore represent a state of anergy.

BROOKE, B. N. (1972), *Surg. Clins N. Am.*, **52**, 971.

62. Objective Measurements in Anal Control after Surgery for Imperforate Anus:

I. TAYLOR, H. L. DUTHIE, R. B. ZACHARY, and R. H. SMALLWOOD, Royal Infirmary and Children's Hospital, Sheffield.

Measurements of force in the anal canal, electrical activity of the internal anal sphincter, and rectal pressure have been made in 20 children after operations for varying degrees of imperforate anus. The degree of continence was compared with the following parameters: (1) the force in the anal canal on voluntary squeezing, (2) the response of the internal anal sphincter to rectal distension, (3) the presence of a functioning puborectalis sling, (4) sensation on rectal distension, and (5) rectal pressure on distension. The normal inhibitory response in the anal canal on rectal distension was found in 6 patients who had good continence. An abnormal response of an increase in force in the anal canal was found in 6 patients who had moderate or poor continence. By giving numerical values to the changes in the above five parameters a multifactorial assessment was made which correlated well with the degree of continence. In any such assessment sensory, motor, and reflex factors should be combined.

63. Gastrin and Recurrent Ulcer after Vagotomy:

C. G. CLARK and J. H. WYLLIE, Department of Surgery, University College Hospital Medical School, London.

Recurrent ulceration after vagotomy and pyloroplasty is usually associated with incomplete vagotomy, but incomplete vagotomy occurs in 50 per cent of patients. Byrnes et al. (1970) have shown that fasting plasma-gastrin levels in patients with recurrent ulcer are significantly higher than in asymptomatic postvagotomy patients, suggesting a specific involvement of gastrin in the aetiology. An investigation of gastrin levels and gastric secretion was therefore made in 12 patients with recurrent ulceration. Vagotomy was incomplete in all cases as judged by the insulin test. Plasma gastrin was measured by radioimmunoassay (Wyllie et al., 1972). The basal plasma-gastrin level did not differ from that in unoperated patients. Similarly the plasma-gastrin response stimulated by meat extract (Oxo) or insulin was either normal (truncal vagotomy) or slightly reduced (selective vagotomy).

These results suggest that gastrin does not play a major role in the aetiology of recurrent ulcer after vagotomy and drainage.

64. Inactivation and Degradation of Synthetic Human Gastrin I by Homogenates of Intestinal Mucosa: H. R. HUNZIKER (J. H. Wyllie), Department of Surgery, University College Hospital Medical School, London.

The bioassay technique of Smith et al. (1970) was used to demonstrate inactivation of synthetic human gastrin I (S.H.G. I) during its incubation at *p*H 6·8 with homogenates of rat intestinal mucosa. Chemical analysis showed that the inactivation process was characterized by deamidation of the C-terminal phenylalanine amide residue. Sequential hydrolysis of the peptide bonds followed.

This inactivation of S.H.G. I was carried out most actively by lysosomal and microsomal fractions of the homogenates which inactivated respectively 1·22 ± 0·10 and 3·31 ± 0·24 nmol. of S.H.G. I per 10 minutes for each mg. of protein. Treatment of the microsomal fraction with 0·26 per cent sodium deoxycholate did not disrupt the endoplasmic reticulum but it completely solubilized the enzyme which deamidates S.H.G. I. This enzyme was found to have similar properties to lysosomal cathepsin-C.

It thus appears likely that S.H.G. I is degraded by lysosomal enzymes and not by specific enzyme systems; this would explain the ability of homogenates from a variety of tissues to degrade gastrin *in vitro*. Since only certain organs appear to inactivate gastrin *in vivo* (Temperley et al., 1971) the existence of specific gastrin receptors or transport systems on the cell membrane may be inferred.

SMITH, G. M., LAWRENCE, A. J., COLIN-JONES, D. G., and SCHILD, H. O. (1970), *Br. J. Pharmacol.*, **38**, 206.

65. An Important Duodenal Role in Gastrin Release: J. R. HAYES, T. L. KENNEDY, JOY ARDILL, and K. D. BUCHANAN, Departments of Medicine and Surgery, Queen's University, Belfast.

The plasma-gastrin response to a standard protein meal has been studied in normal subjects and in patients with duodenal ulceration before and after surgery. The peak gastrin level following stimulation and its timing were noted.

In control subjects the mean peak gastrin level was 2·5 times the basal level and occurred after 30 minutes. In subjects with duodenal ulceration the mean peak gastrin level was 3·5 times the basal level and occurred after 45 minutes. However, in patients with pyloric stenosis the peak gastrin level was only 1·5 times the basal level and was markedly delayed, occurring at 60 minutes.

Two groups of postoperative patients were studied. In patients with vagotomy and no drainage procedure the peak gastrin level was 2·5 times the basal level and occurred at 45 minutes, whereas in patients with vagotomy and a gastro-enterostomy a much smaller peak which was only 1·4 times the basal level occurred at 45 minutes. A group of patients with the dumping syndrome following vagotomy and pyloroplasty had peak gastrin levels after only 15 minutes.

These results suggest that the passage of food into the duodenum plays an important role in the normal release of gastrin.

66. Histamine Release in Man and Acute Gastroduodenal Ulcers: W. SEIDEL, W. LORENZ, A. DOENICKE, G. MANN, and R. UHLIG, Surgical Clinic and Department of Experimental Surgery and Pathological Biochemistry, University of Marburg/Lahn, Germany.

Exogenous histamine causes acute erosions and ulcers in the gastro-intestinal tract of man and animals (Katz and Siegel, 1968). Since acute gastroduodenal ulcers are often observed after operations the release of endogenous histamine could be important in their pathogenesis. For this reason the plasma-histamine concentrations were measured fluorometrically in 60 male probands (10 for each drug) after anaesthetics (thiopentone 5 mg. per kg., methohexitone 2·5 mg. per kg., propanidid 7 mg. per kg.) and plasma substitutes (dextran-60, gelatin, Ringer's solution, 500 ml. per test person), and in 20 patients before and on the first 3 days following intra-abdominal operations.

After thiopentone, methohexitone, and propanidid, the plasma-histamine concentrations rose from 0·7 ± 0·4 ng. per ml. to 4·2 ± 3·1, 2·0 ± 0·9, and 3·8 ± 2·1 ng. per ml. respectively ($P < 0{\cdot}01$). Following dextran and gelatin in 2 and 8 cases respectively the plasma histamine reached values of 3 ng. per ml. Ringer's solution was without effect. In 3 patients histamine concentrations of 2 ng. per ml. were measured 2 days following operation. During the histamine infusion a half-maximum gastric secretion was correlated to 3 ng. per ml. of plasma histamine.

Since acute erosions were observed after histamine tests on gastric secretion, histamine release probably facilitates the development of 'stress' ulcers following surgery.

KATZ, D., and SIEGEL, H. J. (1968), *Prog. Gastroenterol.*, **1**, 67.

67. The Effect of Locally Administered 15(R) 15 Methyl-E_2 Methyl Prostaglandin on Basal and Pentagastrin-induced Acid Secretion in Man: D. C. CARTER, S. M. M. KARIM, D. BHANA, and P. A. GANESAN (A. P. M. Forrest), University of Edinburgh and Makerere University, Kampala, Uganda.

The inhibition of acid secretion in man by orally administered prostaglandin has not been described previously. In 19 tests in male volunteers 100, 150, or 200 μg. of 15(R) 15 methyl-E_2 methyl prostaglandin (PG) in 10 ml. of saline were instilled via the nasogastric tube after a 30-minute basal period. Aspiration was recommenced 30 minutes later and continued for 12 × 15 minute collections. Control tests where saline alone was instilled were performed in the same individuals. In 12 tests the maximal acid output (M.A.O.) in response to pentagastrin (6 μg. per kg. I.M.) was compared to the M.A.O. in 10 paired tests in which 200 μg. of PG were instilled 30 minutes prior to pentagastrin injection.

Inhibition of unstimulated acid secretion was seen in all the cases after 150 and 200 μg. of PG. The reduction in 3-hour output after 200 μg. of PG ranged from 98·5 to 37·3 per cent (mean 75·2 per cent) of the corresponding control values, and the inhibition was statistically significant ($P < 0{\cdot}01$). The M.A.O. after pentagastrin was lowered in all but 1 case by 200 μg. of PG, and the mean reduction of 64·8 per cent for the 12 paired tests was significant ($P < 0{\cdot}05$).

It is concluded that this PG analogue inhibits basal and pentagastrin-induced acid secretion when administered locally.

68. Isolation of a Gastric Secretory Hormone from Pig Intestinal Mucosa: R. C. KESTER, J. G. CHANDLER, H. ROSEN, and M. J. ORLOFF (Professor Sir Donald Douglas), The Departments of Surgery, Dundee Royal Infirmary, and University of California, San Diego, United States.

Previous studies have demonstrated that the intestinal phase of gastric secretion and portacaval shunt-related gastric hypersecretion are due to a jejunal hormone (Orloff et al., 1970). This study was directed at isolating this hormone from pig intestinal mucosa, using similar principles to those employed by Gregory and Tracy

(1964) for the isolation of gastrin. Assuming that the hormone is a small heat-stable peptide similar to other digestive hormones, 500-gallon batches of intestinal mucosa were boiled and centrifuged, and the supernatant was incubated with DEAE cellulose to absorb the active agent. After removing the active material from the cellulose with sodium hydroxide the *p*H was adjusted to 4, precipitating a substance which returned to solution at *p*H 7 and was soluble in isopropanol. This material was redissolved in saline and sterilized. Twenty-five extracts were tested by intravenous infusion into fasting dogs with Heidenhain pouches. Control studies using diluent were done before each test. A threshold response of 397 μEq. was elicited by a dose of approximately 1 g. Above 2 g. there was a highly significant mean total acid secretory response of 1115 μEq. and there was a typical dose–response relationship. The gastric stimulatory substance extractable from pig intestinal mucosa by a method that selectively isolates heat-stable acidic peptides is thought to be the hormone responsible for the intestinal phase of gastric secretion and for portacaval shunt-related gastric hypersecretion.

69. Pyloric Reflux in Duodenal Ulceration and Its Relationship to Smoking: R. FIDDIAN-GREEN, R. C. G. RUSSELL, and M. HOBSLEY, Department of Surgical Studies, The Middlesex Hospital, London.

The possibility that pyloric reflux may be excessive in patients with duodenal ulcer has been investigated in 59 patients and 50 control subjects. Gastric aspirates were collected during a plateau of maximum secretion (histamine diphosphate 0·04 mg. per kg. per hour), and reflux was estimated in terms of sodium concentrations. Details of smoking habits and length of history of symptoms were recorded.

The mean volume of reflux in the duodenal ulcer group was significantly greater than in the control group ($t = 3{\cdot}24$, $P < 0{\cdot}005$). There was a positive correlation between reflux and both length of history and average daily number of cigarettes smoked. Adjustment for length of history enhanced the correlation between reflux and smoking ($r = 0{\cdot}684$, $P < 0{\cdot}01$).

Abnormal reflux may be a factor in producing duodenal ulceration. Smoking may be a factor in producing reflux.

70. Pyloric Reflux and Gastritis in Man: R. FIDDIAN-GREEN, P. A. J. BALL, R. C. G. RUSSELL, and M. HOBSLEY, Department of Surgical Studies, The Middlesex Hospital, London.

Benign gastric ulceration occurs in an area of gastritis. If pyloric reflux is the cause of this gastritis the concentration of reflux within the stomach contents must be the critical factor, since a certain amount of reflux is a normal event.

Reflux concentrations are related to sodium concentrations. In 50 control subjects, 59 duodenal ulcer (D.U.) patients, and 28 gastric ulcer (G.U.) patients gastric aspirates were obtained during a plateau of maximal stimulation, and the sodium concentration was measured. The sodium concentration was significantly higher in G.U. patients than in D.U. patients or control subjects ($P < 0{\cdot}001$), 20 mEq./l. being the intermediate concentration between the level in G.U. patients and that in the other two groups.

Similar studies were performed in 17 further patients (G.U. or D.U.) who were subsequently subjected to gastrectomy. The specimens were examined histologically by two independent observers for the presence or absence of gastritis. No patient with a sodium concentration in the gastric juice of less than 15 mEq./l. had gastritis, while all the patients with a concentration exceeding 15 mEq./l. had gastritis.

High concentrations of reflux juice in gastric contents are associated with gastritis. In this series *all* the patients with a benign G.U. had such high levels of reflux.

71. The Effect of o-(β-Hydroxyethyl)-rutosides (HR) on Cutaneous Digital Xenon Clearance in Patients with Peripheral Atherosclerosis: J. C. MILLIKEN, G. D. KEYE, and M. J. FOX (W. G. Fegan), Department of Clinical Research, Sir Patrick Dun's Hospital, Dublin.

A method of estimating digital cutaneous blood-flow by an atraumatic isotope-labelling technique has been described (Fox and Milliken, 1972). McEwan et al. (1970) suggested that local rather than regional blood-flow insufficiency is the cause of skin lesions in peripheral vascular disease and that in patients with less than optimum capillary blood-flow or tissue perfusion HR could significantly improve tissue perfusion and oxygenation.

In 15 patients with severe foot ischaemia arteriography using the ^{131}I-albumin technique for visualization of the popliteal branches showed that 38 of a possible 45 infrapopliteal vessels were stenosed or occluded. Of the patients who responded clinically to the oral administration of HR, 1·0 g. daily, xenon-clearance studies were carried out in 7 before and after 4 weeks' treatment. The clearance data were expressed as K values, where $K = 0{\cdot}693/T_{\frac{1}{2}}$ and $T_{\frac{1}{2}}$ represents the biological half-life of the isotope in minutes. Pretreatment K values averaged 0·397 (range 0·301–0·630) and post-treatment values averaged 0·811 (range 0·630–1·155). These findings indicate that cutaneous xenon-clearance values provide useful evidence of clinical progress in chronic ischaemia.

72. The Relationship between Ultrasound Assessment and Angiography in Occlusive Arterial Disease of the Lower Limb: J. CHAMBERLAIN (A. I. S. Macpherson), Royal Infirmary, Edinburgh.

The Doppler ultrasound technique has been used to assess the haemodynamics of the peripheral circulation in patients with arterial disease (Yao et al., 1969). Using this method the resting pressure index (ankle systolic pressure/brachial systolic pressure) and the response after exercise of the systolic pressure at the ankle were determined in 62 limbs. The angiograms in all the patients were assessed and graded according to the occlusions present (Morton et al., 1967).

Following exercise four types of abnormal response of the ankle systolic pressure were found (curves grade 1–4). In patients with a single aorto-iliac lesion a normal or slightly lowered pressure index was found, with a grade 3–4 post-exercise curve. In patients with localized femoropopliteal disease a low-pressure index usually accompanied a grade 1–2 post-exercise curve. In multiple occlusions there was a lower pressure index with a more severe grade of curve. If the profunda circulation was involved angiographically, then this resulted in a lower resting pressure index with a grade 3–4 curve. These results correlated well with the numerical assessment of the angiograms.

It is concluded that in patients who have a very low resting pressure index and with a grade 3–4 post-exercise curve the profunda circulation is impaired, even though clinical examination may not suggest this.

73. The Prediction of Organ Viability: K. C. Calman and P. R. F. Bell, Department of Surgery, Western Infirmary, Glasgow.

The techniques and clinical applications of organ preservation would be extended considerably if a simple and reliable method for the prediction of organ survival was available. During investigations of organ storage the changes in adenine nucleotide content in the rat kidney have been studied.

Both kidneys were clamped for 0–120 minutes at normothermia. One kidney was removed for estimation of ATP, ADP, and AMP; the clamp on the other kidney was released and survival was determined. The total kidney adenine nucleotide content (ATP+ADP+AMP) was plotted according to whether the animal survived or died; on this basis there was a good separation between the two groups ($P<0{\cdot}001$). If the renal adenine nucleotide contents were below 0·8 µmol per g. the animals died and when the nucleotide contents were above this level the animals survived.

The total adenine nucleotide level in organs may be used to predict survival. Two corollaries follow: (1) variations in adenine nucleotide levels should occur when an organ is perfused with different solutions, and this has been confirmed; (2) increasing the ATP content of organs (e.g., by perfusion with insulin, intermediary metabolites of Persantin) should effectively increase the storage time and this has also been confirmed.

74. The Influence of Serum and Cellular Factors in the Depression of Phytohaemagglutinin (PHA)-induced Transformation of Lymphocytes in Gastro-intestinal Carcinoma: R. M. Grant, C. Harris, W. Mathieson, and J. N. Norman, Department of Surgery, University of Aberdeen.

Depression of PHA-induced lymphocyte transformation in cases of carcinoma may be due to the presence in the serum of a factor produced by the tumour. Such a factor would occur in the highest concentration in the venous blood draining a tumour.

In 6 cases of gastro-intestinal carcinoma the PHA-induced transformation of peripheral venous blood lymphocytes cultured in media containing sera derived from autologous peripheral venous blood, autologous inferior mesenteric venous blood from close to the tumour, and homologous group AB blood has been studied.

Maximal lymphocyte transformation occurred where the serum was derived from pooled homologous AB blood. By comparison, depression of lymphocyte transformation occurred where the serum was derived from either of the autologous sources. This depression was greatest where serum from the inferior mesenteric venous blood had been incorporated. Further depression in transformation was noted where lymphocytes from the inferior mesenteric venous blood were cultured in serum from the same source.

These results, while suggesting the presence of a factor in the serum causing depression of lymphocyte reactivity, also indicate that changes in the lymphocytes themselves might be important.

75. Phytohaemagglutinin Transformation of Peripheral and Lymph-node Lymphocytes in Patients with Gastro-intestinal Cancer: P. J. Guillou, T. G. Brennan, and G. R. Giles, University Department of Surgery, Leeds (St. James's), and University Hospital, Leeds.

Regional lymph-nodes draining experimental tumours show enhanced immunological activity (Alexander et al., 1967) and this response is considered to be important in the control of tumours such as breast cancer (Deodhar et al., 1972). The phytohaemagglutinin-induced transformation of peripheral and mesenteric lymph-node lymphocytes has been compared in 8 patients with gastro-intestinal cancer and 7 patients with benign abdominal disease.

When cultured in autologous serum, 39·7 ± 3·8 per cent of peripheral lymphocytes from patients with cancer transformed, compared with 50·4 ± 4·6 per cent from control subjects. Culture of these lymphocytes in homologous AB serum resulted in transformation rates of 41·7 ± 5·9 per cent in patients with cancer (4 increased, 2 decreased) and 50·1 ± 6·4 per cent in control subjects (all essentially unchanged).

In control subjects the mean transformation rates in nodes from small-bowel mesentery was 41·2 per cent and in paracolonic nodes was 45·6 per cent. Similar studies in patients with cancer produced mean transformation rates of 27·7 per cent for mesenteric lymph-nodes and 29·7 per cent for cells from nodes directly draining the neoplastic lesion. Culture of lymph-node cells in homologous AB serum resulted in increased transformation rates.

The mesenteric lymph-nodes of patients with gastro-intestinal cancer showed depressed rather than enhanced immunological competence.

76. The Measurement of Growth Rate in Rectal Carcinoma: G. Bone and R. Camplejohn (I. D. A. Johnston), Departments of Surgery and Pathology, University of Newcastle upon Tyne.

It is suggested that tumour growth depends upon an increased proliferation of malignant cells as compared with adjacent normal cells. Fourteen patients with carcinoma of the rectum were studied. The relative growth rates of the tumours and normal rectal mucosa were measured by an *in vivo* stathmokinetic technique (Refsum and Berdal, 1968). Vincristine, 0·045 mg. per kg. body-weight, was given to produce mitotic arrest. Biopsies were taken from the tumour and normal rectal mucosa before and up to 4 hours after the intravenous injection of a single dose of vincristine. The mitotic index rose after the administration of vincristine and the rate of increase was determined from the biopsy specimens, and using this information the potential doubling time and mitotic duration were calculated.

The mean potential doubling time for the rectal carcinoma was 250 hours, and for normal rectal mucosa 90 hours. The mean mitotic duration for rectal carcinoma was 3 hours, and for normal rectal mucosa 2·1 hours.

It is concluded that in rectal carcinoma the growth rate is slower than that of normal rectal mucosa. Tumour growth must therefore be due to a reduced cell loss compared with normal mucosa.

77. Skin Disinfection—A Cause of Coliform Wound Infection? D. Shaw (Sir Donald Douglas), Department of Surgery, University of Dundee.

Miles predicted in 1942 that infections due to Gram-negative bacilli would become more prevalent after the suppression of Gram-positive cocci. Preoperative skin disinfection, the reduction or elimination of normal skin flora, and postoperative wound sepsis caused by coliform organisms have not been studied. The aim of this work was to elucidate any adverse relationship.

Skin preparation in the operating theatre followed the recommendation of the Medical Research Council Sub-committee Report (1968). A skin biopsy was taken from the wound edge immediately the incision was complete and was placed in nutrient broth containing a chlorhexidine inhibitor. After culture the organisms were identified.

Specimens were taken from 244 patients having elective surgery; all had clean operations. There was growth of organisms from 40·2 per cent. The wound-infection rate for coliform organisms was 5·1 per cent in patients whose specimens grew skin flora and 11·6 per cent in patients whose specimens had no growth. The difference is statistically significant.

The killing of resident flora by skin disinfection appears to be a factor in some cases of wound infection due to coliform organisms.

78. Intraperitoneal Noxytiolin as an Experimental Chemotherapeutic Agent: S. DESAI and C. W. JAMIESON, Surgical Unit, St. Mary's Hospital, London.

Following claims that local instillation of noxytiolin (Noxyflex) has chemotherapeutic value in bladder tumours (Garrett, 1969) it was reported (Jamieson, 1970) that noxytiolin inhibits the growth of tumour cells in culture at very low concentrations (0·0025 per cent). The present study was designed to detect any local or systemic chemotherapeutic effect of noxytiolin *in vivo*.

Four groups of 10 BALB/C mice received intraperitoneal injections of 1×10^5 Ehrlich's ascites tumour cells; this dose of tumour cells consistently produced ascites. The tumour growth rate was measured by daily weighings of the animals and the duration of their survival after injection. Intraperitoneal injections of 5 and 15 mg. of noxytiolin per kg. body-weight were given on days 1 and 7 after the injection of tumour cells. Identical groups of control mice received a sham injection of TC 199 on the same days. Fifteen mg. of noxytiolin per kg. body-weight produced a highly significant slowing of the growth of tumours when compared with the control mice.

The experiments were repeated using the same dose of noxytiolin, but the noxytiolin and the control injections were given subcutaneously. No difference in the growth of tumours was observed in 40 mice.

Local instillation of noxytiolin has a chemotherapeutic effect, supporting its toxicity *in vitro*, but systemic administration has no such value in this tumour model.

SHORT NOTES OF RARE OR OBSCURE CASES

PNEUMOMEDIASTINUM IN A CASE OF PERFORATED RETROPERITONEAL HERNIA

BY P. G. RANSLEY
HAROLD WOOD HOSPITAL, ROMFORD, ESSEX

THE unusual association of a pneumomediastinum and small-bowel obstruction was explained with the finding of a perforated retroperitoneal hernia. This complication of a retroperitoneal hernia does not appear to have been reported previously.

CASE REPORT

Mr. H. G., aged 74 years, was a gipsy of relatively fixed abode who had been under the care of physicians for several years with chronic bronchitis and emphysema. He was a very cachetic patient, never exceeding 45 kg. in weight owing to a combination of alcoholism and a malabsorption state following a partial gastrectomy 25 years previously. He was breathless at rest.

On 14 Jan., 1971, he was admitted to hospital at his general practitioner's request. At that time he showed little change from his normal state and a chest radiograph showed no change from previous examinations. While in hospital he developed slight abdominal distension with normal but active bowel-sounds, but on 25 Jan. he suddenly collapsed with a rigid distended abdomen. His blood-pressure was 90/60 mm. Hg. and his pulse was 110 per minute. Erect abdominal films demonstrated multiple small-bowel fluid levels and the chest radiograph now showed a pneumomediastinum (*Figs.* 1 and 2).

Following resuscitation the patient underwent emergency laparotomy. The appearances at operation were of long-standing small-bowel obstruction. The collapsed and distended jejunal segments met in a mass of inflammatory tissue just lateral to the duodenojejunal flexure. Closer examination revealed a loop of bowel herniated into the left lateral paraduodenal fossa. On freeing the herniated loop a ragged perforation was visible at the apex. The bowel recovered sufficiently to be considered viable, the perforation was closed, and the walls of the fossa were apposed. He made an excellent immediate recovery but his chest condition deteriorated over several days and he died 1 week postoperatively.

DISCUSSION

Spontaneous mediastinal emphysema or pneumomediastinum was probably first described by Laennec in 1879 (quoted by Hamman, 1939) but it has received scant attention in the medical literature, being usually associated with trauma or rupture of an emphysematous bulla. Air in the mediastinum can track downwards into the retroperitoneal tissues (Hamman, 1939) and the reverse is sometimes seen following presacral insufflation.

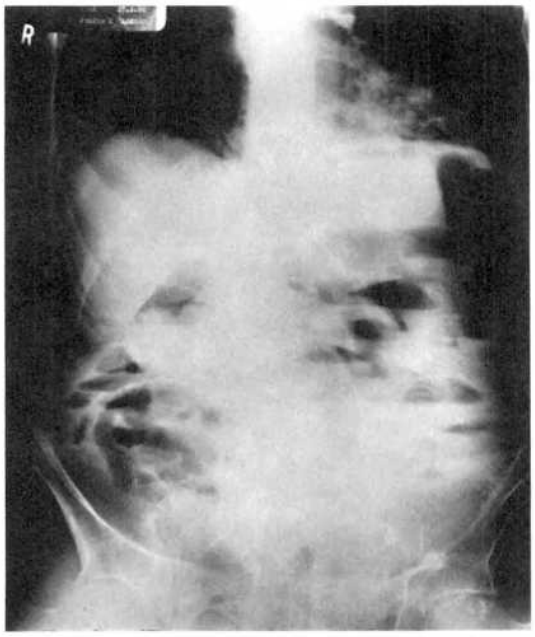

FIG. 1.—Erect radiograph of the abdomen, showing small-bowel obstruction.

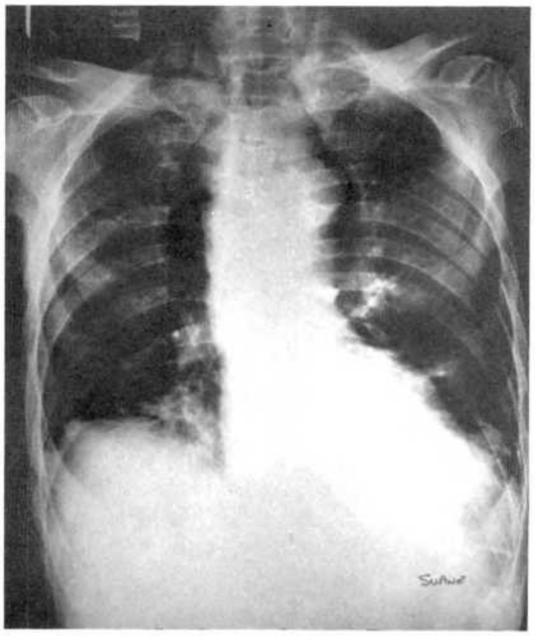

FIG. 2.—Chest radiograph, demonstrating pneumomediastinum.

Paraduodenal fossa hernia is a surgical rarity which was well described by Moynihan (1906) and is usually a diagnosis made at laparotomy. It is probably a congenital abnormality dependent upon disorders of midgut rotation and not a 'herniation' (Andrews, 1923). Preoperative suspicion may be raised by a long atypical history of subacute obstruction, or the finding of an unusual pattern of obstructed loops on radiographic examination, but it is rare for the diagnosis to be made prior to exploration.

The interest in the present case lies in the fact that although a diagnosis of perforation of an obstructed intestinal loop was made preoperatively, the complete diagnosis was missed. The presence of air in the mediastinum with small-bowel obstruction should have suggested a retroperitoneal perforation, with air tracking upwards into the chest.

Acknowledgement.—I would like to thank Mr. J. E. Talbot, F.R.C.S., for permission to publish this case who was admitted under his care.

AN UNUSUAL METASTASIS OF CARCINOMA OF RECTUM

By J. C. B. PENFOLD and C. V. MANN
ST. MARK'S HOSPITAL, LONDON

THE following case history is presented to draw attention to the possibility of metastases from carcinoma of the rectum developing in unusual situations when early ligation of the vascular pedicle is employed as part of the operative technique.

CASE REPORT

At a routine follow-up examination Mr. W. B. was found to have a 1·5-cm. asymptomatic nodule in the position of the right posterior internal haemorrhoidal venous plexus. The anal mucosa moved freely over the module.

A restorative resection for a moderately well-differentiated adenocarcinoma of the upper third of the rectum had been performed 9 months previously. At operation early ligation of the vascular pedicle had been performed and the rectal stump had been irrigated with a 1-in-400 perchloride of mercury solution prior to anastomosis. The anal sphincters had been stretched to four fingers at the conclusion of the operation.

Examination of the specimen had shown an adenocarcinoma of the ulcerating type, 7 cm. in diameter and nearly circumferential. There had been 7 cm. of normal bowel below the growth. Microscopic examination of the specimen had shown it to be an adenocarcinoma of average grade. It had spread through the rectal wall and had invaded the perirectal fat (Dukes's B case). Twelve lymph-nodes had been examined and found to be tumour free. Some growth had been found in the adjacent extramural veins.

Because of the position of the nodule and the operative anal stretch, it was considered most likely to be a thrombosed internal haemorrhoid. However, at review 3 months later the nodule was 2 cm. in size. The patient was admitted for a wide excision on a clinical assumption of malignancy.

The lump together with at least 2·5 cm. of uninvolved surrounding tissue was locally excised; this excision totally divided the external sphincter but some of the internal sphincter and puborectalis sling remained. The wound was left open.

Postoperatively the patient was at first completely incontinent, but control gradually improved. At discharge from hospital 3 weeks later he was continent to solid faeces.

The excised tissue proved to be an average-grade adenocarcinoma of similar histology to that of the original tumour.

It is now considered that the patient has had optimal curative treatment for the recurrence and no further surgery is indicated.

PATHOGENESIS OF THE SECONDARY GROWTH.—This appears to be an example of embolic retrograde venous spread. The presence of extramural venous invasion in the original operative specimen and the early ligation of the vascular pedicle were probably the causative factors. The growth was not due to direct spread, as there were 7 cm. of normal bowel below the excised original tumour and rectal examination of the rectal stump is still completely normal, nor is it an example of implantation, as the nodule was situated below the anal mucosa which moved freely over it. There has never been any haemorrhoidal wound to facilitate local penetration and the rectal stump was irrigated at the time of operation.

DISCUSSION

This is a most unusual site of secondary spread of carcinoma of the rectum. A search of the records of St. Mark's Hospital was only able to demonstrate similar haemorrhoidal venous involvement in 3 cases and all these were in very advanced carcinoma of the rectum. Anal metastases from rectal cancers have been reported before, but those appeared to have arisen by different modes of spread compared with this case (Killingback, Wilson, and Hughes, 1965).

Recent reports have suggested that early vascular pedicle ligation is followed by an increased incidence of systemic metastases (Hughes and Cuthbertson, 1962). The present case supports this view that retrograde vascular flow occurs following pedicle ligation, thereby allowing systemic tumour embolism to take place.

It has been noted before that the presence of extramural venous invasion is a common finding in those who have or develop hepatic metastases (Bussey, 1971).

Careful examination of the operative specimen has enabled us to determine the pathogenesis of this secondary deposit and to encourage us to believe that local excision will be sufficient treatment.

TORSION OF A GASTRIC LEIOMYOMA

By E. R. WALROND and R. R. SAHOY
DEPARTMENT OF SURGERY, UNIVERSITY HOSPITAL OF THE WEST INDIES, JAMAICA

SUMMARY

A patient with an extraluminal gastric leiomyoma, which presented as an emergency because of torsion, is reported. This is thought to be the first report of such an occurrence. The diagnosis was not made preoperatively in spite of intensive investigation.

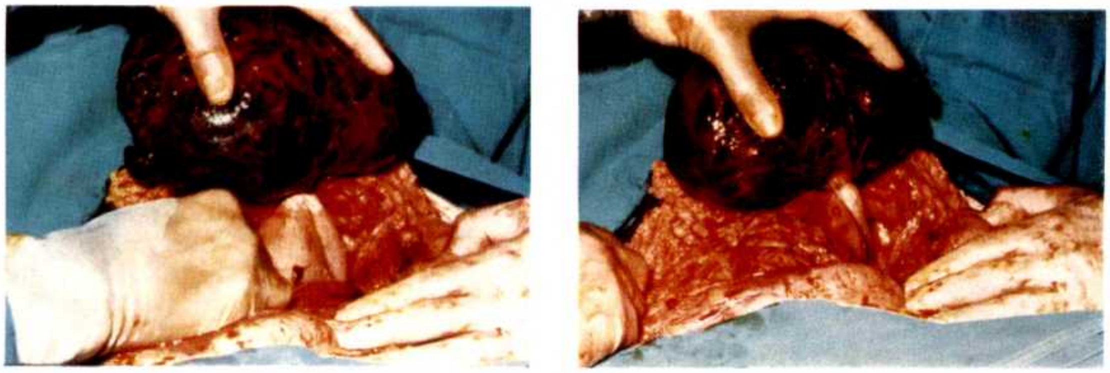
EXTRALUMINAL gastric leiomyomas are uncommon and usually present as a mass. The following case report is of a patient who presented as an acute abdominal emergency but with no evidence of gastro-intestinal bleeding.

CASE REPORT

Mrs. I. C., aged 59 years, was admitted to the University Hospital of the West Indies, Jamaica, with a 12-hour history of peri-umbilical and left hypochondrium pain and vomiting. The pain had been sudden in onset, having woken her up. The vomitus consisted of bile. There was no significant previous gastro-intestinal history.

On examination the patient was distressed because of severe pain, and the significant findings were confined to the abdomen. A large tender mass was palpated in the left hypochondrium, and an enlarged uterus with fibroids was palpated on vaginal examination. She was admitted to the medical wards with a diagnosis of splenomegaly. Investigations on admission showed a haemoglobin of 13·5 g. per 100 ml. and a white-cell count of 12,400 per c.mm. with a polymorph leucocytosis. She continued to vomit bile after admission and her abdomen became more distended. A diagnosis of perinephric abscess was suggested but an intravenous pyelogram was normal. Surgical consultation was sought 48 hours after her admission and at that time it was noted that she was anaemic and that the femoral pulses were unequal; the abdominal mass was smooth and tender and did not move on respiration. A diagnosis of ruptured aortic aneurysm or haemorrhage into a pancreatic cyst was considered. An emergency aortogram showed a normal aorta displaced to the right by an avascular mass. A barium-meal examination showed the stomach to be displaced anteriorly but otherwise normal.

At laparotomy the abdomen contained 2 litres of dark blood; the mass was palpated in the lesser sac and was exposed through the gastrocolic omentum. It was oval in shape, measuring 20 × 10 cm., and haemorrhagic, and was attached to the posterior wall of the antrum of the stomach by a pedicle on which the tumour had twisted in a clockwise direction (*Fig.* 1). The tumour was excised with a cuff of normal stomach to reveal ulceration of the stomach mucosa over the base of the pedicle. The patient made an uneventful recovery. Histological examination confirmed an infarcted leiomyoma, with cells containing clear cytoplasm in many areas.



A B

FIG. 1.—Operative photographs of the exogastric leiomyoma (A) twisted and (B) untwisted.

DISCUSSION

Leiomyomas constitute 1·6 per cent of all gastric tumours which present clinically (Marshall, 1955). They usually project into the lumen of the stomach and have an associated ulcer on the mucosal surface. The patients frequently have peptic-ulcer-type symptoms or evidence of upper gastro-intestinal bleeding. Extraluminal gastric leiomyomas are very unusual and few are pedunculated; they may present clinically because of a large mass. The diagnosis of extraluminal gastric leiomyomas is difficult. Schofield and Fox (1965) and Smithwick, Beisecker, and Leand (1969) described separate cases in which the tumour enlarged into the lesser sac and a diagnosis of pancreatic pseudocyst was made. Salmela and Kohler (1969), in reviewing the radiographic appearances of 59 mesenchymal tumours of the stomach, mentioned an exogastric leiomyoma which had displaced other organs. Wolf (1968), in describing a massive exogastric leiomyoblastoma, found that barium-meal examination was unhelpful, and the diagnosis was made on noting a large right gastro-epiploic artery on selective coeliac axis angiography. Seinnreich, Freidman, Dacso, and Stern (1966) described a large exogastric leiomyoblastoma which simulated a uterine fibroid; no abnormalities were shown by the barium meal examination. Arsac, Martin, Tocquet, and Delavierre (1967) investigated extensively a case which had presented with a pleural effusion, the diagnosis only being made at an exploratory operation.

The patient described here presented as an acute abdominal emergency with a painful tender mass. It became evident that she was bleeding into the peritoneal cavity. The diagnosis was not made after extensive investigations including aortography and a barium meal. In essence investigations showed an avascular tumour in the lesser sac displacing other organs. An aortic aneurysm was excluded, but the clinical progress was not typical of a pancreatic lesion. We have been unable to trace any other case of exogastric leiomyoma in the literature which presented with torsion in this way. However, there are 3 reports of exogastric leiomyomas or leiomyoblastomas which presented with bleeding into the peritoneal cavity owing to ulceration of the peritoneal surface of the tumour (Secher, 1968; Smithwick and others, 1969).

TETRAPLEGIA IN RHEUMATOID ARTHRITIS WITH COMPLETE RECOVERY AFTER SURGERY

By A. J. POLYZOIDES and J. R. PEARSON

ROYAL ORTHOPAEDIC HOSPITAL, BIRMINGHAM

SUMMARY

1. A patient with tetraplegia caused by subluxation of the lower cervical spine in rheumatoid arthritis is presented. The clinical history, early complication, and delayed diagnosis are described.
2. Compression of the dura mater by rheumatoid granulation tissue and vertebral subluxation are suggested to be responsible for the cord damage.
3. Failure of conservative treatment after a week is a strong indication for surgery.
4. Posterior decompression of the cervical spine and splitting of the dura mater are recommended.

Tetraplegia caused by subluxation of the lower cervical spine in rheumatoid arthritis was first described by Hauge in 1958.

Recognition of the onset of tetraplegia is not easy because of the deformities of rheumatoid arthritis and the difficulty in eliciting neurological signs which involve joints such as the elbow and knee.

Sharp and Purser (1961) described the atlanto-axial subluxation in rheumatoid arthritis in detail but this subluxation, despite its high incidence of 25 per cent in rheumatoid patients, rarely produces neurological complications.

The number of patients reported with complete tetraplegia caused by lower cervical rheumatoid subluxation remains very small and complete neurological recovery is unusual. Hopkins (1967) reported 4 patients, 2 of whom had a partial recovery while 2 died. Crellin, Maccabe, and Hamilton (1970) described 1 patient with tetraparesis who had complete recovery after 1 year following anterior cervical fusion.

The present case is interesting because of the development of tetraplegia and subsequent complete recovery following decompression of the cervical spine and splitting of the dura mater.

CASE REPORT

A man aged 51 years, who was a fitter in the car industry, was transferred to the Royal Orthopaedic Hospital on 16 June, 1970, with complete tetraplegia below the fifth cervical root level.

The clinical history started in 1945 when at the age of 26 the patient was admitted to an Army hospital complaining of severe burning pain in both heels.

In 1958 he complained of low-back pain and a diagnosis of ankylosing spondylitis was made in another hospital and the patient was sent to have spa treatment. In the same year, swelling in the proximal interphalangeal joints of the right middle and left index fingers was noticed by the patient and the diagnosis was changed to rheumatoid arthritis.

In January, 1970, neck pain with paraesthesia in the right hand became a serious complaint. In May, 1970, the patient complained of weakness in both arms and the right leg; he was sent to St. John's Hospital, Droitwich, for physiotherapy. The visiting physician diagnosed tetraparesis and radiographs showed cervical rheumatoid subluxation of C.V.4 over C.V.5 (*Fig.* 1).

The patient was immediately transferred to a general hospital and skull traction was applied to immobilize the neck in extension. As there was neurological deterioration to complete tetraplegia after 1 week he was transferred to the Royal Orthopaedic Hospital and surgery was undertaken the following day.

On admission the patient was comfortable in a cervical plastic collar. He was orientated in time and space and his cranial nerves were normal. Respiration was entirely diaphragmatic and he had no bladder or bowel control; an indwelling catheter was draining urine satisfactorily.

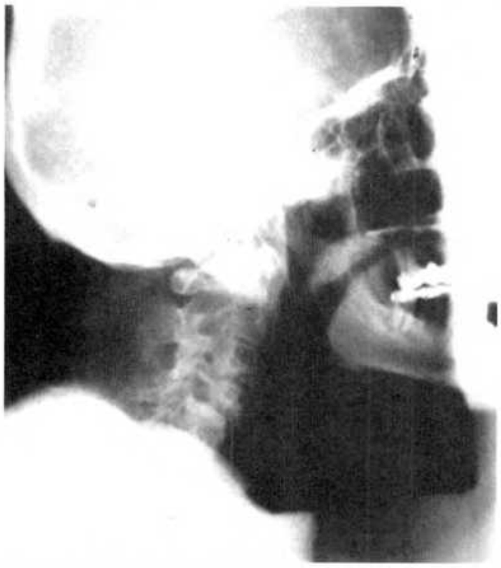

FIG. 1.—Lateral radiograph of the cervical spine, showing moderate subluxation of C.V.4 over C.V.5.

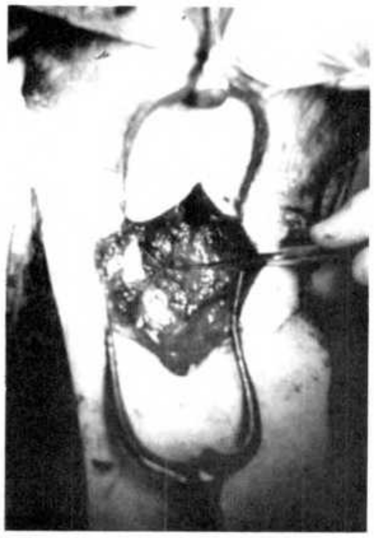

FIG. 3.—Photograph taken during the operation, showing the probe pointing to a circumferential band of granulation tissue constricting the dura.

Both wrists and hands showed chronic rheumatoid changes.

Muscle power was charted according to the Medical Research Council muscle grading and only the deltoid muscles were graded 4, all the other muscles in both the upper and lower limbs being graded 0 and 1.

Deep reflexes were exaggerated in the upper limbs and absent in the lower limbs. Abdominal reflexes were absent and the superficial plantar responses were extensor. The patient was anaesthetic from the fourth intercostal space downwards. The clinical picture was that of complete tetraplegia below the fifth cervical nerve-root.

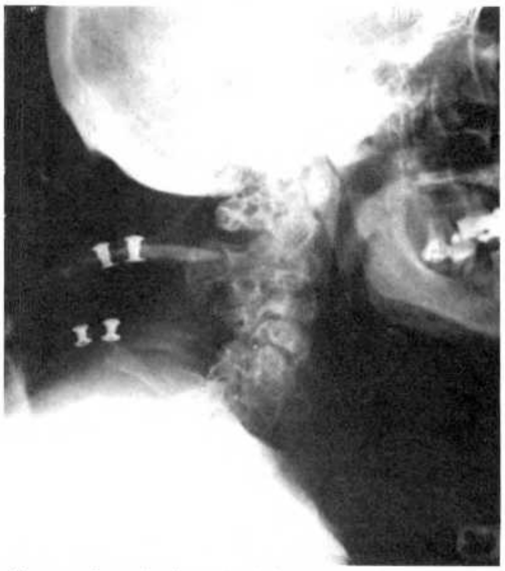

FIG. 2.—Lateral radiograph of the cervical spine with the neck immobilized in a collar with extension, showing reduction of the subluxation.

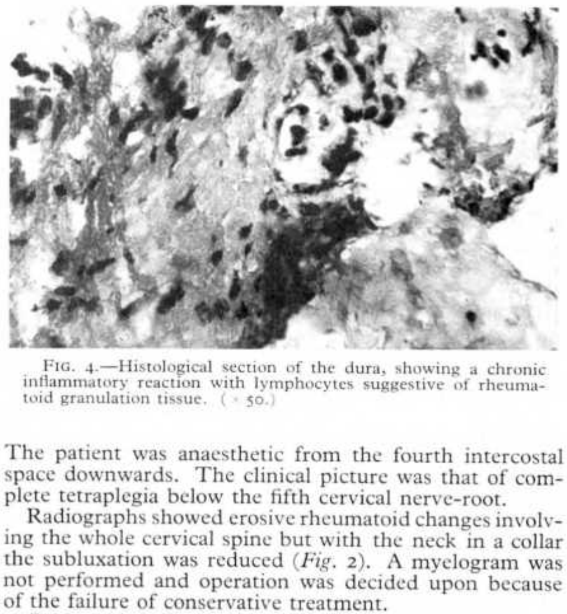

FIG. 4.—Histological section of the dura, showing a chronic inflammatory reaction with lymphocytes suggestive of rheumatoid granulation tissue. (× 50.)

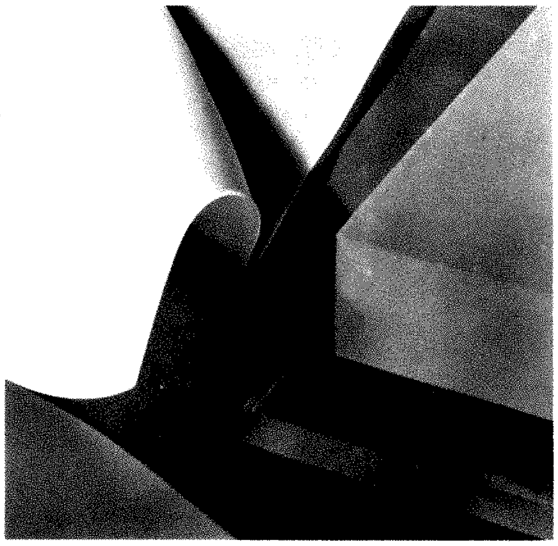
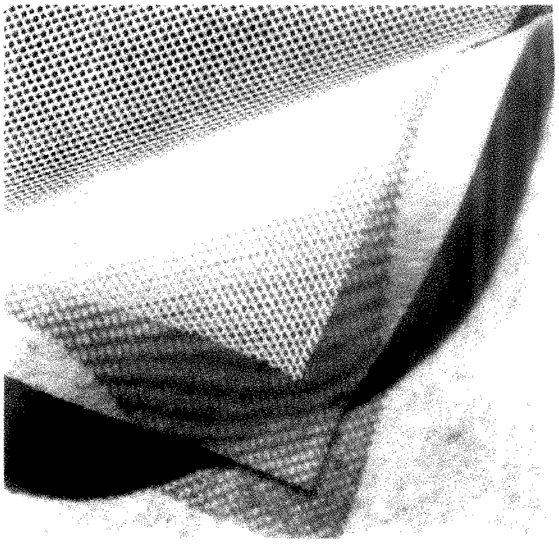
Radiographs showed erosive rheumatoid changes involving the whole cervical spine but with the neck in a collar the subluxation was reduced (*Fig.* 2). A myelogram was not performed and operation was decided upon because of the failure of conservative treatment.

OPERATION.—The patient was intubated and halothane gas and oxygen were administered. He was placed prone with a head-rest extending the neck, the anterior part of the collar being retained to provide support.

Radiographs on the operating table showed complete reduction of the subluxation of C.V.4 over C.V.5 and with the aid of a marker the site of the fourth cervical vertebra was identified. A midline incision was made over the spinous processes. The third and fourth cervical

Of fundamental importance in repair and reconstructive surgery





'Scurasil'

medical quality silicone elastomer products

'Scurasil' is a silicone elastomer material with outstanding physical, chemical and biological properties. Ideally suited to repair and reconstructive surgery, being completely inert and non-reactive in human tissues.

'Scurasil' Film

for protection of anastomoses of vessels and nerves – for prevention of tissue growth leading to stenosis or compression – to prevent tissue adhesion.

Supplied non-sterile, in single sheets 150 x 200 mm. Thickness range 0·25 to 2·50 mm.

'Scurasil' Block

flexible and semi-flexible – for replacement of cartilaginous or bony tissue in facial and other procedures.

Supplied non-sterile, in single blocks of 110 x 80 mm and 5 to 20 mm thick.

'Scurasil' Tubing

for special drainage procedures
for artificial organs and accessories
for transfusion procedures
for extracorporeal blood circuits

Supplied non-sterile, in a comprehensive range of lengths and diameters.

'Rhodergon' and 'Scurasil' are trade marks of Rhône-Poulenc.

'Rhodergon'

polyester surgical fabric

'Rhodergon' surgical fabrics are specifically manufactured for surgical repair and reconstruction procedures.

- No change in properties or characteristics on sterilization or ageing in an organic environment
- Excellent tensile strength allowing secure suture attachment
- Inert – produces no site reaction
- Dependent upon type, ingrowth of tissue occurs.

'Rhodergon' is available in four main types for the following suggested uses:

Special Run-proof Fabric

cellular, satin and knitted – tendon repair – general muscle and hernia repair procedures.

Non-stretch, Non-fray Felt

hernia repair – closure of intra-ventricular septal defects.

Compact Felt

covering of prosthetic implants.

Velvet

prosthesis attachment – closure of cardiac defects – repair of cardiac and arterial incisions.

'Rhodergon' cloth is supplied non-sterile, in 100 x 150 mm pieces.

Our head of table is unique.

The Matburn MS is a dramatic addition to our M table series, which are used in more countries throughout the world than any other operating tables.

The MS controls are grouped on a moveable selector arm at the head end to enable all major table movements to be made without disturbing the surgical team or the sterile area.

It's the most advanced table of its kind.

The single solution

segments were found to be hypermobile. Excision of the spinous processes of C.V.3 and C.V.4 with the medial half of the laminae was carried out, preserving a lateral laminar ridge.

The spinal cord was non-pulsatile and constricted at the level of C.V.4; proximally there was a circumferential infiltration of granulation tissue constricting the dura mater (*Fig.* 3). The dura sheath was opened without incising the arachnoid membrane and therefore there was no leakage of cerebrospinal fluid. A strip of dura mater, 1 cm. long and 0·5 cm. wide, was sent for histological examination to establish the presence of rheumatoid granulation tissue (*Fig.* 4). No attempt was made to excise the remaining granulation tissue as the cord was adequately decompressed and was pulsating.

PROGRESS.—Postoperatively the polythene collar was reapplied. On the fourth postoperative day, muscle grading showed signs of recovery. The muscles of the upper and lower limbs were graded 2 and 3. The superficial plantar responses were flexor. In the following weeks the patient showed steady improvement; by 6 weeks he had bladder sensation and control was returning to normal; in the fourth month his muscle power was graded 4 and he was fully mobilized.

Spinal fusion was not performed as radiographs of the cervical spine in flexion and extension 7 months after operation showed no evidence of the previous subluxation, and spontaneous fusion of the body and apophysial joints was obvious. Spontaneous fusion is anticipated in rheumatoid diseases of the cervical spine (Marmor, 1967).

Seven months after operation the patient was discharged home. At present he is enjoying a leisurely home life, feeding himself, and walking with sticks. A return to his previous job as a fitter is not anticipated but suitable employment will be found as he is very determined to start working again.

DISCUSSION

Lower cervical rheumatoid subluxation is not so well recognized as atlanto-axial subluxation and particular care should be paid to the clinical history of the patient and to early neurological complaints. Repeated radiographs in flexion and extension of the cervical spine should be taken of patients with rheumatoid arthritis, as 40 per cent have involvement of the cervical spine (Sharp, 1957), and more recently Weiss and Freehafer (1964) reported an even greater incidence of 50 per cent. A great number of patients will show atlanto-axial subluxation, and some will show lower cervical subluxation or both (Crellin and others, 1970); the precise incidence is still not known. In the present patient the diagnosis was made after tetraparesis and immobilization of the neck showed deterioration to tetraplegia. Marmor (1967) and Crellin and others (1970) stated that reduction of the subluxation is sufficient for cord recovery; this did not occur in the patient reported here. The operative findings clearly showed that infiltration of the dura mater with rheumatoid tissue is an added cause of compression of the spinal cord which can only be relieved surgically. This added pathology involving the dura mater has been described by Hopkins (1967) but has not been stressed sufficiently to be recognized and documented.

INTERNAL PUDENDAL ARTERIOGRAPHY AFTER PRIAPISM

BY I. LYNN EVANS AND A. E. YOUNG
LEWISHAM HOSPITAL, LONDON

SUMMARY

A case of postpriapic impotence which was investigated by internal pudendal arteriography is described and the possible therapeutic application of intra-arterial vasoconstrictors in the management of priapism is considered.

LONG-continuing priapism is almost invariably succeeded by impotence. The prognosis in individual cases must be judged clinically and on the basis of the duration of the priapism, but the clinician can usually do no more than meet his patient's anxious inquiries with reassurance and optimism. The postpriapic patient has normal penile sensation and ejaculatory reflexes, but may be impotent because he is unable to develop an erection and is thus incapable of intromission.

Arteriography, by showing irreversible arterial inflow occlusion, could avoid a futile search for a cure and perhaps indicate patients who would be suitable for a prosthetic penile implant (Pearman, 1967). This paper reports a case of postpriapic impotence which was investigated by internal pudendal arteriography.

CASE REPORT

The patient, a 39-year-old West Indian, was admitted in October, 1970, 24 hours after the onset of priapism. He had been seen 8 months previously when he had complained of headaches and had been found to be hypertensive. No cause was found to explain his hypertension, and his blood-pressure was controlled on guanethidine and Navidrex-K. One month prior to admission a transient episode of priapism had responded to treatment with diazepam.

On examination no abnormality was detected apart from priapism. The blood-pressure was 130/88 mm. Hg and the haemoglobin genotype was AA. Medical treatment using sedation and intravenous heparin was instituted, and the priapism settled over the next month.

At subsequent out-patients' clinics he complained of inability to develop an erection; the poor prognosis was explained, but he was none the less referred again on two occasions, and eventually to one of the present authors at whose instigation bilateral pudendal arteriography was performed. A catheter was introduced through the right femoral artery and manipulated through each internal iliac artery to each internal pudendal artery, using a Müller catheter guide system. The radiographs thus obtained (*Fig.* 1) displayed a normal pelvic arterial pattern, with the exception of the internal pudendal arteries which were seen to be occluded at the level of the perineal membrane. No arterial filling of the penis was apparent.

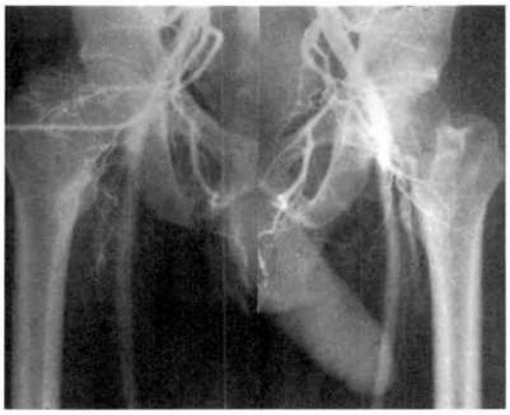

FIG. 1.—Composite right and left pelvic arteriograms, showing the internal pudendal arteries occluded at the level of the perineal membrane.

DISCUSSION

The erectile tissue of the penis draws its arterial supply almost exlusively from the internal pudendal arteries. In normal erection the primary haemodynamic event is active arteriolar dilatation, allowing filling and turgidity of the corpora cavernosa. Restriction of the venous outflow is less important. The return to flaccidity is initiated by arteriolar constriction and shunting into arteriovenous anastomoses.

Priapism may be symptomatic of a variety of diseases or may be 'idiopathic'. Neurological disease, especially spinal cord damage and disseminated sclerosis, may be responsible, as may venous obstruction by malignant disease of the bladder, rectum, or prostate, sickle-cell disease, leukaemia, prostatitis, or trauma. It has also been reported in patients taking anticoagulants or phenothiazines (Dawson Butterworth, 1970). 'Idiopathic' priapism often succeeds prolonged erection or vigorous intercourse.

The account of the genesis of priapism which has gained widest acceptance is that propounded by Hinman (1960):—

1. Prolonged erection allows stasis to develop in the corpora cavernosa.
2. An increased CO_2 tension locally produces a rise in viscosity of the blood in the corpora.
3. Relative venous congestion is produced at the junction of the cavernous spaces with the collecting veins.
4. In addition, oedema of the trabeculae fills the corpora and further impedes venous outflow.
5. Eventually arteriolar occlusion occurs.
6. Trabecular fibrosis develops, irreversibly disrupting the arteriolar supply mechanism.

The fibrosis subsequent upon trabecular oedema occludes the arterial inflow, thus allowing resolution of the priapism but with the penalty of associated impotence. This arterial occlusion has been demonstrated by Lipsky (1970), using direct puncture of the dorsalis penis artery, but to our knowledge pudendal arteriography has not previously been employed in this context. Its demonstration of occlusion of the internal pudendal artery at the perineal membrane suggests that the fibrosis is active throughout the corpora cavernosa. This fibrosis does not necessarily extend as far proximally as the perineal membrane in all cases, as erection of the base of the penis is sometimes maintained (Hinman, 1960).

We hope that this report will stimulate further angiographic studies of priapism, particularly in the acute phase. Baum and Nusbaum (1971) have successfully controlled gastro-intestinal haemorrhage by selective mesenteric arterial infusion of vasopressin, and the same method might be used to treat acute priapism by infusion directly into the internal pudendal arteries.

Acknowledgements.—We wish to thank Dr. J. D. Irving, who performed the arteriography, and Mr. D. Thomas of the Photographic Department.

AN UNUSUAL CASE OF SPONTANEOUS PERFORATION OF THE OESOPHAGUS

BY R. A. BRADBROOK*

DEPARTMENT OF THORACIC SURGERY, SHEFFIELD ROYAL INFIRMARY, SHEFFIELD

SUMMARY

An unusual case is reported of spontaneous per-ration of the oesophagus in which there was a arked absence of initial symptoms. It is suggested ıat this condition be considered in the differential agnosis of extensive hydropneumothorax. The nportance of early diagnosis as a prerequisite to ıccessful treatment is emphasized.

HIS report describes a 60-year-old woman who resented 8 days after rupturing her oesophagus ıring a bout of vomiting. Her only symptoms at ıe time of the incident were of mild dyspnoea and ıgue discomfort in the left chest. A search of the terature has failed to reveal a similar case.

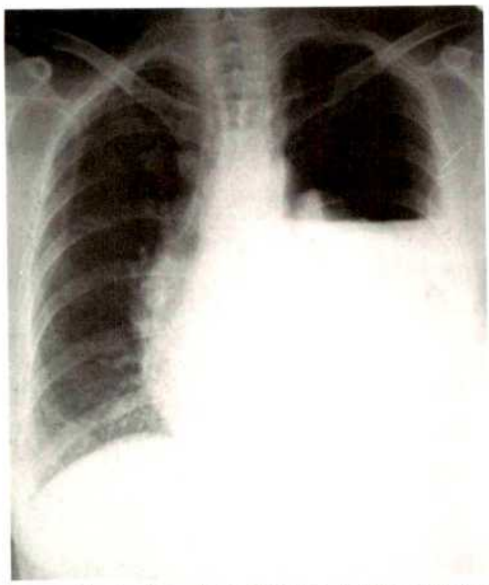

FIG. 1.—Chest radiograph on admission, showing a left-sided hydropneumothorax.

CASE REPORT

Mrs. K. B., a 60-year-old woman, was admitted with history of being perfectly well until 8 days prior to lmission. She had been caring for her family, all of hom had been suffering from gastro-enteritis, when she ıd developed symptoms of severe vomiting and diarıoea. The episodes of vomiting had lasted for 5 hours. s she recovered from the last bout of vomiting, the atient had noted that she had become slightly short of breath and 2–3 hours later had developed a vague aching pain in the left chest and hypochondrium, which radiated through to the back. The pain was not affected by breathing or by coughing.

She had remained in bed at home for 8 days following the onset of her symptoms, during which period there had been a slow deterioration in her general condition with increasing dyspnoea and anorexia.

On admission to hospital her general condition was fair; she was flushed and dyspnoeic although not clinically dehydrated. Her temperature was 36·8° C., the pulse was 104, regular, and of good volume, and the blood-pressure was 140/90.

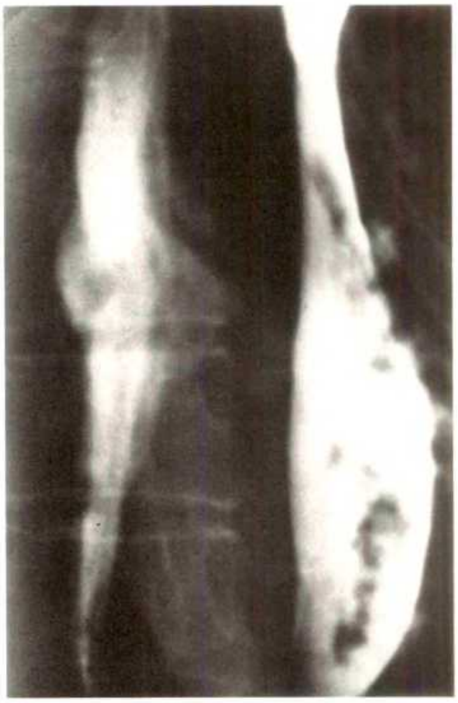

FIG. 2.—Gastrografin-swallow film, showing an oesophagopleural fistula.

On examination of the chest the trachea was deviated to the right with signs of a left-sided hydropneumothorax. There was no evidence of surgical emphysema. There were no other abnormal physical signs. The chest radiograph performed on admission (*Fig.* 1) confirmed the presence of an extensive left-sided hydropneumothorax with complete collapse of the left lung. There was no evidence of mediastinal emphysema.

At this time there was nothing to indicate the underlying pathology. The hydropneumothorax was treated by the insertion of intercostal drains and at the initial drainage procedure 600 ml. of purulent opalescent fluid were obtained. Following thoracentesis the patient's general condition improved although the volume of drainage remained in excess of 450 ml. per 24 hours for the next 4 days. A follow-up chest radiograph performed 2 days after the initial drainage procedure showed almost complete re-expansion of her left lung with only a small residual penumothorax and effusion. On the fifth day after admission the patient's general condition deteriorated further with anorexia and an inability to take fluids by mouth, associated with increasing dehydration. An intravenous fluid replacement régime resulted in a gradual improvement in the patient's general condition, although the inability to take fluids orally continued. On the seventeenth day after admission, in view of the continuing drainage from the left chest (150 ml. per 24 hours), formal drainage of the empyema was carried out with rib resection and insertion of two intercostal drains. Following this procedure there was a marked reduction in the drainage volume, although a small air leak continued. On the nineteenth day after admission the patient began to take fluids orally, and this was followed by a marked increase in the pleural drainage. It became apparent that an oesophagopleural fistula was present. This was confirmed by a gastrografin-swallow examination (*Fig.* 2).

---

* Present address: Royal Devon and Exeter Hospital, xeter, Devon.

In view of the long interval since perforation and the continuing satisfactory general condition of the patient during this period, it was decided that conservative management should be continued. On the twenty-second day after admission a feeding jejunostomy was performed; at this procedure the only intra-abdominal abnormality found was a chronic duodenal ulcer. Following this operation the patient's condition deteriorated; she developed a bilateral bronchopneumonia and sputum culture demonstrated the presence of *Pseudomonas pyocyanea*. Despite appropriate antibiotic and supportive therapy, the patient continued to deteriorate and she died on the twenty-fourth day after admission, 32 days after rupture of the oesophagus.

At post-mortem examination the left pleural cavity was found to contain 500 ml. of purulent fluid. The left lung showed confluent bronchopneumonia; a 7-cm. longitudinal rupture of the lower third of the oesophagus was demonstrated with free communication into the left pleural cavity. There was no evidence of mediastinal abscess; at the site of the rupture the adjacent oesophageal wall was normal.

DISCUSSION

Since the original description by Boerhaave (1724) the dramatic nature of the symptoms following spontaneous perforation of the oesophagus is well known. Barrett (1946) in his now classic and often-quoted paper highlights the symptomatology and the difficulties in diagnosing this condition. The clinical manifestations and diagnostic problems of this condition have been well documented in a series of reports in the world literature (Eliason and Welty, 1946; Kinsella, Morse, and Hertzog, 1948; Moore and Murphy, 1948; Samson, 1951; Moynihan, 1954; Starkey, 1955; Hugh, 1965; McKeown, 1965; Movsas, 1966; Toghill, Raut, and MacGuire, 1968; Callaghan, 1972). Barrett (1947) reported the first cases of spontaneous perforation of the oesophagus which were successfullly treated by direct suture. Since then there have been increasing numbers of reports of similarly successful cases (Starkey, 1955; Hamilton, 1967; Tidman and John, 1967; Toghill and others, 1968; Callaghan, 1972). In the majority of the cases which have been managed successfully, early diagnosis was of crucial importance. In their extensive and detailed paper, Derbes and Mitchell 1965) point out that in their series, in the absence of treatment, only 35 per cent of cases survived for 2 hours, 11 per cent to the end of the second day, an no case lived longer than 1 week. They draw attention to the fact that 83 per cent of the cases occurre in old men; however, no age-group is exempt, rupture of the oesophagus has been reported i neonates (Hohf, Kimball, and Bellenger, 1962).

The mechanism of pressure rupture of the oesophagus, as many authors prefer to call this conditio has been dealt with in remarkable detail by Derbe and Mitchell (1956). They studied the mechani of the process and also the pressures required t produce rupture of the oesophagus. The majorit of perforations of the oesophagus occur in the lowe one-third and into the left side of the chest. Th anatomical siting for this condition is due to a weakness in the wall of the oesophagus in its lower one third, as was first demonstrated by McKenzie (1884 A number of other workers have experimented o cadaveric oesophagi to establish the pressures required to produce a rupture. McKenzie in h original work (1884) found that a pressure of 5 lb per sq. in. was required, Burt (1931) 4·91 lb. pe sq. in., Kinsella and others (1948) 3·69 lb. per sq. in Mackler (1952) 5 lb. per sq. in., while Tidman an John (1967) found that 2·3 lb. per sq. in. was required to rupture the isolated oesophagus but 4·6 lb per sq. in. was necessary for the oesophagus left i situ.

The process of spontaneous perforation of th oesophagus depends on violent contracting of th abdominal muscles during vomiting associated wit a failure of the cricopharyngeus to relax. This produces a rapid rise in pressure within the oesophagu which is stressed beyond its physical limits, resultin in rupture. Mackler (1952) observed in his experimental series that the mucosa ruptured after th muscular wall of the oesophagus had given way.

Bates (1969) points out that in cases where th mediastinal pleura ruptures at the time of perforatio of the oesophagus there is no mediastinitis or resulting toxaemia, and therefore the prognosis is ver much better. This author also emphasizes that i cases which are diagnosed late a conservative régim with antibiotics and chest drainage should be undertaken. Several reports are recorded in the literatur of patients surviving perforation of the oesophagu in which the diagnosis was missed, the resultin empyema being treated by drainage and antibioti (Frink, 1947; Lynch, 1949; Sanderson, 1965 Harma, Koskinen, and Suurkari (1968) reported case in which drainage of the mediastinum wa attempted endoscopically with some success. Bradham, Bridgman, Scott, and Betts (1967) reported cases of spontaneous perforation of the oesophagu in which treatment was delayed with a satisfactor outcome.

The case reported here is most unusual, firs because of the remarkable absence of symptoms the time of perforation and, secondly, the long dela before the patient's general condition deteriorate sufficiently to warrant hospitalization. Both thes manifestations can be explained by the fact that the time of perforation the stomach was probabl empty following repeated episodes of vomiting an therefore little, if any, soiling of the pleura or mediastinum occurred. It is also highly likely that th ıediastinal pleura ruptured at the same time as the esophagus hence avoiding mediastinitis. Only 1 ther case (Bradham and others, 1967) could be found ı the world literature in which the patient survived long delay (18 days) before treatment was started.

The case reported here presented more than the sual diagnostic problems associated with spon- aneous perforation of the oesophagus. In addition, ıere was no radiological evidence of mediastinal mphysema, which is a useful and early diagnostic ign (Naclerio, 1957). The importance of early iagnosis and treatment of spontaneous perforation f the oesophagus cannot be overemphasized if this ondition is to be treated successfully.

Acknowledgement.—I wish to thank Mr. A. G. Norman for permission to publish details of his atient.

REVIEWS AND NOTICES OF BOOKS

Surgical Emergencies in the Newborn. By J. Alex Haller, jun., M.D., Baltimore, and James L. Talbert, M.D., Florida. 11 × 8½ in. Pp. 153 + ix. Illustrated. 1972. London: Henry Kimpton. £6·30.

T is symptomatic of the growing increase of the scope of paediatric surgery that yet another book on surgical mergencies in the newborn should be produced, this ime from the Johns Hopkins Hospital. Its contents eflect the interests of the two authors. Their arrange- nent is novel and perhaps to some may be confusing. The first quarter of the book is devoted to the physio- ogical problems, pre- and postoperative care, and the naking of observations on the newborn baby. It is ollowed by a section on tracheostomy, the insertion of annulas into the great veins, and intravenous nutrition. Another chapter is devoted to respiratory emergencies and it is to be hoped that the treatment advocated for he Pierre-Robin syndrome is not too often followed. t is surprising to find tracheo-oesophageal fistula and esophageal atresia included amongst these respiratory mergencies. There is a long section on cardiovascular mergencies which reflects the modern tendency to ndertake more and more curative operations at a much ounger age than has been the custom in the past. Nevertheless, this section is probably too extensive or most surgeons who undertake the emergency treat- nent of the newborn since they are unlikely to do much cardiac surgery. It must be extremely unusual for a baby to be born with an incarcerated hernia, though this is one of the possibilities mentioned in a very short section on hernia, and the use of gallows traction in the conservative treatment of an incarcerated hernia is not mentioned.

This book provides a satisfactory account of the diagnosis and treatment of surgical emergencies in the newborn child, but it is unlikely to compete successfully for the interest of specialists in paediatric surgery with other more extensive books on this subject which have preceded it. For those who require a shorter account of the problems of the first days or weeks of life this book will be satisfactory and its lower price compared with the more extensive volumes is, of course, an advantage.

Practical Procedures in Diagnostic Radiology. Second edition. Edited by H. M. Saxton, M.B., M.R.C.P., F.F.R., D.M.R.D., Guy's Hospital, London, and Basil Strickland, F.R.C.P., F.F.R., F.A.C.R. (Hon.), Westminster Hospital, London. 9¾ × 6¼ in. Pp. 305 + xii. Illustrated. 1972. London: H. K. Lewis. £5.

After a lapse of 8 years the second edition of this popular book should be welcomed by both trainee and radiological registrars, for it covers a number, if not all, of the more common investigations undertaken in most diagnostic

X-ray departments. This book's size and price have naturally increased a little since the original publication, as has the number of contributors. Certain chapters contain a few references though some of these may be a little out of date. In this age of closed-circuit television within X-ray examination rooms, techniques requiring accurate organ and site localization abound and are the radiologists' responsibility. These include biopsy techniques of the lung, kidney, liver, bone, jejunum, etc., gastro-camera, fibrescopy, and duodenal intubation. It might be expected that these should be included in any future edition. It would also be appropriate if some basic advice was given to the radiologist who is expected to perform right-heart catheterization for the investigation and treatment of pulmonary embolus, as most vascular radiologists are *au fait* with catheterization techniques of the left side of the heart and aorta and its branches. Why not the right? Isotopic organ scanning techniques in relation to diagnostic radiology would also be worthy of mention, if only briefly, as some diagnostic X-ray departments may undertake this work independently of nuclear medicine departments and the handling and application of radionuclides are in the syllabus for diagnostic radiological training. The technique of ductography in conjunction with mammography might also have been included. These omissions, in the mind of the reviewer, are not necessarily critical but might be included at the expense of the unnecessary text and space devoted to an almost historical section on vascular radiology! Do we really have to know about catheter preparation in this age of 'disposables', the availability of which has made the preparation of catheters of less value than formerly. Furthermore, surely direct-vision laparoscopy with air and water tubation now makes uterosalpingography almost obsolete except in the case of suspected uterine abnormalities or cervical insufficiency. These criticisms, mainly of omission, in no way detract from the value and worthiness of this book and the editors and publishers must be again congratulated on their effort in producing such a lucid manual of instructional techniques. It is well recommended.

Stoffwechsel. Edited by DR. R. FREY, Mainz, DR. F. KERN, St. Gallen, and PROFESSOR DR. O. MAYRHOFER, Wien. 9 × 6 in. Pp. 142 + x. Illustrated. 1972. Berlin: Springer Verlag. DM.48.

THIS is a report of a symposium held in October, 1970, in Mainz on metabolic changes in relation to intensive care. The papers presented report assorted aspects of metabolic changes in stress, following injury, and after burns. The ensuing discussions are reported in full and this book is likely to be of interest only to research workers in this particular aspect of pathology and physiology in relation to shock.

The Care of Minor Hand Injuries. Third edition. By ADRIAN E. FLATT, M.A., M.D., M.Chir., F.R.C.S., F.A.C.S., Iowa. $9\frac{3}{4} \times 6\frac{3}{4}$ in. Pp. 293 + xi. Illustrated. 1972. London: Henry Kimpton. £9·70.

THIS is the third edition of a book which was first published in 1959. Readers will agree with the author that strictly speaking there is no such entity as a 'minor injury to the hand'. By his definition, however, such an injury implies 'a relatively small amount of tissue damage, out-patient treatment and freedom from postoperative complications'.

There are those who may well feel that some of the surgical techniques described should not be carried out in an out-patients' department, and that all but the most trivial injuries should be admitted for a period of strict elevation of the hand.

The book is divided into two sections: Part 1 deals with general principles of care and Part 2 describes the care of specific injuries. Part 1 is well written and illu trated and emphasizes most of the important requiremen for successful hand surgery.

In Part 2, however, there is a certain imbalance. F example, skin replacement for pulp loss includes description of the use of local flap-grafts whereas t treatment of tendon injuries is only superficially discusse

Nevertheless, this is a reference book that should be every emergency and accident department. It will found most helpful by students and casualty officers alik

Chirurgie. Ein kurzgefasstes Lehrbuch mit 3 Prüfungsfragen. Second edition. By MARTIN REIFFE SCHEID, Aachen. $7\frac{1}{2} \times 4\frac{3}{4}$ in. Pp. 658 + xiv. Illustrate 1972. Stuttgart: Georg Thieme Verlag. DM.19.80.

THE second edition of this paperback has been carefu revised and it will remain a very useful book for medic students who are conversant with the German languag The subject matter is conveniently arranged and the ind is quite complete. The addition of 94 groups of matchi questions, however, is no gain, as matching questions a the most passive form of testing knowledge.

Outline of Fractures. Sixth edition. By JOHN CRAW FORD ADAMS, M.D., M.S., F.R.C.S., St. Mary's Hosp tal, London. $8\frac{1}{2} \times 5\frac{1}{2}$ in. Pp. 312 + vii. Illustrate 1972. Edinburgh: Churchill Livingstone. £2·25.

THIS little classic continues to grow in popularity and now reaches its sixth edition within a short 15-year perio Its price has been maintained at a very reasonable lev which is well within the student's pocket or purse con taining his or her allowance. The success of this boo has resulted from the clarity of its writing and the hig quality of its illustrations and definitions. One sma point which should be mentioned is that although M Crawford Adams has correctly sensed the requirement of the undergraduate as regards fractures and thei management, one would like to see in the next editio more of the basic sciences which are taught in the pre clinical years brought into this field of trauma.

The references and bibliography have been well selecte and provide an excellent and extensive background f anyone interested in fractures.

The textbook is warmly recommended to all students who should enjoy reading it and even learning from it.

Thromboembolism: Diagnosis and Treatmen Edited by V. V. KAKKAR, F.R.C.S.E., F.R.C.S., King' College Hospital Medical School, London, and A. JOUHAR, M.B., M.R.C.S., Kabi Pharmaceuticals Ltd Ealing, London. $8\frac{1}{2} \times 5\frac{1}{4}$ in. Pp. 241 + xii. Illustrate 1972. Edinburgh: Churchill Livingstone. £3·50.

THERE can be few more dismaying complications to th surgeon than deep-vein thrombosis and pulmonary embo lism. It is heartening that our understanding of thrombo embolism has been on the growing edge of medic knowledge over the past decade. During this time man surgical meetings have been enlivened by a series of excel lent original papers on the subject by V. V. Kakkar and is particularly apt that he should have joined with A. Jouhar, Medical Director of Kabi Pharmaceuticals Ltd., i editing the proceedings of a recent symposium on thrombo embolism to produce such an excellent up-to-the-minut account.

The book as a whole presents a careful survey modern techniques of investigation and treatment wit a scrupulously fair appraisal of their merits. The text logically arranged, easily readable, and enlivened with number of excellent illustrations and diagrams. It divided into four parts. The subtle processes of hyper coagulation and associated phenomena are well describe in Part 1; inevitably this involves laboratory studies b these are presented with ease and clarity. Part 2 will appeal especially to the surgeon, for all the techniques that have so brilliantly displayed the thrombotic processes as they occur are described. For those who have not kept abreast with this work it will make compelling reading. Our methods of prevention are now based on clear insight and it is possible to measure in fairly precise terms the success of any form of treatment, be it the use of a drug, a device to encourage emptying of the soleal veins, or, most practical of all, the active postoperative contraction of calf muscles.

The topic of thrombectomy in the deep vein is not referred to, presumably because it was outside the brief of the symposium. However, this book covers a lot of ground and is certainly a 'must' for the younger surgeon who is programming his personal biological computer for a lifetime's use in surgery; there is no better source from which to glean the best of our present understanding. For the established surgeon it is an important book, for he will find that the half-formed ideas of yesterday have taken a sharply defined shape and that the scourge of thrombo-embolism need not be quite so mysterious and terrifying as of old. The reviewer thoroughly recommends this book to all surgeons and, needless to say, physicians.

Spezielle Frakturen und Luxationslehre: Gesichtsschadel. Edited by H. Nigst, Basel. 10 × 7 in. Pp. 213 + xii. Illustrated. 1972. Stuttgart: Georg Thieme Verlag. DM.164.

This is the first of a series of five volumes which are to be published under the general title, 'A Guide to Special Fractures and Joint Injuries'. Volume I, which is reviewed here, is entitled 'The Facial Skeleton'.

The book is divided into two parts. Part 1 is concerned with diagnosis and the general principals of treatment of facial fractures, and is, therefore, directed particularly to the casualty officer and accident surgeon. The outstanding feature of this section is an excellent account of the radiology (and radiography) of the facial bones.

The book is profusely illustrated throughout and the line drawings and radiographs are of excellent quality. However, the radiographs are printed as positives and in some views the overprinted arrows are so numerous that they tend to obscure detail. Nevertheless, this is a minor criticism and Part 1 is to be recommended for its lucidity.

Part 2 is written for the maxillofacial specialist. It gives a good account of the methods of jaw fixation which are favoured in Swiss and German units, the emphasis being on the plating of mandibular fractures. The book will be read with interest by specialists in this field, but at the price of DM.164 it is expensive reading.

Intravenous Hyperalimentation. Edited by George S. M. Cowan, jun., B.A., M.B., Ch.B., Washington, and Walter L. Scheetz, M.D., Washington. 9 × 6 in. Pp. 225 + xxiii. Illustrated. 1972. London: Henry Kimpton. £5·40.

This book contains the proceedings of the conference on intravenous hyperalimentation held in the U.S. Army Institute of Surgical Research, San Antonio, Texas, in November, 1970. The purpose of the conference was to provide a review of current concepts in intravenous hyperalimentation, to answer some of the questions in this area, and to stimulate further research in the nutritional problems of surgical patients.

The book is comprised of 18 chapters by noted authorities of whom all but two are from North America. They cover the effects of starvation, the metabolism of foodstuffs, energy balance, and the general principles, technique, and experience in the use of hyperalimentation in various surgical conditions. Each chapter is carefully balanced and covers physiology as well as practical points with references and discussion at the end.

The reviewer must confess to a dislike of the rather ugly word 'hyperalimentation' which to him has no real meaning, as the subject covered is really that of intravenous feeding. Hyperalimentation is defined as a technique of total parenteral nutrition which provides nutrients adequate in quality and quantity to support normal growth and development in immature animals and man as well as to ensure a positive nitrogen balance in adults for indefinite periods of time. The basic nutrient solutions used consist of 20–25 per cent dextrose and 4–5 per cent protein hydrolysates or crystalline amino-acids. These are supplemented by electrolytes, vitamins, and other micronutrients as required. Since in Europe intravenous fat preparations are used as the main sources of calories more discussion on this would have been preferred.

The book is excellently produced with well-chosen line diagrams and tables to illustrate various points. It is not a simple book to read at bedtime, but study of it will pay dividends in the care of patients with nutritional problems. It can therefore be warmly recommended to all who have an interest in surgical metabolism.

Kopf- und Hals-Chirurgie. Band 1: Hals. Edited by H. H. Naumann, München. 11 × 8 in. Pp. 518 + xii. Illustrated. 1972. Stuttgart: Georg Thieme Verlag. DM.350.

This handbook of operative surgery is the first to appear of a set of three. Judging from this volume the series rightly calls the field of head and neck surgery its own, for this first book seems to cover its subject-matter very completely. As is usual with books of this kind, it appears to be primarily written for the general surgeon specializing in this particular field, or being forced by circumstances to care for an unfamiliar lesion arising in it. The present volume is restricted to the region of the neck and is subdivided into twelve major sections. As would be expected, the contributors come from such disciplines as otolaryngology, anaesthesiology, and general surgery. The sections are further split up according to particular operations, though occasionally subdivision is on diagnostic criteria as, for example, in the excellent chapter on vascular lesions. The operative procedures are lavishly illustrated in the established step-by-step way in very clear black and white drawings with an artistic stroke of red used sparingly. The sober accompanying text has been arranged closely around the illustrations, making the reading of it very convenient. The text is, however, not just a companion to the drawings; it is expanded to give short summaries of 'errors and safeguards' and of postoperative care. As for the operations selected, it is a very pleasing feature that the editor has picked his choice and has presented the readers with the techniques favoured by himself and which he has found effective in actual practice. This is much more helpful than giving a kaleidoscopic review and leaving the less-experienced reader with an awkward 'judgement of Paris'.

The book can be thoroughly recommended, but will probably be mainly found in medical libraries because of its extremely high price.

Ultrasonics in Clinical Diagnosis. Edited by Peter N. T. Wells, Welsh National School of Medicine. 8½ × 5½ in. Pp. 187 + xi. Illustrated. 1972. Edinburgh: Churchill Livingstone. £3.

Eight contributors, each an expert in his field, have produced this book which has been edited by Professor Wells. Three main sections are included in the text: (1) the basic principles and diagnostic methods, (2) diagnostic applications, and (3) biological effects. An appendix is added dealing with the equipment available. The text is illustrated by numerous reproduced scans explained by labelled drawings.

Although ultrasonic techniques have been known for the past 20 years, it is only in recent years that their place in clinical diagnosis has been established. The editor wishes the book to satisfy the needs of candidates for the Fellowship of the Faculty of Radiologists and to serve as a guide for the higher examination of the Society of Radiographers. It certainly does more than this. The main areas where ultrasonics provide a useful addition to our diagnostic methods are in obstetrical and gynaecological practice, in the investigation of the brain, and, to a limited extent, in certain abdominal areas, e.g., liver and kidneys, abdominal aneurysms, etc. Many other areas where developments are continuing are included in the text, e.g., ophthalmology, cardiology, and even dentistry. The value and limitations of this technique are emphasized by each contributor. No claim is made that ultrasonics can always be the sole diagnostic tool; their use and interpretation should be in conjunction with other diagnostic methods, mostly radiological. The authors point out the value of ultrasonic methods as a screening device, e.g., in the examination of head injuries.

Many clinicians may find the earlier chapters on the fundamental physics a little difficult to follow, but the authors have succeeded in outlining the facts necessary to understand the broad principles of the techniques. In these chapters the principles of the A-scope, the two-dimensional B-scope, and Doppler methods are included.

This book gives an understandable account of the place of ultrasonics in medicine today. It should be read by radiologists studying for both the D.M.R.D. and F.F.R. examinations, and it can be used as a reference book for those developing experience in these techniques. Moreover, it is of value to non-radiologists who wish to know when and how to use this diagnostic tool, and wish to understand its values and limitations.

Hemobilia (Biliary Tract Hemorrhage). By PHIL SANDBLOM, M.D., Ph.D., Sweden. 9¾ × 7 in. Pp. 1 +xxi. Illustrated. 1972. Springfield, Ill.: Charles Thomas. $19.75.

THIS monograph on haemobilia will be a most welcor addition to the library of any surgeon with an interest the surgery of the biliary system and in trauma. Phil Sandblom was for years the leading exponent in Swed in the surgery of portal hypertension, and those wl visited him in Lund will have appreciated his spec flair for dealing with the intricate emergency situatio His first experience of encountering blood-loss from t liver via the common bile-duct over 20 years ago prompt him to call this condition 'hemobilia'. In this mon graph he relates the history of the description of t condition as far back as Glisson in 1654, Morgazin and Portal (although Realdus Columbus described probable case in 1559—the post-mortem of St. Ignati Loyola). The history is followed by chapters on patholog diagnosis, and treatment derived from a collection of 5 published cases in the world literature. Trauma leads the list of causes, and careful history-taking in making preoperative diagnosis is emphasized. Arteriograph cholangiography, and scintiscanning are useful confirm tory investigations. A successful outcome depends large upon early recognition and operation. The general cha ters are followed by those which describe the experienc related to specific causes, such as trauma, inflammatio gall-stones, tumour, and vascular disorders.

As Warren Cole says in his appreciative Foreword, t detail in this book represents an enormous amount work presented in a refreshing and easily followed styl Truly a book to be prized.

BOOK NOTICES

[The Editorial Committee acknowledge with thanks the receipt of the following volumes. A selection will be made from these for review, precedence being given to new books and to those having the greatest interest to our readers].

Les Traumatismes du Thorax. Edited by DE H. LE BRIGAND, Paris. 10½ × 8 in. Pp. 97. Illustrated. 1971. Paris: L'Expansion Scientifique. 38F.

Behaviour of the Human Ureter in Health and Disease. By JAMES A. ROSS, M.B.E., M.D., F.R.C.S., Honorary Consultant in Surgery to the Army in Scotland, PETER EDMOND, F.R.C.S., Edinburgh Royal Infirmary, and IAN S. KIRKLAND, F.R.C.S., Western General Hospital, Edinburgh. 8¾ × 5½ in. Pp. 136 + viii. Illustrated. 1972. Edinburgh: Churchill Livingstone. £3·50.

The Early Diagnosis of the Acute Abdomen. By Sir ZACHARY COPE, B.A., M.D., M.S. (Lond.), F.R.C.S. (Eng.), St. Mary's Hospital, London. 8 × 5½ in. Pp. 210. Illustrated. 1972. London: Oxford University Press. £1·20.

Sauerstoffüberdruckbehandlung. Probleme und Anwendung. By I. PODLESCH, Dusseldorf. 9 × 6 in. Pp. 97. Illustrated. 1972. Berlin: Springer-Verlag. DM.38.

The Biochemistry of Animal Fossils. By RALF W. G. WYCKOFF, Arizona. 8¾ × 5⅝ in. Pp. 164. Illu trated. 1972. Bristol: Scientechnica (Publishers) Lt £5·25.

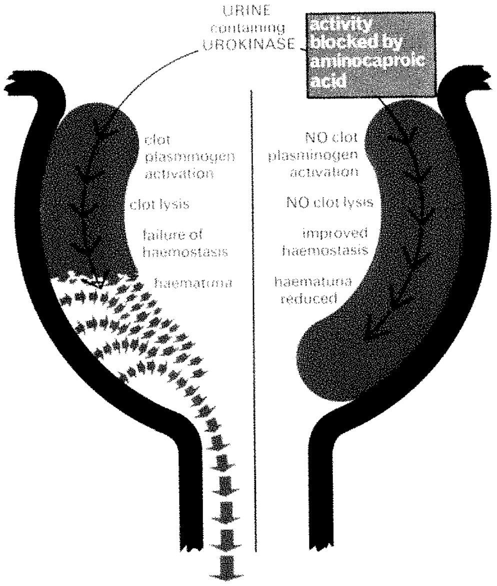
Crohn's Disease. By JAMES KYLE, M.Ch., F.R.C.S Royal Infirmary, Aberdeen. 8½ × 5½ in. Pp. 210. Illu trated. 1972. London: William Heinemann. £3.

Cardiovascular Surgery 1971. Edited by EARLE MAHONEY, M.D., New York. 10 × 7½ in. Pp. 16 Illustrated. 1972. New York: American Heart Associ tion, Inc. $5.

The Upper Cervical Spine. By DETLEF VON TORKL and WALTER GEHLE, Hamburg. 10½ × 7½ in. Pp. 10 Illustrated. 1972. Stuttgart: Georg Thieme Verla DM.48.

Rheinisch-Westfalische Akademie der Wissenshaf ten. By WERNER TH. O. FORSSMANN and CARL-HEIN FISCHER. 9½ × 6½ in. Pp. 79. Illustrated. 197 Opladen: Westdeutscher Verlag. DM.15.

The mechanism of post-prostatectomy bleeding and EPSIKAPRON® control



URINE containing UROKINASE
activity blocked by aminocaproic acid
clot plasminogen activation
clot lysis
failure of haemostasis
haematuria
NO clot plasminogen activation
NO clot lysis
improved haemostasis
haematuria reduced

Epsikapron (aminocaproic acid) is rapidly excreted in the urine in high concentration ; there it inhibits urokinase, the fibrinolytic enzyme in urine. With the haemorrhage-sustaining property of urine blocked, the haemostatic coagulum becomes adequate, and blood loss is diminished substantially.

Epsikapron makes your prostatectomy patient's post-operative course smoother by diminishing :

the need for post-operative blood transfusion
clot retention
catheterization
the risk of infection
the period of hospitalization

Presentation

Epsikapron Solution for Injection 0.4 g/ml Box of 6 ampoules of 10 ml, each containing 4.0g aminocaproic acid (0022/5003) Epsikapron Effervescent Powder 50% Box of 30 sachets, each containing 3.0g aminocaproic acid (0022/5004) Epsikapron Syrup 0.3g/ml Bottle of 250ml (0022/5005)

EPSIKAPRON®

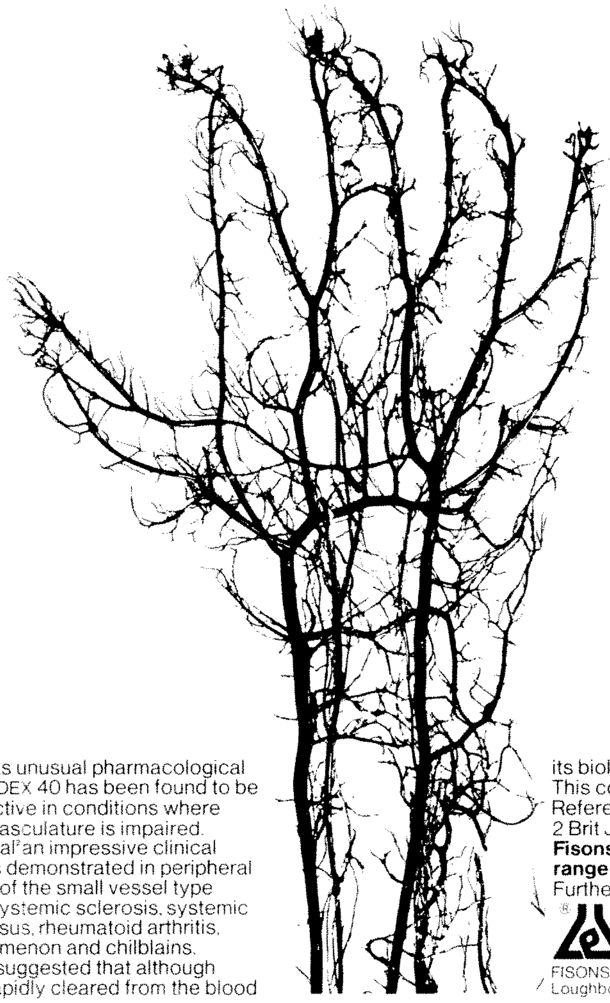
> By reducing intravascular "sludging" – the aggregation of erythrocytes into clumps – it (low molecular weight dextran) improves the flow of blood through small vessels.[1]



Because of its unusual pharmacological properties, LOMODEX 40 has been found to be dramatically effective in conditions where flow in the microvasculature is impaired.

In a recent trial[2] an impressive clinical improvement was demonstrated in peripheral vascular disease of the small vessel type associated with systemic sclerosis, systemic lupus erythematosus, rheumatoid arthritis, Raynaud's phenomenon and chilblains.

The authors suggested that although LOMODEX 40 is rapidly cleared from the blood its biological effect m

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500

An extra 16p per 300 pages will be charged for reprints sent to outside the United Kingdom.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 59. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St Martin's House,* 159 *Clapham High Street, London, SW4 7SU* (telephone 01-622 9225).

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

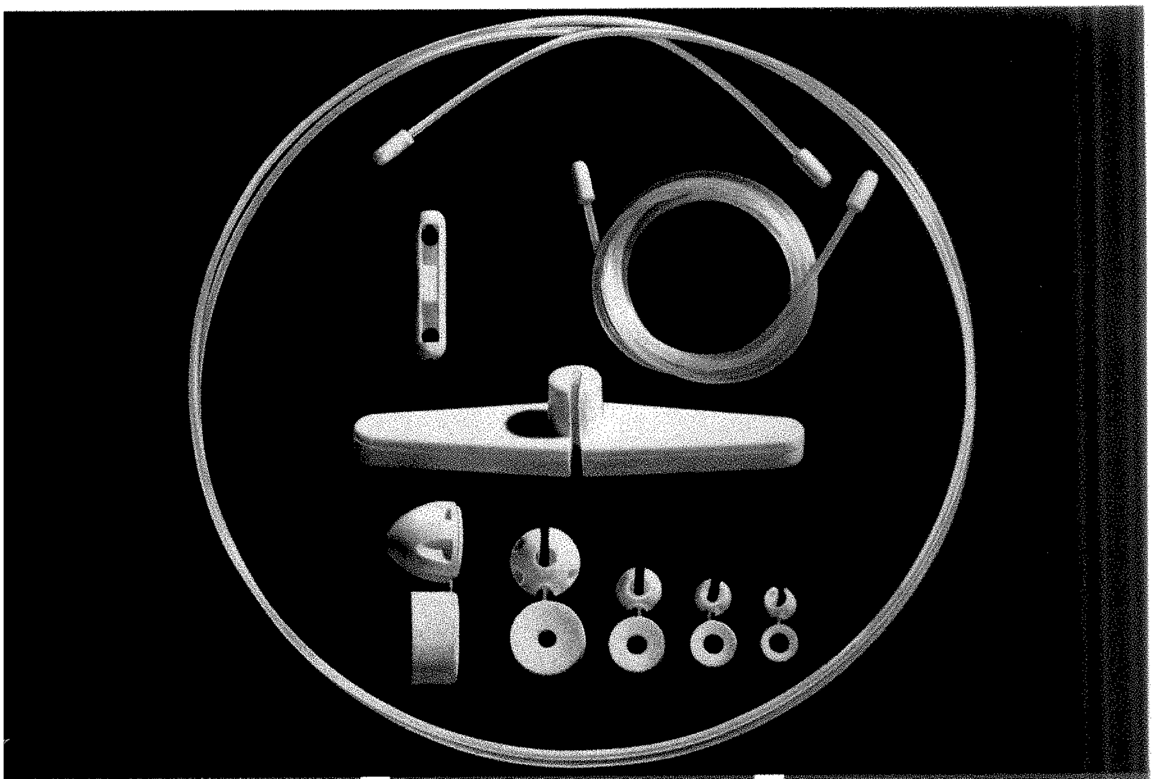
Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

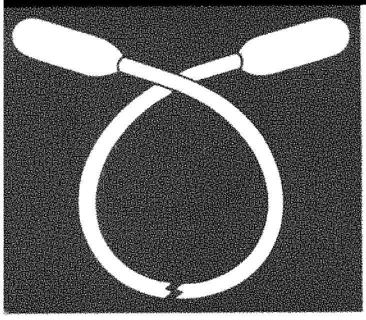
Armour Vein Stripper

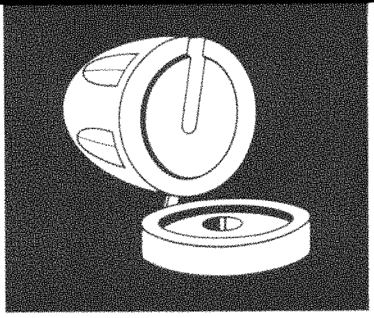
Sterile, disposable, non-toxic and pyrogen-free

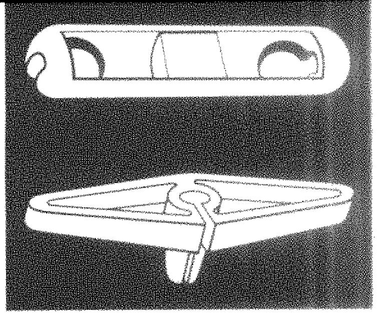
Eliminates time-consuming preparation and cleaning

Sterilised by irradiation









Nylon Cable

Has optimum handling quality.

very end stop individually tested for rmness of attachment.

Breaking load of cable in excess of 50 lb.

Nylon Olives

Snap fit for convenience of assembly.

Clean, well-defined cutting edge.

Hole without edge access prevents cable detachment.

Nylon Coupler and Draw Handle

Smooth, compact, coupling, ensures security of union.

Light, strong, well shaped.

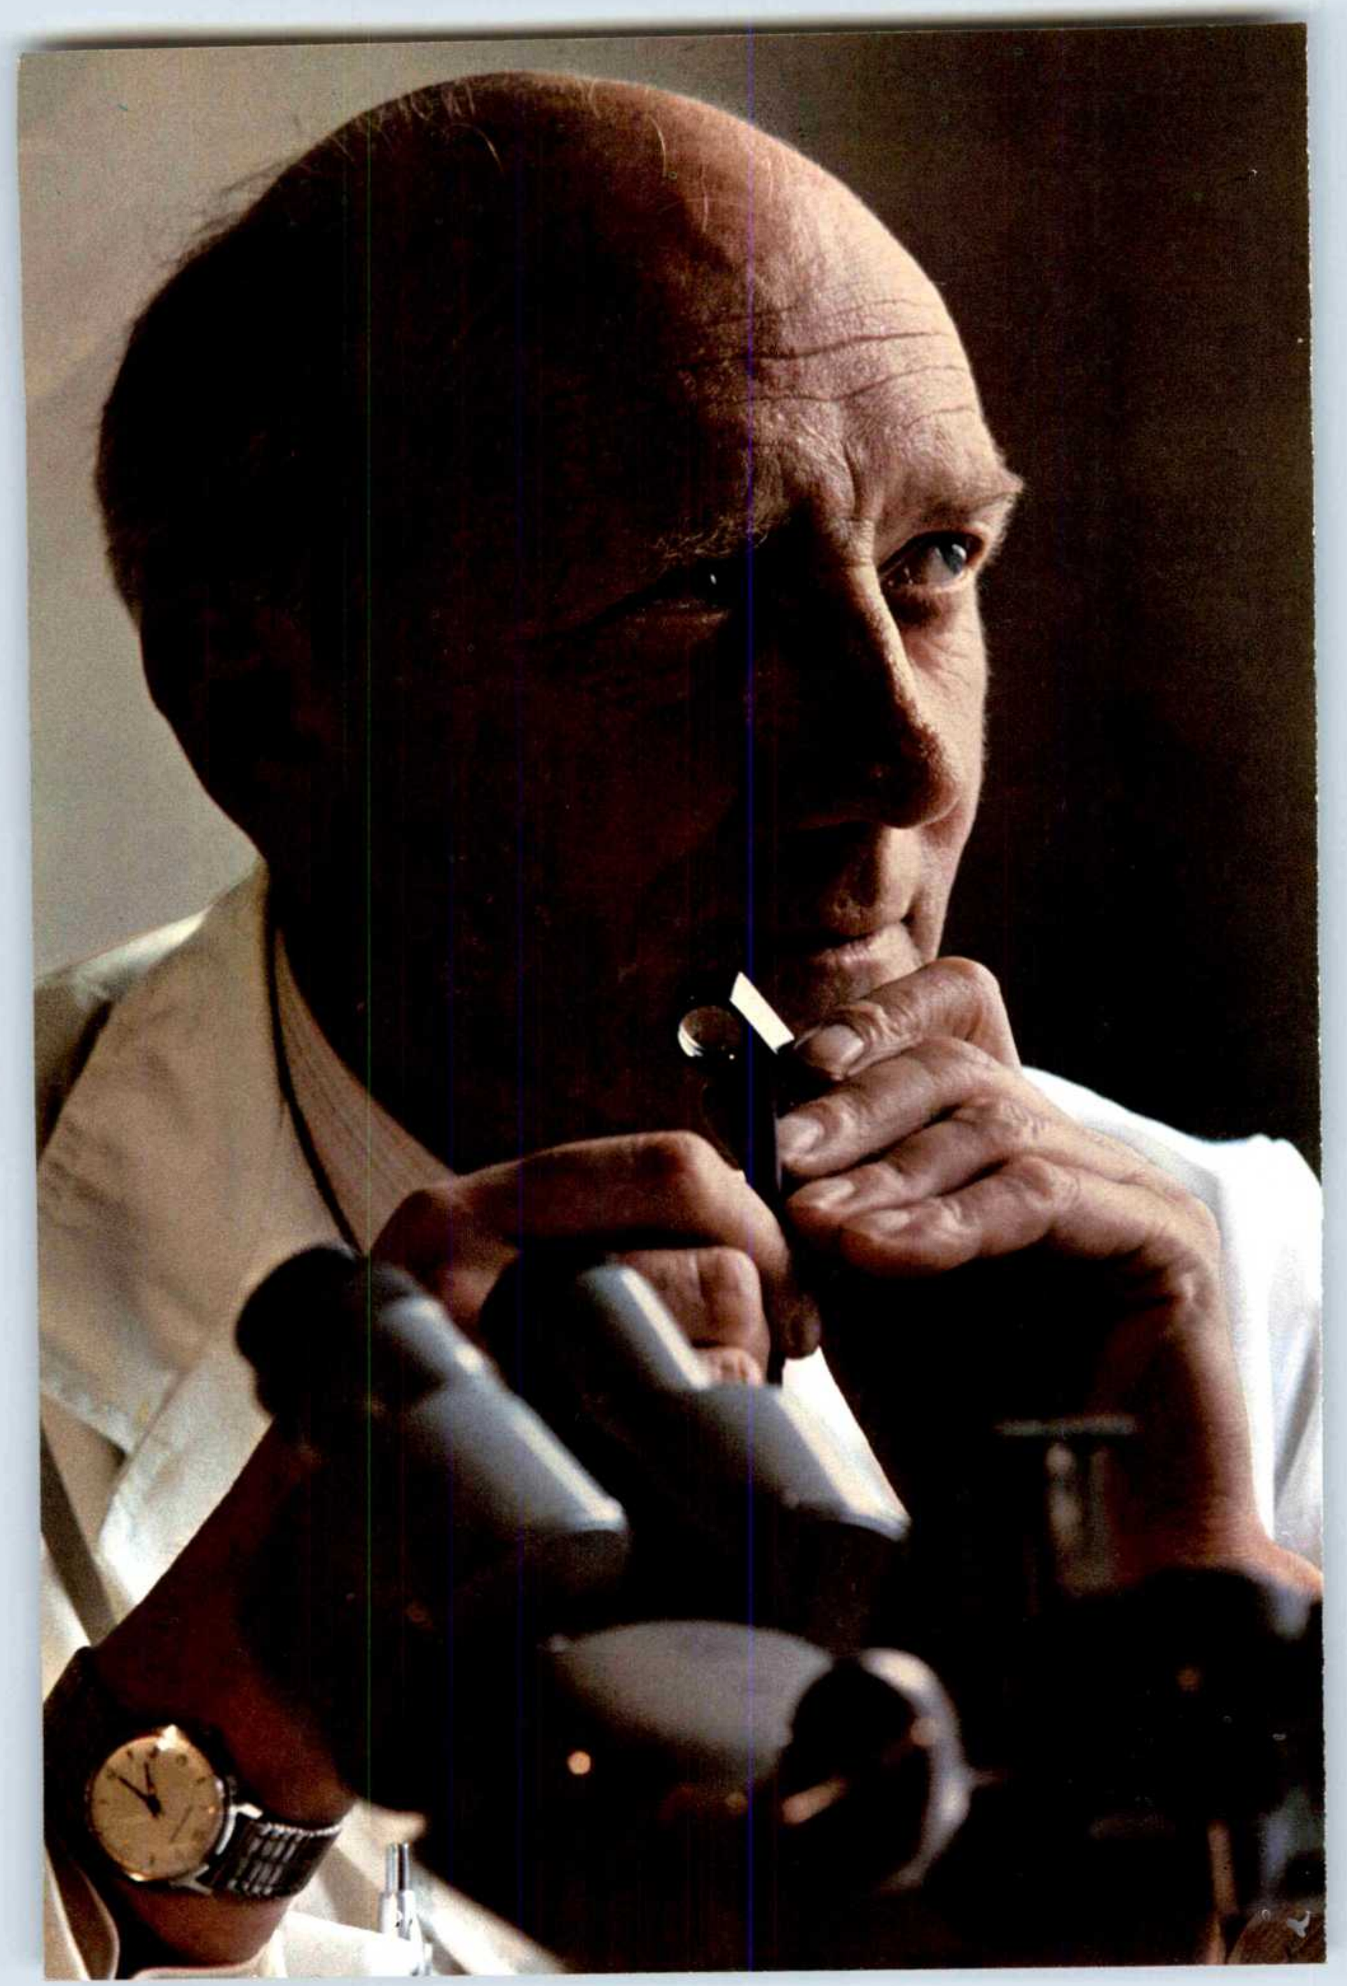
ETHICON*

...leadership
in wound repair

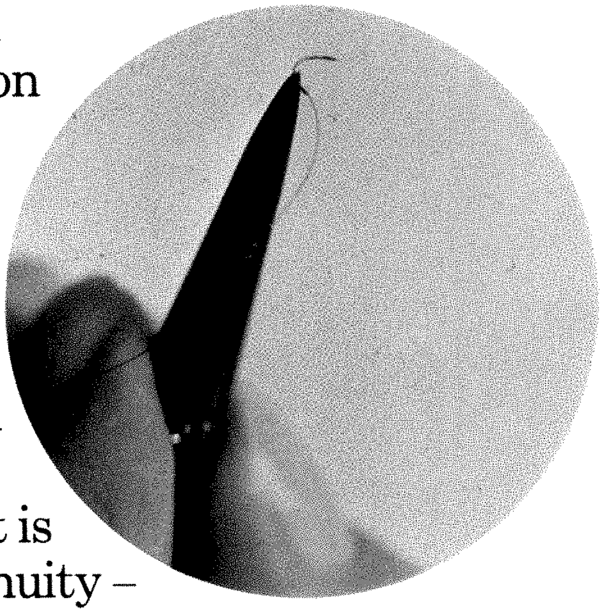


We've given John Mathams a big award for his smallest achievement

Recently John Mathams came out of his back room at the Sighthill plant of ETHICON to receive one of the biggest honours the company can bestow on a research scientist.

We owe him a lot.

So do surgeons. For John made an important contribution to surgery by developing a unique method of attaching micro-needles to ultra-fine materials; the type of needle scarcely visible in our picture. It has important application in ophthalmic surgery.



Behind this achievement is one man's originality and ingenuity – backed by qualities which he shares with everyone at ETHICON: determination and dedication to the highest attainable standards in the service of the surgeon.

ETHICON

ETHICON LIMITED, SCOTLAND

Tissue approximation needs ETHICON precision

Tolerances for ETHICON sutures range from 0·0002″ (for gauge conformity in natural catgut) to 0·0001″ (for 6 mm micro-surgical needles). For every ETHICON suture is shaped by the needs of the surgeon. It is our concern to meet these needs with precision.

ETHICON

Surgical Gut

Dependable strength and absorption properties. Chromic and plain gut presented for every field of surgery.

ETHICON

MERSILK.*

BRAIDED SILK

Silk made to exacting surgical specifications. In many sterile presentations, including 80 MERSUTURES.* Eyeless Needled Sutures.

ETHICON

Surgical Linen Suture

Specially prepared for maximum strength and knot security.

ETHICON

PROLENE.*

MONOFILAMENT POLYPROPYLENE

The most inert suture known with knotting properties superior to those of any other monofilament.

ETHICON

ETHIFLEX.*

PTFE COATED POLYESTER

An inert braided suture possessing both superb handling properties and excellent tensile strength.

ETHICON

ETHILON.*

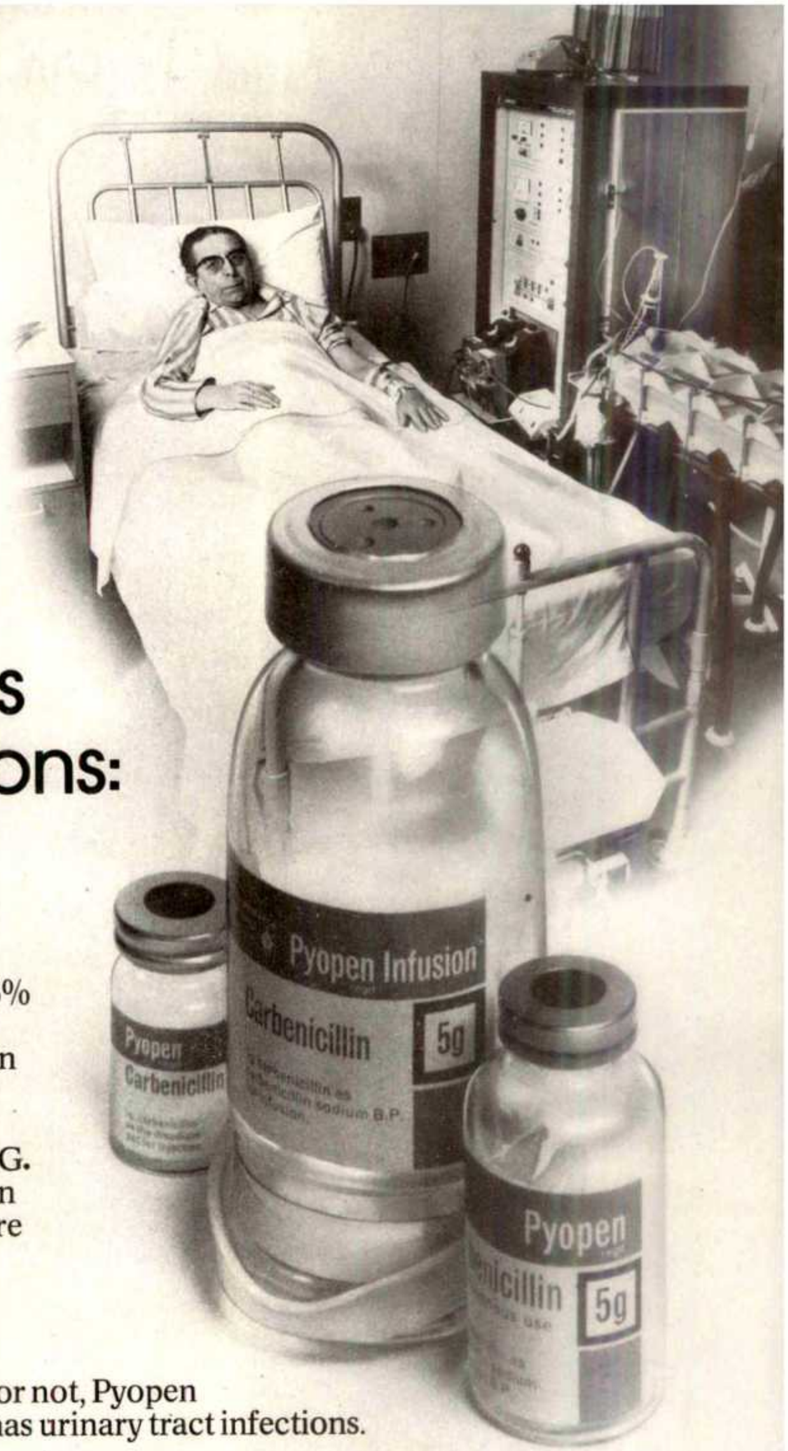
MONOFILAMENT POLYAMIDE 6

Considerably stronger than BPC requirements plus a smooth surface finish of very uniform diameter.

ETHICON*

SCOTLAND

Now, to simplify treatment of pseudomonas urinary infections:



Pyopen

Penicillin safety and a published 76% success rate in 543 patients of varying renal status confirm Pyopen as a simple solution to a difficult problem.

For patients with normal kidneys 5G. 6 hourly is easily given using Pyopen infusion. For patients in renal failure or with impaired renal function a simple dosage of 2G. 8 hourly, by infusion or into the dialysate, is often sufficient.

Whether the kidneys are impaired or not, Pyopen provides the answer in pseudomonas urinary tract infections.

Adult dosage: Chronic urinary tract infection: 5G. 4–6 hourly
Acute uncomplicated infections: 2G. 6 hourly
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen–by infusion or injection

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.

Surgical Gut

absorbable by nature
dependable by Ethicon*

When the need is for an absorbable suture ETHICON surgical gut is the natural choice.

The natural advantages of surgical gut are enhanced at Ethicon by the use of the most modern technology available.

The result is a suture of unsurpassed purity and uniformity upon which the surgeon can rely.

ETHICON*

RADIOTOM 619
for surgical diathermy

The *RADIOTOM 619 is a universal electrosurgical apparatus designed to meet all the clinical requirements of general surgery and the special requirements of neurosurgery.

The RADIOTOM 619 can be placed on a trolley. The small dimensions and the low weight of the unit also make it possible to mount it in a ceiling column, build it into a wall or to use it on a wall bracket or a floor column.

UBRETID®
distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of **UBRETID** ampoules and tablets are available upon request.

ORIGINAL PAPERS

URETEROCELE

By RICHARD E. SHAW
WALSGRAVE HOSPITAL, COVENTRY

SUMMARY

Ureterocele occurs more frequently in the female than in the male and may present at any age. The ectopic ureterocele must be distinguished from the orthotopic variety. Small ureteroceles are often symptomless, but larger ones may cause loin pain, retention of urine, and external prolapse. There is an increased incidence of duplication in cases of ureterocele. Attention is drawn to the significance of dilatation of the intramural ureter which leads to reflux after incision of a ureterocele.

Small symptomless ureteroceles need no treatment. Although perurethral diathermy incision may be followed by reflux there is a place for this treatment in adults. Large ureteroceles and those presenting in childhood should be treated by open excision employing a reflux-preventing technique.

Papers dealing with the subject of ureterocele have often failed to distinguish the ectopic ureterocele from the more common variety of the condition in which the ureter terminates in the bladder. The main feature of ectopic ureterocele is a cystic dilatation of the lower end of a ureter draining the upper component of a double kidney. The swelling bulges into the bladder or urethra or both, while the ureteric orifice is situated in the urethra. Careful study of the descriptions of cases of ureterocele in papers purporting to deal with the simple type often reveals examples of the ectopic variety, and renders suspect some of the conclusions reached about the features of the disorder. The ectopic ureterocele should be regarded as an entirely separate and distinct entity. Royle and Goodwin (1971) suggested that the non-ectopic variety should be distinguished by the name 'intravesical ureterocele', but this may lead to confusion as the ectopic type is also usually intravesical in part. The term 'orthotopic' has been employed in some recent papers to designate the non-ectopic ureterocele and this is a more acceptable word.

Ureterocele has been defined as 'an intravesical dilatation of the lower end of the ureter' (Aas, 1960). A ureterocele presents a striking appearance on cystoscopy. A typical example is seen as a cystic swelling in the position of a ureteric orifice. It has a thin wall and a translucent appearance. There is considerable variation in size from quite tiny cysts to large swellings occupying an appreciable part of the bladder capacity (*Fig.* 1). The orifice is most frequently situated on the antero-inferior surface and is circular and very small. The orifice of a large ureterocele may not be visible on cystoscopy. Frequently a ureterocele exhibits rhythmical activity, the cyst filling progressively with urine at each peristaltic wave, and then collapsing suddenly as a fine jet escapes from the orifice. The cycle then begins again. In these cases the observer may fail to recognize a ureterocele if the examination takes place during the phase of collapse, and the diagnosis may be missed, especially when cystoscopy is hurried or if the patient's fluid intake has been reduced prior to general anaesthesia. Other ureteroceles do not exhibit rhythmical change and maintain a constant appearance. An unusual event is sometimes observed: as the bladder fills with lotion the ureterocele suddenly becomes inverted, producing an appearance resembling that of a diverticulum. This can only happen when the intramural part of the ureter is considerably dilated. The author has observed this phenomenon following the incision of a ureterocele.

RADIOLOGICAL APPEARANCES

Ureteroceles show up extremely well on intravenous pyelography. The smaller ones have the well-known 'cobra-head' appearance (*Fig.* 2), but the large ones are more spherical in shape (*Fig.* 1). In either case the shape of the cyst is outlined by a thin dark line.

Some accounts describe a narrowing of the ureter as it passes through the bladder wall, but this is only relative to the dilatation of the remainder of the ureter, and in fact the intramural ureter is quite markedly dilated. This dilatation has an important bearing on the possibility of reflux after incision. The degree of obstruction to the upper urinary tract is usually minimal; moderate dilatation of the ureter, sometimes confined to its lower-third region, is the rule (*Fig.* 3). In a few cases a minor degree of hydronephrosis is present and large ureteroceles may be associated with quite marked ureteric dilatation (*Fig.* 1). Occasionally the contrast between gross dilatation of the lower ureter and the normal calibre of the upper ureter is remarkable. Mention should be made of a type of simple ureterocele which has an unusually thick wall. This ureterocele does not collapse on diathermy incision and is associated with severe obstruction to the upper urinary tract.

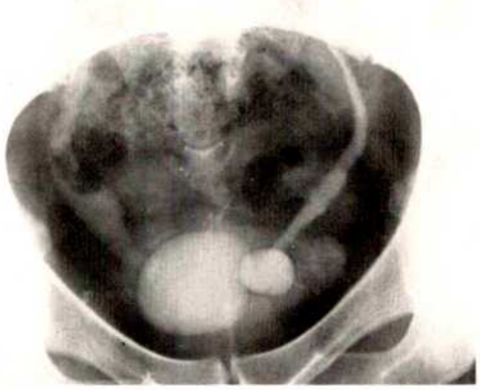

FIG. 1.—*Case* 1. Intravenous pyelogram showing large bilateral ureteroceles. The right-hand one caused retention by prolapsing into the internal meatus.

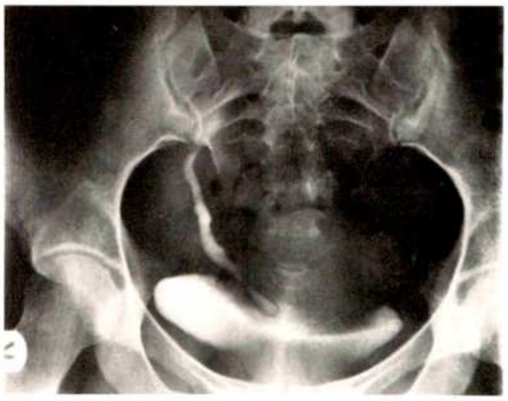

FIG. 2.—Intravenous pyelogram showing the typical 'cobra-head' appearance of a small ureterocele.

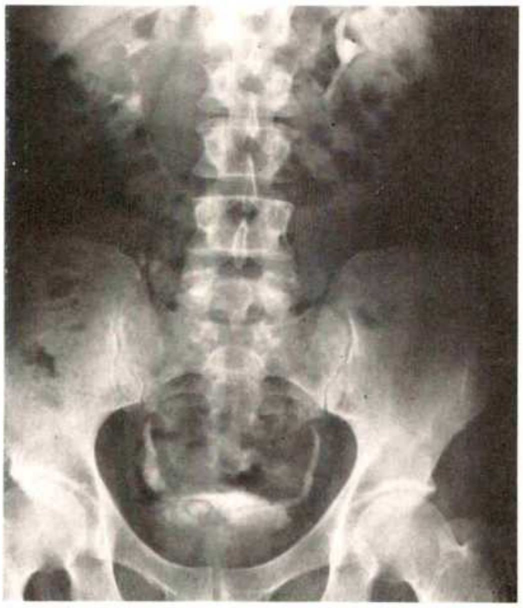

FIG. 3.—Intravenous pyelogram showing bilateral ureteroceles. The left ureterocele has a typical 'cobra-head' shape but the large right one is spherical. Note the minor degree of dilatation of the lower third region of each ureter.

The appearance of a ureterocele on pyelography is so typical that the question of differential diagnosis hardly arises. However, a stone impacted in the intramural part of the ureter can occasionally give rise to the appearance of a stone inside a ureterocele. This condition may, however, be distinguished by observing that the dark halo around the stone has a fuzzy, ill-defined character, which is quite unlike the clearly etched dark line of a ureterocele. Datta, Singh, and Bapna (1971) have recently drawn attention to the 'false ureterocele' associated with stones impacted in the intramural ureter.

MATERIAL AND METHODS

The material comprises 47 ureteroceles in 32 patients who have been seen personally in the past 20 years. Because of the destruction by fire of medical records in Coventry in 1967 the details are incomplete in 3 cases. Examples of ectopic ureterocele have, of course, been excluded.

Sex Incidence (*Table I*).—There is a predominance of females in this series, 60 per cent of the cases being female. This is precisely the sex incidence recorded by Aas (1960), whose series comprised adults only. On the other hand, Thompson and Kelalis (1964) found a female-to-male ratio of 4 : 1. Probably the predominance of females is less than these figures suggest, the relatively more frequent cystoscopy of women for minor urological symptoms yielding a number of cases of symptomless ureterocele.

Table I.—SEX INCIDENCE IN THE PRESENT SERIES

Sex	*No. of Cases*	*Percentage*
Male	12	37
Female	19	60
Not known	1	3
	32	100

Age (*Table II*).—The cases are evenly distributed between the age-groups, except that the oldest age-group is spared and only 2 cases were encountered over the age of 60 years. A similar even distribution of cases was found in the series described by Thompson and Kelalis (1964), and Aas (1960) reported similar findings.

Side affected (*Table III*).—Half the cases were bilateral and half unilateral. Among the unilateral cases the two sides were fairly equally represented. Thompson and Kelalis (1964) commented on the infrequency of bilateral cases among males in their series, only 4 bilateral male cases occurring in 176 patients. However, this has not been found in the present series, as 5 of the 15 bilateral cases were male.

Table II.—AGE DISTRIBUTION IN THE PRESENT SERIES

Age-group (yr.)	*No. of Cases*
0–9	4
10–19	3
20–29	4
30–39	4
40–49	7
50–59	4
60–69	2
70 plus	0
Unknown	4

Table III.—SIDE AFFECTED BY URETEROCELE IN THE PRESENT SERIES

Position	*No. of Cases*
Left	9
Right	6
Bilateral	15
Not known	2
	32

Table IV.—SYMPTOMS ASSOCIATED WITH URETEROCELE IN THE PRESENT SERIES

Symptom	*No. of Cases*
Haematuria	11
Dysuria	8
Frequency	8
Abdominal pain	7
Loin pain	5
Retention of urine	3
Backache	1
Prolapse through external meatus	2
Epididymitis	2

Symptoms (*Table IV*).—The commonest symptoms are those associated with urinary-tract infection, namely frequency, dysuria, and haematuria. Undoubtedly some cases of ureterocele are discovered as incidental findings during investigation of recurrent urinary symptoms, especially in female patients. It is difficult, therefore, to relate these symptoms to ureterocele. Loin pain, however, was significant in 5 patients and 7 others complained of unilateral abdominal pain which may well have been caused by the ureterocele. A similar pattern of symptomatology was reported by Thompson and Kelalis (1964). Large ureteroceles may be associated with more acute symptoms if the cyst prolapses into the urethra, causing retention of urine or even presentation of the ureterocele at the external urinary meatus.

Treatment of Ureterocele (*Table V*).—Eight ureteroceles received no treatment. Twenty-nine ureteroceles were incised by diathermy through a cystoscope. In 2 cases in which there was gross hydronephrosis and hydro-ureter, nephro-ureterectomy was performed, and in another case in which duplication was present, heminephro-ureterectomy was carried out. In 1 case open diathermy incision of bilateral ureteroceles was performed, and in 2 instances where the patients presented with a prolapsing ureterocele a transvesical operation was carried out to excise the ureterocele and to advance the ureter into the bladder through a mucosal tunnel.

Table V.—METHODS OF TREATMENT EMPLOYED FOR 47 URETEROCELES IN THE PRESENT SERIES

Method of Treatment	*No. of Ureteroceles*
Transurethral diathermy incision	29
Transvesical incision	2
Nephro-ureterectomy	2
Heminephro-ureterectomy	1
Open excision of ureterocele and reimplantation of ureter	3
No treatment	8
Not known	2
	47

Table VI.—RESULTS OF TREATMENT OF 16 URETEROCELES ASSESSED BY FOLLOW-UP INTRAVENOUS PYELOGRAPHY

Result	*No. of Cases*
No residual ureteric dilatation	11
Slight dilatation of ureter and/or calices	3
Moderate dilatation of ureter and/or calices	2
	16

Results of Treatment.—It is rather difficult to assess the symptomatic results of treatment since many cases are discovered incidentally and the ureterocele itself is often symptomless. Loin pain is the most frequent significant symptom and this is certainly relieved. Objectively, the pyelographic improvement is usually satisfactory. *Table VI* shows that out of 16 ureteroceles for which follow-up intravenous pyelograms were available, the dilatation of the ureter and calices which had previously been present had disappeared completely in 11 cases and there was only a minor degree of residual dilatation in 3 cases and moderate dilatation in 2. As would be expected, the latter group comprised those in which the initial obstruction had been greatest. No follow-up intravenous pyelogram showed evidence of persistence or recurrence of the ureterocele.

URETERIC REFLUX AND THE TREATMENT OF URETEROCELE

The presence of dilatation of the intramural part of the ureter which is seen so clearly on the intravenous pyelogram indicates the probability of reflux after incision of a ureterocele. Indeed, the cyst in most cases is probably the only protection which exists against the presence of reflux, and one would expect every case to reflux after incision of the cyst. In the present series postoperative micturating cystograms were carried out in respect of 17 ureteroceles and 5 were found to reflux. The examination was, however, made at varying periods after the incision had been carried out but never less than 1 year after treatment. It is possible that the dilated intramural ureter may contract so that reflux ceases spontaneously with the passage of time. Paradoxically it is feasible that some reflux does take place in the untreated ureterocele. Such a case has been described by Amar and Scheer (1964), and Royle and Goodwin (1971) also maintain that reflux does sometimes take place. This point never seems to have been satisfactorily clarified, but the orifice of the ureterocele is so small that it is unlikely that the degree of reflux can be of great significance; on the other hand, it may be quite marked after incision of the cyst.

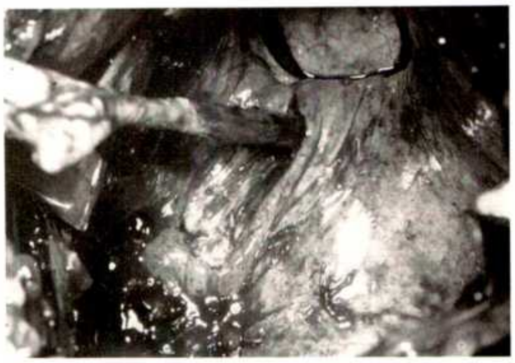

FIG. 4.—Open operation for a large ureterocele. A substantial length of ureter is easily mobilized. Note how the space left by the excised ureterocele leaves room for a long submucosal tunnel.

The likelihood of producing ureteric reflux should induce the surgeon to reconsider the treatment of ureterocele and to question whether any treatment is necessary in many cases. Although the results were satisfactory in 3 out of 4 children who were treated by perurethral diathermy incision in this series, a thoughtful surgeon would be reluctant to employ a procedure which induced reflux in a child. If surgical treatment is considered necessary in a child this should take the form of an open operation employing some reflux-preventing procedure. In adults the dangers associated with reflux are less, and it is questionable whether renal function is at risk in the absence of infection. Certainly, none of the present cases who had reflux after incision appeared to be adversely affected by it, and there was no evidence of any case suffering from declining renal function or recurrent infection. Therefore, in adults with symptoms such as loin pain caused by ureterocele simple perurethral diathermy incision would appear to be a satisfactory form of treatment. A small ureterocele causing minimal obstruction and no symptoms may be left untreated. There is no evidence that the obstruction to the upper urinary tract is progressive and complications such as stone formation are rare. Follow-up of untreated cases is advisable. Large ureteroceles are not suitable for perurethral diathermy and should undergo suprapubic excision, together with a reflux-preventing procedure by one of the techniques described below. Follow-up should include cystoscopy and it is surprising how normal the appearance of the ureteric orifice is after operation. Micturating cystography should also be carried out to determine whether or not reflux is present.

TECHNIQUE OF OPERATIONS FOR URETEROCELE

1. Perurethral Diathermy Incision.—Although the technique of diathermy incision of a ureterocele is simple the operation may miscarry if not performed correctly. A ureteric meatome is passed through the operating cystoscope and the wire is extruded and inserted into the small ureteric orifice. The cystoscope is inclined in order to place tension on the wire, and with the diathermy switched to full cutting current as for transurethral resection the pedal is touched momentarily. The wire cuts through the wall of the ureterocele which collapses at once. If the diathermy power is inadequate the tissue may be coagulated rather than cut, and it is much more difficult to repeat the incision when the cyst has collapsed. When the orifice is not accessible the cyst is punctured at a convenient point on its inferior surface. The cut should be some 3 mm. in length.

Alternative methods of treating the ureterocele include dilatation of the orifice with ureteric bougies, and simple puncture of the cyst with a diathermy needle, but there is a possibility of recurrence of the ureterocele with these forms of therapy.

2. Suprapubic Operation.—Large ureteroceles require a suprapubic approach. Simple incision of the cyst is not satisfactory. Reflux will result and there will also be a large amount of redundant cyst wall which may cause obstruction. Hutch and Chisholm (1966) have described an operation for the suprapubic repair of the condition. They stress the necessity of repairing the dilated hiatus if postoperative reflux is to be prevented. In their operation an incision is made around the base of the ureterocele after suprapubic exposure of the bladder cavity. The cyst is dissected off the bladder wall and the ureter is then mobilized and brought down into the bladder. One is surprised by the ease with which a substantial length of ureter is mobilized (*Fig.* 4). If the ureter is very dilated it may need to be 'tailored'. The ureterocele is excised, the hiatus is repaired, the end of the ureter is sewn to the trigone, and the vesical mucosa is repaired over the mobilized ureter. The author has carried out a similar procedure performed entirely intravesically on 3 ureteroceles in 2 patients and has found it to be a very easy and satisfactory operation. It is questionable whether repair of the hiatus is as important as Hutch and Chisholm (1966) claimed, since a long submucosal tunnel for the ureter is easily contrived and this should be more than adequate to prevent reflux. In the cases in the present series prevention of reflux has been confirmed by subsequent micturating cystography. Boatwright (1971) described an alternative operation in which a part of the wall of the ureterocele is retained for reconstructing the ureter, and a similar procedure was described by Mason (1971). All these techniques promise to be extremely satisfactory ways of carrying out open operation for ureterocele. Hutch and Chisholm (1966) maintained that small ureteroceles may be treated by a linear meatotomy performed on the surface of the cyst below the ureteric orifice, i.e., an inferior meatotomy. This cannot be done transurethrally and requires open operation. They maintain that this procedure guards against reflux, but it is difficult to believe that this operation has wide application.

COMPLICATIONS OF URETEROCELE

Calculus Formation.—Stasis caused by the ureterocele establishes conditions favourable for stone formation especially if infection supervenes. The well-known phenomenon of a stone within a ureterocele was not encountered in this series, but 3 patients had renal calculi and in 1 instance stones were also present in the dilated ureter. Aas (1960) reported an incidence of urinary calculi of 39 per cent in 52 patients with ureterocele. Possibly there was an element of selection in the cases of Aas (1960), for Lowsley and Kirwin (1956) give the frequency of renal calculi as 4 per cent, and this is certainly more in harmony with the present author's experience of the disorder.

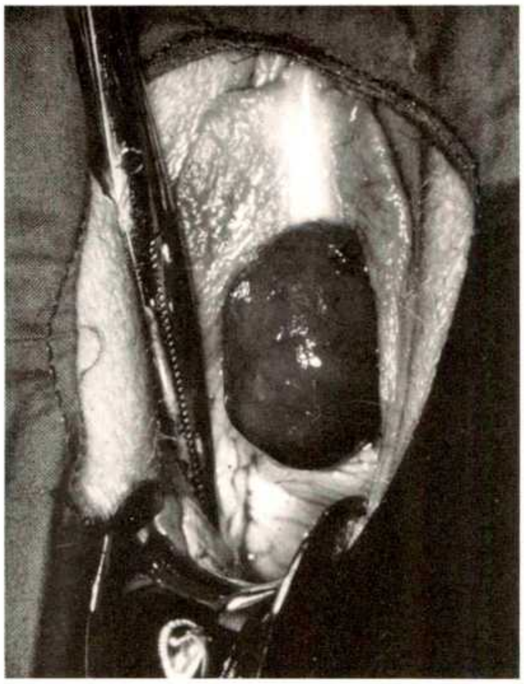

FIG. 5.—*Case* 2. Ureterocele prolapsing through the external urinary meatus. Note the drop of urine escaping from the ureteric orifice at the upper part of the swelling.

Retention of Urine.—A large ureterocele may prolapse into the internal urinary meatus and cause retention of urine, although this is often of a transient nature. Three examples were encountered in this series. Retention takes place in characteristic episodes in which the patient complains of pain in the loin which is immediately relieved on spontaneous termination of the retention.

CASE REPORT.—

Case 1.—A 45-year-old woman was admitted in February, 1964, with a 13-year history of periods of retention of urine which were always associated with pain in the right loin. She had learned by experience that if she walked about the retention would be relieved and followed by immediate disappearance of the loin pain. On the occasion of her admission this had failed and the retention and loin pain had persisted. The intravenous pyelogram (*Fig*. 1) showed large bilateral ureteroceles and it was clear that her symptoms were caused by prolapse of the right ureterocele into the internal urinary meatus. Both cysts were treated by diathermy incision through a cystoscope with permanent relief of symptoms. A second intravenous pyelogram in 1964 showed no evidence of ureterocele on either side and there was considerable reduction in the ureteric dilatation. A micturating cystogram demonstrated reflux on the right side but not on the left, and the patient has remained free of urinary symptoms up to the present time.

Prolapse.—Not only may a ureterocele fall into the internal meatus causing retention, but it may also pass through the urethra to prolapse at the external urinary meatus. Clearly this can only take place in the case of a large ureterocele in a patient of the female sex. This series includes 2 examples of prolapse of a ureterocele.

CASE REPORT.—

Case 2.—A 36-year-old woman was seen in March, 1970, with a 6-week history of cystitis. She had also observed that from time to time a lump presented in the vagina. Two weeks previously there had been considerable blood-loss from the vagina. Forty-eight hours prior to admission the vaginal swelling had returned and its presence had been accompanied by pain, frequency, and urgency. On examination the patient was in considerable distress, and a large red swelling was seen on the anterior vaginal wall with urine spurting from a tiny orifice (*Fig*. 5). The intravenous pyelogram (*Fig*. 6) which was carried out after reduction of the swelling demonstrated a right ureterocele with considerable ureteric dilatation. The patient was very anaemic, the haemoglobin being 8·2 g per cent. The ureterocele was gently pushed back into the bladder under anaesthesia and a balloon catheter was inserted to prevent recurrence of prolapse. Two days later, after correction of the anaemia by transfusion, operation was performed. By a transvesical approach the cyst was excised and the ureter was advanced under a submucosal tunnel, using a technique similar to that described by Hutch and Chisholm (1966). Cystoscopy 6 months later showed a right ureteric orifice of surprisingly normal appearance, and a micturating cystogram confirmed the absence of reflux.

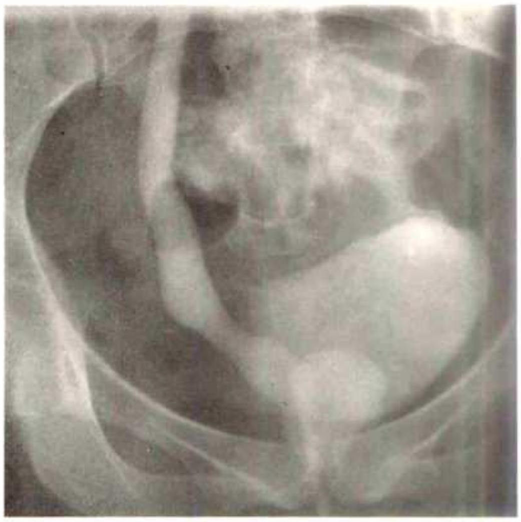

FIG. 6.—*Case* 2. Intravenous pyelogram showing a large ureterocele and a grossly distended ureter (a urethral catheter is in situ).

A striking feature of this case was the severe blood-loss which had taken place from the congested prolapsed cyst, and it is of interest that in a second case of prolapse of a ureterocele in a young woman the haemoglobin estimation on admission was moderately reduced owing to blood-loss from a semi-strangulated ureterocele.

URETEROCELE AND DUPLICATION

There is undoubtedly an increased incidence of renal duplication in cases of ureterocele. In this series of 47 ureteroceles, 4 (9 per cent) were associated with duplication. In 1 instance the two ureters united above the bladder, but the other 3 cases were examples of complete duplication, and in each instance the ureterocele was related to the ureter from the upper segment. This appears to be invariably the case. As in the case of ectopic ureteroceles the orifice of the ureter from the lower segment may be elevated on the surface of the ureterocele associated with the other ureter. Aas (1960), in his study of ureteroceles in adults, reported that of 16 patients with bilateral ureteroceles, none showed signs of renal duplication, but 38 per cent of 36 unilateral cases did so. However, study of his case reports shows that examples of ectopic ureterocele, in which duplication is invariable, are included. The confusion between ectopic and orthotopic ureteroceles is common to most papers, except the most recent, dealing with this subject, and the incidence of duplication has therefore been exaggerated. Indeed, reports of very high incidences of duplication should be examined critically to ensure that cases of ectopic ureterocele have not been included. Cases of orthotopic ureterocele associated with duplication should not be accepted as such unless the orifice has been definitely established as lying in the bladder and not in the urethra.

AETIOLOGY OF URETEROCELE

A number of theories have been advanced to explain the development of ureterocele and they are well summarized by Aas (1960) and will not be detailed here. It is likely that the cause of the condition lies in the minute size of the ureteric orifice; this obstructs the discharge of urine and results in dilatation of the ureter. That portion of the ureteric wall which is adjacent to the vesical mucosa is unsupported and distends to form a cystic swelling. It is equally probable that the small size of the ureteric orifice is a congenital anomaly which develops when the membrane covering the lower end of the ureter in early embryonic life fails to disappear completely. There is very little evidence that ureterocele ever develops as a secondary phenomenon following the passage of a calculus through the ureteric orifice or from other diseases affecting this structure. Although the prime cause of the condition is almost certainly developmental, a ureterocele may take many years to form and may not be fully developed until adult life. In 2 or 3 cases the author has observed at repeated cystoscopy the development of a ureterocele over a period of time. For example, a woman of 42 years had been seen at the age of 27 with urinary trouble, and cystoscopy by another urologist had shown nothing abnormal. The patient had been seen by the author 6 years later with similar troubles and cystoscopy at that time had also shown quite normal appearances. However, in 1970 a further examination revealed that a ureterocele was present on the left side which had certainly been absent on the previous occasions. In cases of unilateral ureterocele the opposite ureteric orifice is often smaller than normal.

Acknowledgements.—My thanks are due to Mr. J. R. Geddes and Mr. F. J. C. Matthews for referring patients with this condition; to Mr. H. D. James for the photographs; and to Mrs. J. Jenson for secretarial help.

AN EVALUATION OF THE STRENGTH OF THE POSTERIOR WALL OF THE INGUINAL CANAL IN WOMEN

By F. GLASSOW

SHOULDICE HOSPITAL, TORONTO, CANADA

SUMMARY

In the period 1945–71, 124 women with primary direct inguinal hernia were operated upon. During the same period indirect inguinal hernias in women were noted to be thirteen times more common than the direct type. The commonest site of protrusion of the direct hernia was immediately medial to the inferior epigastric artery. In contrast, in a series of 110 women with recurrent inguinal hernia the majority of the hernias were direct and, of these, most were either situated medially in the posterior wall of the inguinal canal or involved the whole posterior wall.

The significance of these findings in relation to the repair of femoral and inguinal hernias in women is discussed.

During the 26-year period from 1 Jan., 1945, to 1 Jan., 1971, approximately 70,000 hernia repairs were performed in the Shouldice Hospital, Toronto. Some 15,000 of these repairs were performed personally. In this period 1672 primary inguinal hernia repairs and 414 primary femoral hernia repairs were performed in women. Of the inguinal hernias, 1548 were indirect and only 124 were direct, so that in women primary indirect hernia was thirteen times more frequent than the primary direct type. This latter type of hernia, representing only 1 out of every 560 hernia admissions, is so rare that some surgeons may not have encountered a case.

The significance of the rarity of primary direct inguinal hernia in women does not appear to be widely known. It is obviously of importance when considering the most suitable type of operation for repair of a primary inguinal hernia in a woman. Indeed, a primary inguinal hernia in a woman is always best considered to be indirect in type until proved otherwise (Glassow, 1963). Less obviously the knowledge of the rarity of primary direct inguinal hernia is also important in deciding whether it is better to perform a primary *femoral* hernia repair in a woman from above or below the inguinal ligament.

As well as the 1672 primary inguinal hernia repairs 110 repairs in women were performed for recurrent inguinal hernia; 45 for indirect recurrences and 65 for direct recurrences. In every instance the original repair or repairs had been performed elsewhere. The personal experience gained from these recurrent hernia repairs was also important in the development and formulation of the opinions expressed in this article. No detailed discussion of primary direct inguinal hernia in women has been found in the surgical literature. It was therefore considered worth while to report the results of analysis of this series of 124 primary direct inguinal hernias in some detail in order to assess the essential characteristics of this type of hernia. Attention was focused in particular on the exact site in the posterior wall of the inguinal canal through which the direct hernia protruded.

ANALYSIS OF MATERIAL

From a review of the case records of women with primary inguinal hernia the following observations are considered significant.

Primary indirect inguinal hernia is common in women and primary direct inguinal hernia is uncommon. The posterior wall of the inguinal canal in a woman can be considered, therefore, to be typically a strong structure. Detailed examination of the case records of patients with direct inguinal hernia supports this conclusion (*Table I*). In particular, more than two-thirds of all such hernias were situated laterally, immediately medial to the inferior epigastric vessels. In only one-third of these cases, i.e., approximately 2 per cent of all the cases of primary inguinal hernia in women, was any other part of the posterior wall weakened by a direct hernia, and of these, the ones presenting far medially were the smallest and most uncommon. Furthermore, primary bilateral direct inguinal hernia in women is particularly rare (Glassow, 1969), only 9 cases being recorded in the present series. Ipsilateral primary direct inguinal and primary femoral hernia in a woman is also extremely rare, although it is common in men (Glassow, 1971).

DISCUSSION

The accumulated weight of these observations stresses the normal strength of the posterior wall of the inguinal canal in women. It is reasonable, therefore, to suggest that this structure should be left intact by the surgeon wherever possible. However, in all hernia repairs, whether inguinal or femoral, a decision in this respect has to be made.

Because the posterior wall of the inguinal canal is usually strong in women prophylactic repair of a primary indirect inguinal hernia is less important than in men, in whom this structure is often weak. In repair of the rare primary direct inguinal hernia in women it is necessary to divide the posterior wall, either partially or completely, in order to perform an adequate overlapping type of repair, as is used in the Shouldice Hospital, Toronto (Glassow, 1964, 1973).

Table I.—MAIN FEATURES OF 124 CASES OF PRIMARY DIRECT INGUINAL HERNIA IN WOMEN

	No.		PERCENTAGE	
No. of patients older than 50 years (average age 57 years)		79		63·7
Right side		70		56·5
Bilateral direct		9		7·3
Site of hernial protrusion through posterior wall of inguinal canal.—				
Just medial to inferior epigastric vessels (lateral one-half)		88		71·0
Sac excised	43		34·7	
Sac not excised	25		20·2	
Fatty only	20		16·1	
Through medial third of posterior wall of inguinal canal		17		13·7
Sac excised	7		5·5	
Sac not excised	0		0	
Fatty only	10		8·2	
Through centre of posterior wall of inguinal canal		7		5·5
Through all of posterior wall of inguinal canal		12		9·8
Associated with ipsilateral indirect inguinal hernia:—		30		24·5
Indirect sac	19		15·6	
Indirect fatty only	11		8·9	
Associated with ipsilateral femoral hernia		3		2·4
Associated with simultaneous contralateral hernia repair.—		25		20·2
Inguinal hernia on other side		21		17·0
Indirect	12		9·8	
Direct	9		7·2	
Femoral hernia on other side		4		3·2
Known recurrences following repair at Shouldice Hospital, Toronto		2		1·6

It is one of the purposes of this article, however, to stress these considerations with respect to the repair of a primary *femoral* hernia in a woman. The Lothiessen type of repair for a femoral hernia divides the posterior wall, thus necessitating a subsequent inguinal repair. In a subinguinal or low approach for the repair of a femoral hernia the posterior wall is completely avoided. On these grounds the subinguinal operation appears to have much to recommend it and indeed would seem preferable if the associated recurrence rate is low. The treatment and technique of repair of femoral hernia in the female based on the experience gained here are dealt with in detail elsewhere (Glassow, 1965, 1966). A recurrence rate of 1·3 per cent was achieved (Glassow, 1970a).

A brief consideration of the 110 instances of recurrent inguinal hernia repair in women is pertinent to this discussion. It is remarkable that recurrent indirect inguinal hernias in this series were two-thirds *less* common than direct inguinal hernia recurrences, although primary indirect hernias were thirteen times *more* common than the primary direct type. Because the original operations had been performed elsewhere, no records concerning the type of the original hernias and their repair were available. Hence the following arguments regarding the aetiology of the recurrences are only surmise. It is not easy, however, to avoid the conclusion that a number of the direct inguinal recurrences were the result of weakening caused by the previous repair of the posterior wall of the inguinal canal, which could have been either a Lothiessen repair for a femoral hernia or division of the posterior wall during repair of an inguinal hernia. Further weight is lent to this supposition by the fact that in 57 cases (88 per cent of these direct recurrences) the hernia was either situated far medially or protruded through all of the posterior wall, which are both uncommon sites for a *primary* direct inguinal hernia in a woman. In only 5 (8 per cent) of the cases was the direct recurrence found laterally, adjacent to the inferior epigastric vessels, which is the most typical site of the primary direct inguinal hernia (*Table I*).

All these observations support the experience gained here, namely that the low or subinguinal operation for a primary femoral hernia in a woman is a good operation attended by a low recurrence rate. Wakeley (1940), Tanner (1942), Butters (1948), Monro (1950), and Lytle (1957) have all made similar observations but they did not distinguish between the sexes. In women, therefore, the subinguinal approach is recommended as the operation of choice for an elective primary femoral herniorrhaphy. It follows that the main indication for the high or supra-inguinal operation in a woman who has a primary femoral hernia is the presence of a coincidental ipsilateral inguinal hernia. An earlier review has shown this combination to be relatively uncommon in women (Glassow, 1965). When an inguinal element is present it is almost invariably indirect in nature. Indeed, the risk of missing an undiagnosed ipsilateral inguinal hernia during a low repair of a primary femoral hernia in a woman, by not exploring the inguinal region, was estimated to be of the order of 1 per cent (Glassow, 1965, 1970b).

It must be emphasized that these remarks do not apply to the treatment of primary femoral hernia in men. This condition has been separately reviewed (Glassow, 1971) in a series of 687 consecutive repairs performed in the Shouldice Hospital, Toronto, in a 25-year period. Of these, no less than 355 (53 per cent) were associated with an ipsilateral inguinal hernia, this hernia being twice as frequently direct as indirect. This is in marked contrast to the situation in women described in detail in this paper. It is an important differentiating feature in any consideration of the aetiology of primary and recurrent femoral hernias in the two sexes. In some of the cases of combined ipsilateral inguinal and femoral hernias in men the diagnosis of the inguinal element was made clinically, but in many it was only discovered at operation. In men, therefore, in contradistinction to women, it is usually necessary to explore the inguinal region during the repair of a primary femoral hernia, even though the subsequent femoral repair is usually performed from below the inguinal ligament. It is not surprising, therefore, that the recurrence rate for repair of primary femoral hernia in men is higher than that in women, being 2·2 per cent in the series of Glassow (1971).

CONCLUSION

A series of 70,000 herniorrhaphies, including a personal experience of 15,000, in a 26-year period from 1945 to 1970 forms the background for the ideas presented here. During this time operations for 1672 primary inguinal hernias and 414 primary femoral hernias in women were performed. These cases form the basis for this study.

The posterior wall of the inguinal canal in women is demonstrably strong in most instances. Evidence is adduced from an experience of 1548 primary indirect inguinal hernias and 124 primary direct inguinal hernias in women, indicating that this latter condition is relatively rare. The usual site for a direct hernia is immediately medial to the inferior epigastric vessels. Other situations are more rare. Further evidence to support the fact that the posterior wall of the inguinal canal is a typically strong structure is given, including a brief discussion of the aetiology of recurrent inguinal hernia in women. Treatment of primary indirect and direct inguinal hernias in women should recognize this fact.

In women repair of a primary femoral hernia can be very satisfactorily performed from below the inguinal ligament, with a recurrence rate of between 1 and 2 per cent. This route avoids division of the posterior wall of the inguinal canal, as in the 'high' operation.

In men, because a primary femoral hernia is accompanied by an ipsilateral inguinal hernia in more than 50 per cent of cases, these considerations do not apply.

THE MANAGEMENT OF VARICOSE VEINS

By JOHN SEDDON

WARRINGTON INFIRMARY, LANCASHIRE

SUMMARY

A clinical trial was carried out to compare the effectiveness of compressive sclerotherapy with that of the traditional operative procedures in the treatment of varicose veins. One hundred and ten patients were treated by compression sclerotherapy and 91 patients by operation.

The results showed that there was no significant difference in the therapeutic value of the two procedures.

DURING recent years the technique of injection therapy for the treatment of varicose veins and their complications has been revised and extended. A major contributor to this therapy has been Fegan (1967) of Dublin and the term 'compressive sclerotherapy' has been applied to this non-operative form of treatment.

Compressive sclerotherapy is based on the concept that all varices are due to incompetence of the perforating veins connecting the deep and superficial venous systems. As a consequence the venous blood-flow is reversed during muscular contraction, resulting in a greatly increased pressure in the superficial veins with eventual varicosity. If the blood-flow in the incompetent perforating veins can be interrupted, then the progression to varicosity can be halted and reversal to normality hoped for. This can be achieved by ligation and division of the perforating veins, by the traditional Trendelenburg and stripping procedure, and thirdly by obliterating the T-junction of the perforating veins with the superficial veins, using a sclerosant, and subsequently applying continuous pressure to keep the treated veins empty and to produce adhesions of the walls and eventual fibrosis. The concept of valvular incompetence at the saphenofemoral and/or saphenopopliteal junctions is still valid but whether this is primary or secondary in nature is still unknown. It is claimed that using compressive sclerotherapy results in a considerable diminution of saphenofemoral incompetence which tends to support the concept of perforator incompetence.

Several previous studies concerning the value of compressive sclerotherapy have already been published. Fegan (1967) found that 81·8 per cent of patients were satisfied with the treatment and considered themselves cured. De Jode (1970) obtained good results in 83 per cent of 201 legs. However, in that series patients with major saphenous incompetence were treated by operation and thus a degree of selection was evident. A random trial carried out by Hobbs (1968) suggested that incompetence of the saphenous system was effectively treated by either method. In an evaluation of treatment by compressive sclerotherapy Reid and Rothnie (1968) found it to be an effective method but used multiple injections of varicose veins to produce a diffuse sclerosis.

MATERIALS AND METHODS

Like many hospitals there was a large waiting list for patients requiring operative treatment for varicose veins at the Warrington Infirmary, and 4 years ago it was decided that it would be an interesting study to compare the results of the traditional operative procedures with the non-operative method of treatment. Owing to the extremely variable pathology and clinical presentation of varicose veins it was decided to restrict this study to patients in whom operation would usually have been the recommended treatment, i.e., all the patients who had demonstrable incompetence of the saphenous systems and/or venous ulceration due to posterior tibial perforator incompetence.

Table I.—TYPE OF TREATMENT IN 201 PATIENTS WITH VARICOSE VEINS

Treatment	*No. of Legs*	
Compressive therapy		149
Complicated by ulceration	15	
Operation		125
Complicated by ulceration	5	
Total		274

Table II.—AGE DISTRIBUTION OF 201 PATIENTS WITH VARICOSE VEINS

Age-group (yr.)	*Percentage of Patients* *Compressive Sclerotherapy*	*Operation*
10–19	0	1
20–29	12	9
30–39	33	34
40–49	29	32
50–59	13	20
60–69	8	4
70–79	5	0

Accordingly, 201 patients were studied during the years 1967 to 1968 and those offered operative treatment were alternated with those offered compressive sclerotherapy. As a result, 110 patients (149 legs) were treated by compressive sclerotherapy and 91 patients (125 legs) underwent the traditional operative procedure. In 15 of the 110 patients who had compressive sclerotherapy the varicose veins were complicated by ulceration; ulceration was present in 5 of the 91 patients who underwent operation (*Table I*). The age distribution of both groups of patients was also studied and two-thirds of the cases were in the 30–50 age-group (*Table II*).

Operative treatment consisted of the usual Trendelenburg procedure, namely ligation and division of the saphenous vein at the saphenofemoral junction and also ligation and division of the groin tributaries and stripping of the saphenous vein, or multiple ligations if this was not possible. Subfascial ligation and division of the perforator veins were carried out in cases of ulceration, after healing had been achieved, by the use of compressive bandages or admission to hospital if necessary.

With regard to compressive sclerotherapy, the technique was more or less similar to that described by Fegan (1967). The perforator veins were detected by palpation and marked out. They were then injected with the leg elevated so that the vein was completely emptied. A compressive bandage was then applied and an elastic stocking supplied. The injected substance was sodium tetradecyl sulphate and the patients were seen at intervals of 3 weeks until treatment was regarded as complete. The treatment was carried out by consultant surgeons.

RESULTS

The follow-up period extended from 12 to 18 months and all the patients had completed their treatment at least 12 months prior to inclusion in this study. The results were assessed by another consultant surgeon as well as by the author.

Table III.—RESULTS OF COMPRESSIVE SCLEROTHERAPY FOR VARICOSE VEINS

Result	*No. of Cases*
Residual varices	19
Recurrence	7
Failure of technique	3
Recurrent ulceration	2

Compressive Sclerotherapy (*Table III*).—Residual varices were considered to be present in 19 legs (13 per cent). However, 'residual varices' is a term that is difficult to apply to this form of treatment, for it usually means that the treatment has not been completed. However, when wearing of the compression bandages was discontinued, as indicated by the apparent completion of treatment, a trial period of wearing an elastic support only was instituted. If at the end of this time varices were present they were regarded as residual.

Varices which had been treated with apparent success recurred in 7 legs. They were reinjected with a satisfactory result. The technique failed completely in 3 legs as the sclerosant did not appear to have any effect, and all these cases had to be treated by operation. Recurrent ulceration occurred in 2 legs; 1 case was reinjected with satisfactory results, while the second patient had a further recurrence, and subsequent venographic studies showed him to have an obliterated femoral vein. This was probably the result of a deep femoral venous thrombosis which he had had 10 years previously.

Operative Treatment (*Table IV*).—Residual varices were present in 20 legs of those treated by operation and they were all re-treated successfully by local injections. Recurrent varices occurred in 5 legs and again these were re-treated by injection therapy. There was no case of recurrent ulceration.

COMPLICATIONS

Compressive Sclerotherapy (*Table V*).—Thrombophlebitis occurred in 5 patients. It was usually quite localized but in 1 patient it extended in the internal saphenous vein almost to the saphenofemoral junction and she required admission to hospital. The other patients were treated by bandaging only and remained mobile. There was no case of deep venous thrombosis or pulmonary embolism.

One of the recognized complications of compressive sclerotherapy is an injection ulcer and it is usually due either to extravenous injection or more commonly to leakage of the sclerosant fluid outside the vein wall. It is more liable to occur when veins lying close to bone are injected. An injection ulcer occurred in 1 patient in this series.

Table IV.—RESULTS OF OPERATION FOR VARICOSE VEINS

Result	*No. of Cases*
Residual varices	20
Recurrent varices	5
Recurrent ulceration	0

Table V.—COMPLICATIONS OF COMPRESSIVE SCLEROTHERAPY FOR VARICOSE VEINS

Complication		*No. of Cases*
Thrombophlebitis*		5
Injection ulcer		1
Sensitivity to sodium tetradecyl sulphate		3
Eczema—generalized	1	
Eczema—localized	1	
Persistent nausea following injections	1	

* One case required admission to hospital.

Table VI.—COMPLICATIONS OF OPERATION FOR VARICOSE VEINS

Complicated	*No. of Cases*
Wound sepsis	1
Secondary haemorrhage	1
Deep venous thrombosis with pulmonary embolism	1

Sensitivity to sodium tetradecyl sulphate is regarded as rare. It occurred in 3 patients in this series. In the first case there was a generalized eczema. The eczema was localized in the second patient, and in the third patient there was persistent nausea following the injections and these were discontinued and operation was performed.

Operative Treatment (*Table VI*).—Wound sepsis is always a possible complication, particularly when operating in the groin, and this occurred in 1 patient. Secondary haemorrhage is unusual and is usually associated with sepsis; this complication occurred in 1 patient. A third patient developed a deep venous thrombosis in the operated leg with a subsequent pulmonary embolism. Anticoagulant therapy was carried out with a successful outcome.

DISCUSSION

The Advantages and Disadvantages of Each Procedure.—Compressive sclerotherapy has many advantages. All the patients can be treated in an out-patients' department, they are fully mobile, and treatment does not interfere with their daily occupation. The results to date are equal to those obtained by operation but compressive sclerotherapy avoids the necessity for anaesthesia. There is no apparent danger of pulmonary embolism and the cost is very much smaller. One can also treat large numbers of patients and there is no doubt that the waiting list in our particular hospital has been drastically reduced.

There are a number of disadvantages of compression sclerotherapy:—

1. Wearing bandages for several weeks is disliked by some patients. They find the bandages extremely

inconvenient and, of course, unless they are put on carefully they are liable to slip down and redressings are required.

2. Patients have difficulty in washing and bathing, but many patients have found ingenious ways of overcoming this by the use of plastic bags and leg supports.

Table VII.—COMPARISON OF THE RESULTS OF COMPRESSION SCLEROTHERAPY WITH THOSE OF OPERATION FOR VARICOSE VEINS

RESULT	COMPRESSION SCLEROTHERAPY	OPERATION	TOTAL NO. OF CASES
Recurrent varices	7	5	12
Residual varices	19	20	39
Recurrent ulcer	2	0	2
Failure of technique	3	0	3
Satisfactory	118	100	218
Total	149	125	274

$\chi^2 = 2{\cdot}3333$; $P < 0{\cdot}50$. There is thus no significant difference between the two procedures.

3. Owing to the possible slight incidence in venous thrombosis associated with the contraceptive pill, this has to be discontinued during the period of treatment.

The advantages of operation are that treatment is completed in a much shorter time. However, there are the obvious disadvantages of having to be hospitalized for a certain period of time and requiring several weeks off work.

CONCLUSIONS

The statistics presented in this paper (*Table VII*) suggest that the end results of both methods of treatment are largely the same, and that the method of compressive sclerotherapy probably achieves a success rate equal to that of surgery. Complications of compressive sclerotherapy are few and no less acceptable than those of surgery. However, failures do occur for several reasons and surgery may well be required for cure. Thus, surgery continues to have an essential part in the management of varicose veins, although there is no doubt that compressive sclerotherapy is a very valuable adjunct.

Acknowledgements.—I am indebted to Professor Fegan who accorded me the privilege of visiting his clinic and observing the technique, and to the United Liverpool Hospitals for financial support for this study. I wish to express my appreciation to Mr. Donald Young, Consultant Surgeon, Warrington Infirmary, who assisted me in this study and also to the nursing staff of the Infirmary and Dispensary, Warrington.

THE VALUE OF PLASMA GAMMA-GLUTAMYL TRANSPEPTIDASE IN THE DETECTION OF HEPATIC METASTASES

BY T. T. IRVIN, J. P. EDWARDS, AND J. C. GOLIGHER
DEPARTMENT OF SURGERY, UNIVERSITY OF LEEDS

SUMMARY

It has been suggested that measurement of the plasma enzyme gamma-glutamyl transpeptidase (GGTP) may be useful in the detection of hepatic metastases.

To assess the value of GGTP as a screening test for hepatic metastases, 40 cases of gastro-intestinal carcinoma were studied prior to surgery.

Ten patients had hepatic metastases, and in 5 of these the plasma GGTP was within normal limits. Abnormal GGTP results were always associated with elevation of the plasma alkaline phosphatase, and preoperative clinical examination of the liver proved to be the most accurate method for the detection of hepatic metastases.

A SMALL proportion of patients who develop recurrent or metastatic disease after surgery for gastro-intestinal cancer may be salvaged by further surgery (Gilbertsen and Wangensteen, 1962; Friesen, Hardin, and Kittle, 1967). It appears that a cure may be possible even in patients who present with hepatic metastases when these are suitable for surgical extirpation (Foster, 1970).

Early detection of recurrent disease is clearly important if further surgery is to be curative but detection of hepatic metastases may be difficult. Radio-isotope scans of the liver and angiography are useful diagnostic aids but are quite impracticable for all the patients routinely attending the follow-up clinic. Aronsen, Nosslin, and Pihl (1970), however, have reported a high degree of accuracy in the detection of hepatic metastases by measurement of the enzyme gamma-glutamyl transpeptidase (GGTP) in serum.

The present study was designed to determine the value of GGTP as a screening test for the detection of hepatic metastases in cases of gastro-intestinal cancer.

MATERIAL AND METHODS

All the cases of carcinoma of the stomach, colon, or rectum who were admitted to the Professorial Surgical Unit, Leeds General Infirmary, over a period of 5 months were studied. There were 31 cases of colonic or rectal carcinoma (17 male and 14 female) and 9 cases of gastric carcinoma (5 male and 4 female). Sixteen control patients (14 male and 2 female) were also studied. These were patients who had been referred to the Out-patients' Department with a diagnosis of groin hernia or varicose veins.

No patient had a history of liver disease, jaundice, or alcoholism and in each case it was ascertained that the patient was not receiving barbiturates or anticonvulsant drugs which might result in elevation of the plasma GGTP (Rosalki, Tarlow, and Rau, 1971).

Table I.—Results of Liver-function Tests (Mean ± S.D.) in Control Patients and in Patients with Gastro-intestinal Carcinoma with or without Hepatic Metastases

	Control Group (16 Cases)	Patients with Gastro-intestinal Carcinoma	
		No Hepatic Metastases (30 Cases)	Hepatic Metastases (10 Cases)
Age (yr.)	50±16	64±6	63±11
SGOT (I.U per litre)	15±5	12±4	27±20
SGPT (I.U. per litre)	11±5	8±3	20±16
Alkaline phosphatase (K.A. units per 100 ml)	8±1	8±2	22±18
Total protein (g. per 100 ml.)	7·5±0 6	7 1±0 6	7 3±0 5
Albumin (g. per 100 ml.)	4 3±0 3	3 8±0 4	3 8±0 4
Globulin (g. per 100 ml.)	3 2±0 6	3 3±0 5	3 5±0 5
Bilirubin (mg. per 100 ml.)	0·5±0·2	0 4±0 2	0 6±0·3
GGTP (I.U. per litre)	20±11	15±10	95±114

Plasma GGTP was measured by the method of Naftalin, Sexton, Whitaker, and Tracey (1969) and compared with the results of routine liver-function tests in all the cases. Glutamic oxalo-acetic transaminase (SGOT) and glutamic pyruvic transaminase (SGPT) were estimated on an LKB reaction rate analyser using Boehringer Corporation (UV) test combinations. Plasma alkaline phosphatase was determined by the method of Axelsson, Ekman, and Knutsson (1965), and bilirubin by the method of Simmons (1968). Total plasma proteins were determined by the biuret method (Technicon method sheet AA 11, No. 14), and plasma albumin by the method of Northam and Widdowson (1967).

The findings on preoperative clinical examination of the liver by one or other of two house-surgeons were recorded in all the cases of gastro-intestinal carcinoma and correlated with the subsequent laboratory results and information obtained at laparotomy. At operation the liver was systematically and thoroughly examined for evidence of metastases.

RESULTS

Control Cases.—The results of the liver-function tests in the control cases are shown in *Table I*. The mean age of the 16 patients in this group was 50 years (S.D. ± 16). The routine

Table II.—Correlation between GGTP Results, the Results of Routine Liver-function Tests, and Findings on Preoperative Clinical Examination in Patients with Hepatic Metastases

Case No	Age and Sex	SGOT (I.U per litre)	SGPT (I U. per litre)	Alkaline Phosphatase (K.A units per 100 ml.)	Total Protein (g. per 100 ml)	Albumin (g per 100 ml)	Globulin (g. per 100 ml.)	Bilirubin (mg. per 100 ml)	GGTP (I.U. per litre)	Primary	Hepatomegaly on Preoperative Examination	Findings at Laparotomy
1	54 F.	7	5	9	6 7	2 9	3 8	0 2	23	Colon	Yes	Metastases right lobe of liver
2	59 F	60	41	44	7 3	3 6	3 7	0 8	321	Colon	Yes	Metastases both lobes of liver
3	75 M.	60	50	63	6 8	3 9	2 9	0 6	311	Colon	Yes	Metastases both lobes of liver
4	67 M.	22	14	24	7 5	4·4	3 1	0 6	98	Rectum	Yes	Metastases both lobes of liver
5	62 F.	37	41	11	7 6	4 0	3 6	0 3	28	Rectum	Yes	Metastases both lobes of liver
6	59 F.	36	16	31	8 3	3 9	4 4	0 7	75	Colon	Yes	Metastases both lobes of liver
7	67 M	13	10	6	6 9	4·0	2 9	0·7	10	Colon	Yes	Metastases both lobes of liver
8	65 F.	13	8	11	6 9	4 0	2 9	0 2	33	Rectum	Yes	Metastases both lobes of liver
9	58 M.	7	8	6	6 8	3 6	3 2	1 0	5	Stomach	No	Metastases left lobe of liver
10	69 M.	12	7	16	7 9	3 7	4 2	0 9	48	Stomach	Yes	Metastases right lobe of liver

liver-function tests were within normal limits in each case and the mean value for plasma GGTP was 20 I.U. per litre (S.D. ± 11) with a range of 5–34 I.U. per litre. No correlation was found between the age of the patient and GGTP results.

Cancer Cases without Hepatic Metastases.—Thirty of the 40 patients with gastro-intestinal carcinoma had no evidence of hepatic metastases at laparotomy. The mean age of these 30 patients was 64 years (S.D. ± 6) and the results of the liver-function tests are shown in *Table I*. Plasma GGTP was within the control range in all the cases, as were the other liver-function tests with the exception of the plasma proteins. The mean plasma albumin in this group was significantly lower than the value obtained in the control group ($t = 4{\cdot}779$; $P < 0{\cdot}001$), and in 3 patients with carcinoma the albumin : globulin ratio was reversed. In 3 cases, all with normal liver-function tests, hepatic enlargement was recorded on preoperative clinical examination but no abnormality was found on examination of the liver at laparotomy.

Cancer Cases with Hepatic Metastases.—Ten of the 40 patients with gastro-intestinal carcinoma had hepatic metastases at operation. The mean age of the patients in this group was 63 years (S.D. ± 11) and the mean values for the liver-function tests are shown in *Table I*. In *Table II* the individual liver-function tests are correlated with the findings on preoperative clinical examination and at laparotomy. Plasma GGTP was significantly elevated in 5 patients (*Cases* 2, 3, 4, 6, and 10), all of whom had hepatic enlargement on preoperative examination and abnormal plasma alkaline phosphatase results. In 3 of these cases (*Cases* 2, 6, and 10) there was reversal of the albumin : globulin ratio, and the transaminases were significantly raised in 3 cases (*Cases* 2, 3, and 6).

In 5 patients the plasma GGTP was within the control range despite the presence of hepatic metastases and preoperative evidence of hepatic enlargement in 4 of the 5 cases. The plasma alkaline phosphatase was also normal in all 5 cases, but in 1 patient (*Case* 5) the SGOT was abnormal and in another case (*Case* 1) the albumin : globulin ratio was reversed.

DISCUSSION

Szczeklik, Orlowski, and Szewczuk (1961) reported very high serum GGTP levels in 7 patients with metastatic liver disease, and in some of these cases abnormal GGTP results were obtained before there was any disturbance in the routine liver-function tests. Rutenburg, Goldbarg, and Pineda (1963) obtained abnormal values for GGTP in 59 of 65 patients with hepatic metastases, and 35 per cent of the patients with abnormal GGTP results had a normal serum alkaline phosphatase. Again, Kokot, Kuska, Grzybek, and Cekanski (1965) found that the serum GGTP was significantly elevated in 89 per cent of anicteric patients with metastatic liver disease, and Aronsen and others (1970) obtained the same degree of accuracy for this test in the diagnosis of liver metastases in 51 anicteric patients. It was also noted in the latter study that the serum alkaline phosphatase was a less reliable test than GGTP for the detection of liver tumour and it was concluded that GGTP would be a useful test for the screening of patients for hepatic metastases.

In the present study plasma GGTP results were abnormal in only 50 per cent of the patients with hepatic metastases, and in each of these cases the plasma alkaline phosphatase was also abnormal. In the remaining cases with liver metastases both enzymes were within the normal range. It is difficult to account for the difference between these results and the results of previous studies, but it cannot be explained by the fact that plasma GGTP was measured in the present study whereas serum GGTP was measured in the previous studies. We have found no difference between the results of GGTP measured in plasma and serum in control subjects (Edwards, 1971), and our results are in agreement with those of Rosalki, Rau, Lehmann, and Prentice (1970).

Preoperative clinical examination detected 90 per cent of the cases with hepatic metastases and a false-positive clinical diagnosis was made in 10 per cent of cases. However, we have not produced evidence that clinical examination alone is of practical value as a screening test for hepatic metastases as only 1 of the cases in the present study was suitable for liver resection and this was the only case which was not detected on preoperative clinical examination.

It appears that determination of the plasma GGTP is unlikely to surpass any of the conventional liver-function tests in the detection of hepatic metastases. Our results are in accord with those recently described by Baden, Andersen, Augustenborg, and Hanel (1971). In the latter study more than 50 per cent of the patients with hepatic metastases from gastro-intestinal carcinoma had normal serum GGTP results and GGTP was not more accurate than alkaline phosphatase in the detection of liver tumour.

INTRAPERITONEAL NOXYTIOLIN AS AN EXPERIMENTAL CHEMOTHERAPEUTIC AGENT

By S. DESAI and C. W. JAMIESON
SURGICAL UNIT, ST MARY'S HOSPITAL, LONDON

SUMMARY

The effect of intraperitoneal noxytiolin on the growth of Ehrlich's ascites tumour in mice has been studied. A dose of 1 g. per kg. body-weight produced a significant slowing of the growth of ascites tumours. However, systemic administration (subcutaneous) had no significant chemotherapeutic effect in this tumour model.

NOXYTIOLIN (Noxyflex) is a simple compound of low toxicity on systemic administration and has been found to have a wide bacteriostatic effect *in vitro* and some antifungal and antiprotozoal activity (Block, 1967; Horsfield, 1967; Ross, 1967). It has been thought to be of value in reducing the mortality of faecal peritonitis when instilled into the peritoneum (Browne and Stoller, 1970), and its use as a local adjuvant in the treatment of patients with vesical carcinoma by supervoltage has been claimed to improve the prognosis (Garrett, 1969). The fate of noxytiolin *in vivo* and its exact mode of action is not known, but it is possible that it acts simply by release of formaldehyde. In a previous communication (Jamieson, 1972) the effect of noxytiolin on the viability of human tumour cells (HeLa) in monolayer culture was studied and it was shown that concentrations of more than 0·0025 per cent caused significant inhibition of the growth of tumour cells in culture.

MATERIALS AND METHODS

Mice.—Male mice of strain BALB/c, weighing between 13 and 20 g., were obtained from the breeding colonies of Animal Suppliers (London) Ltd.

Tumour Cells.—Ehrlich's ascites (E.A.) tumour-cell line was obtained from Dr. T. A. Connors of the Chester Beatty Research Institute, London, and maintained by serial transplantation. The tumour cells were harvested under full aseptic conditions and suspended in TC 199 medium (Wellcome Reagents Ltd.; Morgan, Morton, and Parker, 1950). Cell counts were made using a Model B Coulter Counter. The viability of cells was determined by the ability of live cells to exclude trypan blue; 1 ml. of cell suspension was mixed with 0·5 ml. of 1 per cent trypan blue and incubated for 20 minutes at 37° C. Cells excluding trypan blue and those taking up the dye were counted in a haemocytometer chamber, and the results were expressed as a percentage of cells excluding dye. The average viability during each set of experiments was 85–90 per cent.

The tumour cells were inoculated intraperitoneally in each experiment. The growth rate of the tumour was measured by daily weighings of the animals, and the duration of the survival of the animals after the inoculation of E.A. cells was noted.

In a preliminary experiment (experiment I) groups of 12 mice were inoculated with 1×10^4, 1×10^5, 1×10^6, and 5×10^6 E.A. cells suspended in 0·25 ml. of TC 199 medium to determine the effect of varying cell dosage on the rate of tumour growth and survival (*Fig.* 1). Doses of 5×10^6 and 1×10^6 produced rapid growth of tumours, making it necessary to sacrifice the mice at 18 days. Mice receiving 1×10^4 cells continued to live for more than 30 days but exhibited inconsistent takes of tumours, whereas 1×10^5 cells produced consistent takes and satisfactory growths of tumours, and therefore in all subsequent experiments the dosage of 1×10^5 E.A. cells was used.

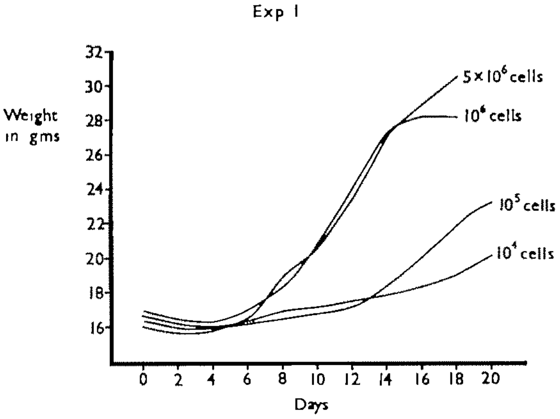

FIG. 1.—The effect of varying cell dosage on the rate of growth of Ehrlich's ascites tumour in BALB/c mice.

Noxytiolin Preparation.—This drug was obtained in its pure form and was stored at 5° C. Fresh solutions of the required concentration were made up for each experiment in TC 199 medium and were sterilized by filtration.

The L.D.$_{50}$ dose of noxytiolin for intraperitoneal administration has been shown to be 1650 mg. per kg. body-weight for mice (Consultox Laboratories Ltd., London, 1965). In the present study to test the toxicity of noxytiolin a group of 10 BALB/c mice was given 15 mg. of noxytiolin (1 g. per kg. average body-weight) intraperitoneally and the dose was repeated 7 days later; a control group was given sham injections of the TC 199 medium on the same days. This amount of noxytiolin had no apparent deleterious effects and experimental animals showed no difference in weight-gain or vitality from the control group up to 30 days of the experiment.

Experimental Protocol to study the Chemotherapeutic Effect of Noxytiolin.—In experiments II and III two groups of 10 BALB/c mice, having received intraperitoneal inoculations of

1×10^5 E.A. cells, were given intraperitoneal injections of 15 mg. of noxytiolin on the first and seventh days after the inoculation of 1×10^5 E.A. cells. For each experimental group there was a control group of 10 mice which received an intraperitoneal inoculation of 1×10^5 E.A. cells and sham injections of TC 199 medium on the first and seventh days after inoculation.

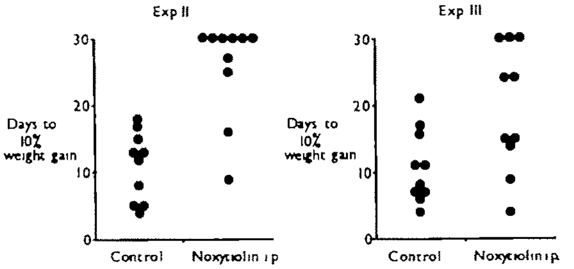

FIG. 2.—The effect of intraperitoneal noxytiolin (1 g. per kg.) on the rate of growth of Ehrlich's ascites tumour (1×10^5 cells) in BALB/c mice.

In experiments IV and V the same doses of noxytiolin were administered subcutaneously on the first and seventh days after the intraperitoneal inoculation with 1×10^5 E.A. cells. A control group of mice received tumour cells intraperitoneally and TC 199 medium subcutaneously on the same days.

Finally, the experiments were repeated using a lower dose of 5 mg. (0·33 g. per kg. average body-weight) of noxytiolin on the first and seventh days after the inoculation of 1×10^5 E.A. cells.

Assessment of the Rate of Tumour Growth.—In our laboratory normal 6–8-week-old BALB/c mice show an average weight-gain of 4 per cent (0·5 g. in a 15-g. mouse). Therefore mice exhibiting a 10 per cent weight-gain and abdominal distension were considered to show evidence of definite tumour take. Some mice in the intraperitoneally instilled noxytiolin groups (experiments II and III) reached 30 days without developing ascites but all of these developed skin metastases. As the mice that had reached a 10 per cent weight-gain due to ascites tumour had invariably died by day 30 (11 out of 20 without reaching a 15 per cent weight-gain), those remaining were sacrificed and given a nominal value of 30 days to enable a statistical analysis to be made.

Statistical Analysis.—The data of experiments II and III were analysed collectively, using the Mann-Whitney test (Snedecor and Cochran, 1967). The same analysis was applied to experiments IV and V.

RESULTS

The results were as follows:—

1. In experiments II and III (*Fig.* 2), in which 15 mg. of noxytiolin were administered intraperitoneally, there was a significant inhibition of ascites tumours when compared with the control animals. The number of days in which the mice increased in weight by 10 per cent owing to development of ascites tumours was significantly higher compared with that for the control mice ($P = 0{\cdot}0001$).

2. In experiments IV and V (*Fig.* 3), in which 15 mg. of noxytiolin were given subcutaneously, no significant protective effect was observed.

3. In experimental groups of mice in which 5 mg. of noxytiolin were given either intraperitoneally or subcutaneously, no protective effect was obtained.

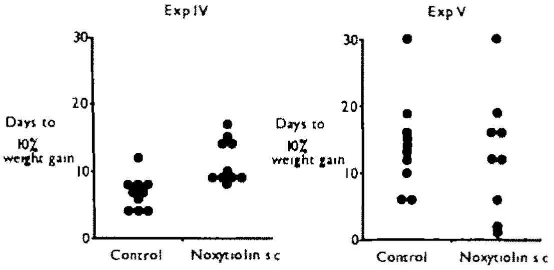

FIG. 3—The effect of subcutaneous noxytiolin on the rate of growth of Ehrlich's ascites tumour (1×10^5 cells) in BALB/c mice.

DISCUSSION

In an earlier report (Jamieson, 1972) the concentration of noxytiolin producing inhibition of tumour cells (HeLa) in culture was much lower (0·0025 per cent) than the reported bacteriostatic concentration of the drug.

The mode of action and fate of noxytiolin *in vivo* remain unknown. However, in one series it appeared to offer increased survival when used as a local instillate in cases of advanced bladder tumours, and it is remarkably free from toxic effects (Garrett, 1969, 1970). The present study tends to support this view, but in this tumour model the concentration of the drug required for inhibition of ascites tumour is very high (1·5 per cent) and its protective effect is only seen when used as a local instillate, suggesting that its action is short-lived and perhaps only local.

Acknowledgements.—The authors wish to thank Mrs. Margaret Ryder and Mrs. Sheila Siggins for technical assistance, and Geistlich Ltd. for supplies of noxytiolin and financial assistance in this investigation. We also wish to thank Dr. T. A. Connors of the Chester Beatty Research Institute for providing the Ehrlich's ascites tumour, and Mrs. Doreen Irving for statistical advice.

DEPRESSION OF IMMUNE RESPONSIVENESS IN BREAST AND LARGE-BOWEL TUMOURS AS MEASURED BY HETEROPHILE ANTIBODY ACTIVITY

By GARETH G. THOMAS* and MILES FOX†
ROYAL HOSPITAL, SHEFFIELD

SUMMARY

Decrease in heterophile antibody activity to cow, pig, and sheep red blood-cells was found in groups of patients with large-bowel and breast tumours irrespective of the extent and spread of the tumour or the length of known history. The significance of these observations is discussed in the light of known cancer-surveillance mechanisms. The findings may reflect decreased host immunological resistance to these tumours even in the early stage of their development, and the measurement of heterophile antibody activity may provide a useful and uncomplicated screening test.

IT has been shown that a balance may well be present between immunological defence mechanisms and the growth of certain tumours, and there is evidence that in some cases at least an immunologically mediated host resistance is involved (Fairley, 1969; Mathé, 1969). It has also been demonstrated that in some patients with tumours there is reduced reactivity on the part of the host. Whether this is a primary or secondary event, the behaviour of the disease and final prognosis will be influenced by the defence that the host is able to offer (Burnet, 1970; Klein, 1970; Whittaker and Clark, 1971).

A rise in heterophile antibodies has been found in some recipients of human transplants in the presence of immunological rejection (Iwasaki, Talmange, and Starzl, 1967; Rapaport, Kano, and Milgrom, 1968). These observations have prompted the present experiments to investigate whether alterations in heterophile antibody titres could reflect the presence, rate of growth, and invasive characteristics of mammary and large-bowel tumours.

MATERIALS AND METHODS

The study comprised 51 patients with carcinoma of the breast and 46 with carcinoma of the large bowel. All the patients were admitted to hospital for primary surgical treatment of their tumours and a blood sample was taken prior to surgery. Fifty patients admitted for non-malignant 'cold' surgery (herniorrhaphy, varicose veins, etc.) were used as controls.

Twenty ml. of blood were collected in a dry sterile tube, the clot was allowed to retract, and the serum was further separated by centrifuging. The serum was decomplemented by heating to 56° C. for 30 minutes and stored at −20° C. until a convenient time for the agglutination studies.

Agglutination activity of each serum sample was then tested in serial dilutions against cow, pig, rabbit, rat, and sheep red blood-cells. Results were read after 24 hours' incubation at 37° C. and the value taken as the last dilution at which agglutination occurred.

RESULTS

In a pilot study agglutinations of sera from 12 patients with carcinoma of the large bowel and 12 with carcinoma of the breast were compared with those of 13 control subjects. The titres for cow, pig, and sheep were significantly lower in patients with tumours compared with those of the control subjects, but virtually equal when tested against rabbit and rat red blood-cells. Agglutination studies with rabbit and rat red blood-cells were therefore not pursued further.

Table I.—SIGNIFICANCE (*P*) OF HETEROPHILE HAEMAGGLUTININ TITRES TESTED AGAINST DIFFERENT ANIMAL RED BLOOD-CELLS IN PATIENTS WITH TUMOURS COMPARED WITH THOSE IN CONTROL SUBJECTS OF THE SAME AGE-GROUP

AGE-GROUP	PIG RED BLOOD-CELLS		COW RED BLOOD-CELLS		SHEEP RED BLOOD-CELLS

Fig. 1 shows the distribution of haemagglutinin titres (means) to pig, cow, and sheep red blood-cells, comparing results according to age in the control subjects with those in patients with large-bowel or mammary tumour. A small reduction of agglutinin titres was demonstrated for pig and cow red blood-cells in control subjects with advancing age, but there was no statistical difference between the youngest and the oldest subjects ($P < 0{\cdot}10$). This trend was also seen in the tumour cases, but in patients with either mammary or large-bowel tumour the readings were lower than in the control subjects. *Table I* gives the statistical breakdown of the differences according to age. Significant differences were seen in patients who were 50 years of age or older, particularly with cow red blood-cell agglutination in large-bowel tumour cases.

---

† Requests for reprints to M. Fox, Royal Hospital, Sheffield.

Figs. 2, 3, and 4 are scatterograms of the haemagglutination titres to cow, pig, and sheep red blood-cells for patients with tumours compared with those of the control subjects, with separation according to sex. Mean results are also given. There was some difference between the heterophile agglutination activity of female and male control subjects but this

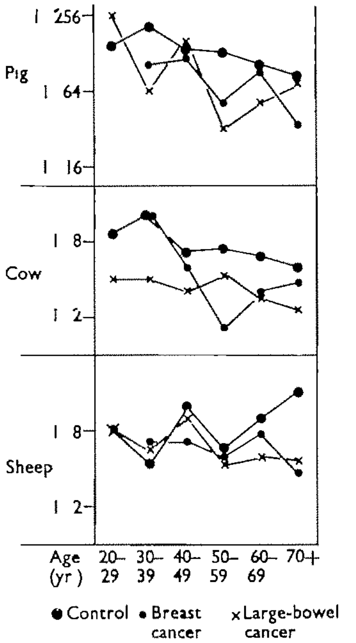

FIG. 1.—Relationship of haemagglutinin titres tested against pig, cow, and sheep red blood-cells to age in patients with breast or large-bowel malignant tumours and in control subjects

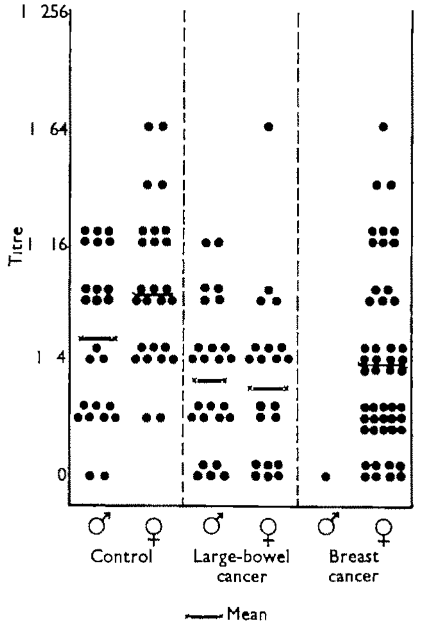

FIG. 2.—Haemagglutinin titres tested against cow red blood-cells in patients with large-bowel or breast cancer and in control subjects.

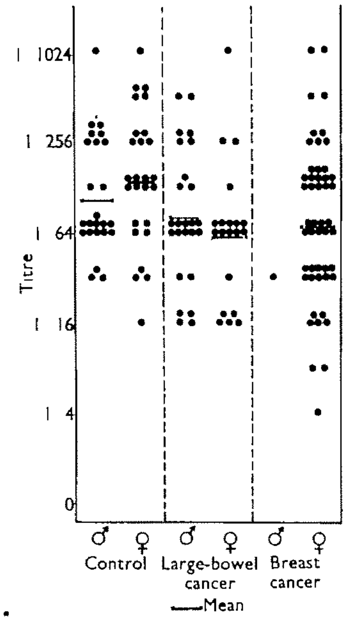

FIG. 3.—Haemagglutinin titres tested against pig red blood-cells in patients with large-bowel or breast cancer and in control subjects.

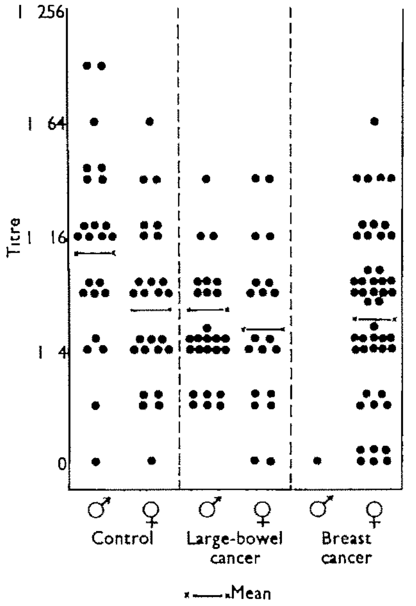

FIG. 4.—Haemagglutinin titres tested against sheep red blood-cells in patients with large-bowel or breast cancer and in control subjects.

was without statistical significance. Results in the tumour cases were compared with those of the control subjects according to sex (*Table II*). Titres from patients with tumours were significantly lower than those of control subjects when tested against cow red blood-cells for all the values examined, against pig red blood-cells in female large-bowel and breast tumour cases, and against sheep red blood-cells in large-bowel tumours.

Table II.—SIGNIFICANCE (*P*) OF COMPARISONS BETWEEN HETEROPHILE HAEMAGGLUTININ TITRES TESTED AGAINST DIFFERENT ANIMAL RED BLOOD-CELLS IN PATIENTS WITH AND WITHOUT CANCER

COMPARISON	COW RED BLOOD-CELLS	PIG RED BLOOD-CELLS	SHEEP RED BLOOD-CELLS
Male patients with carcinoma of the large bowel versus male control subjects	<0·05	>0·10	<0·005
Female patients with carcinoma of the large bowel versus female control subjects	<0·005	<0·01	>0·10
Female patients with carcinoma of the breast versus female control subjects	<0·005	<0·01	>0·10

Table III.—SIGNIFICANCE (*P*) OF COMPARISONS BETWEEN HETEROPHILE HAEMAGLUTININ TITRES TESTED AGAINST DIFFERENT ANIMAL RED BLOOD-CELLS IN PATIENTS WITH TUMOURS DEMONSTRATING VARIOUS FEATURES

FEATURE	COW RED BLOOD-CELLS	PIG RED BLOOD-CELLS	SHEEP RED BLOOD-CELLS
Carcinoma of the breast			
Spread	>0·10	>0·10	>0·10
Lymphocytic infiltration	>0·10	<0·10	>0·10
Fibrosis	>0·10	>0·10	>0·10
Differentiation	>0·10	<0·25	<0·005
Length of history	<0·10	>0·10	>0·10
Carcinoma of the large bowel			
Spread	>0·10	>0·10	>0·10
Lymphocytic infiltration	<0·10	<0·10	>0·10
Differentiation	>0·10	>0·10	<0·10
Length of history	>0·10	>0·10	>0·10

Agglutination titres were also reviewed in relation to the degree of histological differentiation. The tumours were graded into three categories according to differentiation (poor, moderate, and good). Mean titres were generally lower in the well-differentiated tumours than in the poorly differentiated ones, but the difference in readings between neoplasms which were poorly differentiated and those showing differentiation was statistically significant in only the sheep red blood-cell titrations (*Table III*).

A further breakdown of the agglutinin results was carried out according to the spread of the tumour and the degree of lymphocytic infiltration, fibrosis, and length of history. Two categories were made in each. The tumour was either localized or had spread into lymph-nodes and/or further; lymphocytic infiltration and fibrosis were either absent or minimal, or marked; the tumour had presented for under or over 3 months. No significant differences of agglutinin values were found among any of these groups (*Table III*).

DISCUSSION

There is evidence that the immune response against tumours resembles an allograft reaction with cell-mediated immunity playing the major part (Klein, 1970). The concept of immunological surveillance by the body against tumours advocated by Burnet (1970) has been summarized and placed into four groups by Keast (1970): (1) cancer occurs characteristically at the extremes of life when the immune system is either maturing or is weakened; (2) the incidence of tumours is increased by immunosuppressive drugs and (3) experimentally by thymectomy; (4) the rare diseases that involve a deficiency of cell-mediated immunity are characterized by a high incidence of tumours in those subjects who survive long enough to allow their development.

Increased heterophile activity in the presence of immunological rejection of allografts is known (Iwasaki and others, 1967; Rapaport and others, 1968). In view of similarly mediated mechanisms in some cases of host–tumour resistance, it seemed reasonable to investigate the heterophile response in cancer patients and to compare the results with those in control subjects. These observations have shown a very significant diminution of agglutinin titres to cow, pig, and sheep red blood-cells in groups of subjects with breast or large-bowel tumour.

Previous results using other methods have indicated a reduced immune competence in recurrent or advanced breast cancer (McKay and Baum, 1968; Williams and Roberts, 1968; Whittaker and Clark, 1971). There was some increase when host lymphoid infiltration in and around the tumour was present (Black, Opler, and Speer, 1954; Bloom, Richardson, and Field, 1970). In a series of patients cured by surgery and/or chemotherapy (Lee, Rowley, and Mackay, 1970) the antibody-producing capacity was greater than that in patients with active cancer, but yet was *significantly less* than that of healthy subjects. The present observations using heterophile antibody activity have shown no correlation with the size or extent of the tumour, lymphoid infiltration, length of known history, or amount of interstitial fibrous-tissue formation. Some of the lowest titres were found in patients with small and very early tumours. It is probable, therefore, that in some cases at least the reduced heterophile agglutination activity was present at the very start of the tumour formation and may thus reflect a diminished immunological resistance capability of the host against the neoplasm which facilitates its formation and growth. Low readings were recorded in some normal control subjects. If reduction of heterophile haemagglutinin activity does reflect a decrease of immune surveillance mechanisms it is interesting that a gradual diminution of the titres was observed with advancing age in control patients. Whether the younger subjects, in particular, who were found to have low titres are more at risk to cancer than their average-titre fellows is a subject for a further report.

THE EFFECT OF TOPICAL AMPICILLIN ON WOUND-INFECTION RATE AFTER CHOLECYSTECTOMY

BY C. J. H. LOGAN

THE SURGICAL UNIT, THE ULSTER HOSPITAL, BELFAST

SUMMARY

No carefully controlled trial of the use of topical ampicillin in cholecystectomy wounds has been described. A series of 100 consecutive cholecystectomies performed by one surgeon using this drug in a double-blind manner is reported. The efficacy of topical ampicillin in lowering the wound-infection rate as shown by other authors is not confirmed.

THE commonest complication following cholecystectomy which delays the patient's discharge from hospital is wound infection. Any technique or aid which would reduce the rate of this complication would be of considerable economic benefit to both the patient and to the hospital service. With this in mind a controlled double-blind trial to evaluate the effect of topical ampicillin in cholecystectomy wounds was carried out.

MATERIAL AND METHODS

One hundred patients were operated upon by the author using the same incision (right upper paramedian muscle splitting) and suture materials. Routine cholangiography was performed in each case. A corrugated drain was inserted through a stab incision. This was removed on the fourth postoperative day and the sutures were removed on the ninth and tenth postoperative days. The patients were not selected before operation and were consecutive, only those having added procedures being excluded. The sex distribution and average age of the patients are shown in *Table I*. At the time of operation the patients were arbitrarily placed in one of the categories 'thin', 'medium', and 'fat'. The distribution of these is shown in *Table II*.

Randomly numbered opaque glass phials were prepared by Beechams Research Laboratories and were either empty or contained 250 mg. of ampicillin powder. During cholecystectomy 5 ml. of normal saline were added to each phial by a nurse outside the operating theatre and the solution was then put in the wound after closure of the peritoneum. The wound was not dried until closure was complete.

Table I.—THE SEX DISTRIBUTION AND AVERAGE AGE OF PATIENTS HAVING EITHER AMPICILLIN OR SALINE (CONTROL) IN THEIR WOUNDS FOLLOWING CHOLECYSTECTOMY

	AMPICILLIN	SALINE
Males	12 (23·1 per cent)	9 (18·8 per cent)
Females	40 (76·9 per cent)	39 (81·2 per cent)
Average age (yr)	52·4	53·9

Table II.—THE BUILD OF PATIENTS HAVING EITHER AMPICILLIN OR SALINE (CONTROL) IN THEIR WOUNDS FOLLOWING CHOLECYSTECTOMY

TYPE	AMPICILLIN		SALINE	
	No. of cases	Percentage	No. of cases	Percentage
Thin	5	9·6	8	16·7
Medium	18	34·6	20	41·7
Fat	29	55·8	20	41·7

On the tenth postoperative day the wound was inspected and its state recorded in one of five grades. These were: 0, normal; 1, slight redness; 2, oedema; 3, pus; and 4, disrupted. The code for the phials was broken at the end of the trial.

RESULTS

Twelve patients showed abnormalities of their wounds at 10 days (*Table III*). Eight of these had had ampicillin added to their wounds and in 4 saline only had been added. The majority of the infections were minor and clinically insignificant in both series, being in grades 1 and 2. There were

2 patients in grade 3 who had had ampicillin added to their wounds but there were no control patients in this grade. Of the 2 wounds in grade 4, one was in each group. Grades 1 and 2 are of minor significance and did not prolong the patients' stay in hospital. Grades 3 and 4 are significant infections and it can be seen that the control group fared better than those having ampicillin in their wounds. This infection rate is low but there were 7 patients whose wounds discharged after they left hospital. Three of these were in the control group and 4 were in the ampicillin group. Even taking this into account it can be seen that ampicillin did not reduce the wound-infection rate.

Table III.—THE GRADING OF THE WOUNDS IN WHICH AMPICILLIN OR SALINE (CONTROL) WAS ADDED

GRADE	AMPICILLIN	SALINE
0	44	44
1	3	1
2	2	2
3	2	0
4	1	1
Total	52	48

DISCUSSION

Postoperative systematic antibiotics have not been shown to affect appreciably the rate of wound infections (Johnstone, 1963; Committee on Wound Infections, 1964). It has been suggested that infection in clean wounds takes place at the time of operation and is probably contamination from the noses of the theatre personnel (Browne, Glassow, Martin, and Shouldice, 1959). The inoculum is assumed to be small and therefore the topical application of an antibiotic should overcome the infection.

To institute a trial to test this hypothesis requires care especially in the choice of a control substance. Lactose has been used for this purpose when ampicillin was added to wounds in powdered form (Rickett and Jackson, 1969) but this in itself may not be inert and may encourage bacterial growth. To overcome this normal saline was used as the control solution in the present series and also as the solvent for the ampicillin, and thus the only difference in the two groups was the presence or absence of ampicillin. Although limiting the size of the experiment all the cases were operated upon by one surgeon using an identical technique. This and the fact that all the patients had cholecystectomies make the series more uniform than those of some of the other authors.

Stoker and Ellis (1971) used ampicillin powder (1 g.) in a comparison with noxytiolin and found that the former reduced the incidence of wound infections. The same authors (Stoker and Ellis, 1972) also compared ampicillin powder (1 g.) with penicillin and Sulphadiazine and again showed the efficacy of ampicillin. The number of biliary cases in their second series was small, there being 18 and 19 cases in each group with a control group of 4 cases. Nash and Hugh (1967) reported a dramatic decrease in wound infections using 1 g. of powdered ampicillin in wounds following colonic surgery, and Rickett and Jackson (1969), using 500 mg. of powdered ampicillin, also showed a significant fall in wound infections following appendicectomy. Ryan (1967) showed the efficacy of topical penicillin in reducing infection in a large number of herniorrhaphies where surgery was performed by the author. However, the figures presented in this trial, where ampicillin was used in a smaller dose dissolved in saline, show no significant reduction in wound infection. There are three possible explanations for the difference between these results and those of the other series. First, the dose used was smaller and may have been insufficient to eradicate the inoculum of bacteria. Secondly, the ampicillin was used in a fluid form and therefore it was removed too quickly from the wound while the powdered ampicillin remained for a considerably longer period. Finally, the powdered ampicillin would give a higher local concentration of the antibiotic and this may well be the most important factor in explaining the discrepancy.

Acknowledgements.—I wish to thank Messrs. Beecham Ltd. for supplying the ampicillin and for preparing the phials and Mrs. F. McCartney for her help with the manuscript.

A CONTROLLED TRIAL OF CLOSED WOUND SUCTION

DRAINAGE IN RADICAL MASTECTOMY

BY A. M. MORRIS

PLASTIC SURGERY UNIT, BANGOUR GENERAL HOSPITAL, WEST LOTHIAN

SUMMARY

A controlled clinical trial has been performed to compare the effectiveness of suction drainage with that of static drainage. The trial has shown that in 53 radical mastectomy wounds the rate of wound healing was faster in those cases in which suction drainage was used, with a reduction in incidence of wound infection, breakdown, and necrosis.

THE healing of a radical mastectomy wound presents several difficulties. The incision is long, the flaps are thin, and the volume of blood, lymph, and serous drainage is large. To collect this fluid a traditional method of wound drainage uses one or more lengths of soft rubber or plastic. The fluid drains into pads bandaged to the patient and the volume may be so considerable that during the evening of the operation new pads have to be applied because the fluid soaks through to bed linen or clothing.

Suction drainage for mastectomy wounds was first introduced in 1947 by Murphey, and its use was also described by Raffi (1952). Since then portable units for the evacuation of wounds have been devised (Redon, 1955) and found to have several advantages. In particular they give added comfort to the patient and eliminate the need for bulky compression bandages and frequent changes of dressings (Thoren, 1964); also the wound can be kept dry and cool. Drainage gives rise to an increased incidence of wound infection (Public Health Laboratory Service, 1960; National Research Council, 1964) but it has not been established with certainty whether suction drainage reduces this risk (Medical Research Council Subcommittee, 1968).

Suction drainage has been used in the Guy's Breast Clinic in the past but the small-bore tube then in use tended to become blocked. It could not maintain suction for long so that pockets of fluid accumulated under the flaps and the method was not adopted. A new wide-bore tube (6·4-mm. bore Zimmer) is now available and has been found to be effective in wounds where a large volume of fluid drainage is likely to occur. A controlled clinical trial was carried out to compare the effects of static and suction drainage on the healing of radical mastectomy wounds.

METHODS

The trial was carried out in the first 8 months of 1970. All patients undergoing treatment for early breast carcinoma by radical mastectomy were admitted to the trial. The start of the trial coincided with the opening of the new Guy's Breast Unit at New Cross Hospital and the majority of the patients were treated there and nursed in single rooms. The operations were performed by the consultant and registrar staff of the Breast Clinic. An identical operative technique of radical mastectomy was carried out in all the cases. Proof that the lesion was a carcinoma of the breast was determined either by a biopsy taken up to 6 days before operation or by a frozen-section biopsy immediately before the mastectomy. After marking out the skin incision the upper and lower flaps were infiltrated with a solution of 1 : 400,000 adrenaline in normal saline to separate the tissue planes and to assist haemostasis. A radical mastectomy was then performed leaving the clavicular head of the pectoralis major in place. A full axillary lymph-node clearance was carried out. Haemostasis was achieved by diathermy coagulation of all except the major vessels which were ligatured with chromic 00 cat gut. In the final stage of the operation lavage of the wound was carried out using warm sterile distilled water. Before closure the type of drainage to be used was selected by a third party drawing a labelled ticket from a box. Two lengths of Paul's tube in which side holes were cut were used as static drainage, one for the upper flap emerging at the lower end of the wound, the second via a stab incision in the lower flap to drain it and the axilla. In the suction-drainage series two 6·4-mm. bore tubes were inserted using a trocar, one to drain the upper flap, the other to drain the lower flap and axilla. Both drains were placed to emerge from the lower flap at least 5 cm. apart to minimize any interference with the blood-supply of the lower flap. The wound was closed using interrupted silk sutures, and sealed with a layer of plastic skin (Nobecutane) to make it airtight. In both groups of patients a pressure dressing of wool and two 15-cm. crêpe bandages was applied in order to keep the postoperative conditions as nearly comparable as possible. In the suction-drainage group the suction bottles were connected to the drains and as soon as this dressing was in place the clamps were released and, by firm manual pressure over the flaps, the initial aspiration of any haematoma was encouraged.

Postoperative Treatment.—In both groups of patients the dressings were left undisturbed for 48 hours with additional packs applied when necessary. Subsequently, in the static-drainage group change of dressings with reapplication of wool and crêpe was performed daily until healing took place. The drains were usually retained until the thirteenth day, but if the volume of drainage was slight the drains were removed earlier. On a few occasions when large volumes of fluid were still being obtained the drains were left longer than 13 days. In the suction-drainage group the drains were left until the volume of drainage dropped below 25 ml. in any 24-hour period but were always retained for at least 5 days if the drainage was slight. In both groups the sutures were left in place until the tenth postoperative day, when one-third was removed if the wound healing was proceeding satisfactorily. Half the remaining sutures were removed on the next day and all were removed by the twelfth day.

RESULTS

The following six factors were used in the assessment of the results:—

1. Volume of fluid drainage (*Table I*). For suction-drainage cases the volume of fluid in the bottles was measured and recorded every 24 hours. Accurate measurement of fluid loss in the static-drainage group was not possible, but by weighing the dressings daily a measure of the variation in loss could be made.

Table I.—Measured Drainage

Type of Drainage	Average Time Drain left in Wound (d.)	Average Time of Drainage (d)	Volume of Drainage (ml)
Suction	8·1	7·8	780 total 100 daily
Paul's tube	13·2	10·6	578 total 54·56 daily

Table II.—Delay in Wound Healing

Type of Drainage	Infection		Necrosis				Wound Breakdown			
			Total		*Area greater than 2·5 cm. in diameter*		*Total*		*Length greater than 2 5 cm long*	
	No. of Cases	Percentage	No. of Cases	Percentage	No. of Cases	Percentage	No of Cases	Percentage	No. of Cases	Percentage
Suction	1	4	5	18	3	11	2	7	0	0
Paul's tube	8 $\chi^2=5\cdot68$ $P<0\cdot02$	32	10	40	8 $\chi^2=2\cdot46$ $P<0\cdot20$	32	7	28	5 $\chi^2=4\cdot07$ $P<0\cdot05$	20
Paul's tube (excluding patients over 70 years old)	6 $\chi^2=4\cdot25$ $P<0\cdot05$	29	7	33	5 $\chi^2=0\cdot70$ $P<0\cdot50$	25	5	24	4 $\chi^2=3\cdot54$ $P<0\cdot10$	19

Table III.—Postoperative Care

Type of Drainage	Aspiration of Fluid as an In-patient		Post-discharge Aspiration		Post-discharge Dressings	
	No. of Cases	Percentage	No. of Cases	Percentage	No. of Cases	Percentage
Suction	8	29	7	25	4	15
Paul's tube	3	12	3	12	13	52
Paul's tube*	2	10	2	10	10	48

* Excluding patients over 70 years old.

2. Haematoma or fluid accumulation. The wound was inspected at least once every 3 days for signs of loculated fluid and the volume of fluid aspirated was recorded.

3. Delay in healing defined as an area of breakdown of the wound or necrosis of the skin flaps (*Table II*).

4. Infection, defined as severe sepsis with purulent discharge from the wound or accumulation of pus requiring drainage with frequent dressings and prolonged hospital stay. Routine wound swabs were taken on removal of the drain.

5. Any dressings or aspiration of fluid required after discharge from hospital, or any delay in commencing radiotherapy (*Table III*).

6. Length of postoperative stay in hospital (*Table IV*).

DISCUSSION

Radical mastectomy is still the orthodox treatment for early breast cancer. Technically it is not a difficult operation but there are many details to be observed in obtaining good results. This trial shows that the type of wound drainage is a major factor in determining wound healing. Closed-suction drainage is shown to have several important advantages over open drainage.

The average length of postoperative stay in hospital was 1 week less for the suction-drainage group. This gave a saving over the 9 months of the trial of 28 weeks' hospital stay for the cases in which suction drainage was employed.

Table IV.—Length of Postoperative Stay in Hospital

Type of Drainage	No. of Cases	Age (yr)	Length of Stay (d.)
Suction	28	36–66 (46·9 average)	12–20 (13·6 average)
Paul's tube	25	33–79 (54·2 average)	13–75 (20 6 average)
Paul's tube*	21	33–67 (49·5 average)	13–45 (19 0 average)

* Excluding patients over 70 years old.

The random selection of the patients in this trial by chance included 4 patients over 70 years of age in the static-drainage group. As this might bias the results a comparison has also been made between the suction-drainage and the Paul's-tube groups omitting the patients who were over 70 years old. Suction drainage gave a shorter stay in hospital postoperatively and a significantly decreased incidence of postoperative infection whether the patients over 70 years old were included or not. The incidence of necrosis was also reduced in the group having suction though, as would be expected, the incidence of wound necrosis was greater in the older patients.

The lower incidence of wound breakdown in the suction-drainage group is statistically significant although when the patients over 70 years old are excluded the difference is less significant.

In the trial the only patient in the suction-drainage group whose wound became infected had the suction tubes accidentally clamped off for 24 hours on the fifth postoperative day. The infection developed 48 hours later. In this case the suction method was incompletely applied and this may have contributed to the infection.

With suction drainage the need for a bulky dressing is eliminated. This gives greater comfort to the patient, and the absence of a tight, constricting dressing allows easier movement of the chest postoperatively. The wound can be exposed early, keeping it dry and cool. Frequent changes of dressings are not required with a subsequent considerable saving of nursing time and expense.

The incidence of accumulation of pockets of fluid in the wound is greater when suction drainage is employed, but the fluid can easily be removed by aspiration using a technique similar to that used for aspirating cysts (Tong, 1969) and gives rise to no permanent trouble. The volume of drainage cannot be accurately compared in this series as the method of collection in the Paul's tube series allowed considerable evaporation. However, the amounts of fluid lost were probably comparable for the two series of cases, and it seems unlikely that suction drainage is associated with a significantly increased production of fluid. As there is considerable evaporation from the dressings in the open-drainage method, it may be that the volume of drainage is less when suction drainage is employed. It is interesting that in the cases where the lymph-nodes were found to be involved at mastectomy the fluid loss was greatest.

Acknowledgements.—I am grateful to Professor Sir Hedley Atkins and Mr. J. L. Hayward for their help and advice in performing this trial, and also to Mr. M. Feldstein for preparing the statistical report. I would like to thank Sister N. Sansom and the nursing staff of the Breast Unit for their invaluable help.

TORSION OF THE GALL-BLADDER IN THE AGED

BY R. BOTHRA
HEMLINGTON HOSPITAL, MIDDLESBROUGH, TEESSIDE

SUMMARY

Torsion of the gall-bladder in 2 women in the tenth decade of life is described. The aetiology of the condition is discussed and the importance of keeping the diagnosis in mind in this age-group is stressed.

TORSION of the gall-bladder is an unusual surgical emergency, fewer than 300 cases having been reported. Perhaps because of its rarity the diagnosis is seldom made clinically, the condition generally being recognized only at laparotomy. Although its occurrence has been reported in children—the youngest was aged 5 (Cuervo and Cuervo, 1939)—its highest incidence is in patients between the ages of 65 and 75. Hitherto the oldest reported case was aged 93 (Case, 1951).

The present paper reports 2 cases of torsion of the gall-bladder in the aged. The first of these was aged 96 years, and this appears to be the oldest case so far recorded. The second was also a nonagenarian, aged 92 years, in whom the diagnosis was made pre-operatively.

CASE REPORTS

Case 1.—Mrs. C. H., aged 96 years, was admitted as an emergency on 18 April, 1970, from a cottage hospital where she had been treated for congestive cardiac failure for 3 weeks. The previous day she had suddenly developed abdominal pain and vomiting. On admission she had a temperature of 37·4° C. and a pulse-rate of 100 per minute. The abdomen was distended, with some generalized tenderness. A plain radiograph of the abdomen showed gaseous distension of the gut with some small-bowel fluid levels. A provisional diagnosis of small-bowel obstruction was made.

The abdomen was explored through a right paramedian incision (Dr. P. W. Griffin). Free fluid was present in the peritoneal cavity but no obvious mechanical obstruction was found. A black, pear-shaped tumour was discovered suspended from the inferior surface of the right lobe of the liver on a pedicle which had undergone torsion through one and a half turns. It became clear that this was a case of torsion of the gall-bladder. The pedicle was ligated and the gall-bladder removed. The abdomen was closed without a drain. The patient made a good recovery and was transferred back to the cottage hospital on 4 May, from where she was discharged home on 23 May. She is still alive, now aged 98, and enjoys reasonable health.

PATHOLOGY.—The gall-bladder was grossly congested with early gangrenous changes. It contained several small stones.

Case 2.—Mrs. A. J., aged 92 years, was admitted as an emergency on the evening of 12 Jan., 1972. She had been seen that afternoon in domiciliary consultation, when a provisional diagnosis of torsion of the gall-bladder had been made. There was a history that on the previous afternoon she had been seized with upper abdominal pain accompanied by repeated vomiting. The vomiting had soon stopped, but the pain had persisted and had become localized in the right upper abdomen. Before this episode she had enjoyed good health for her age, was mentally alert, and ambulant. On examination she was thin and had a dorsal kyphosis. She was in considerable pain. Her temperature was normal, pulse-rate was 80 per minute, and blood-pressure was 130/60. There was marked guarding over the right hypochondrium although the rest of the abdomen was soft and not distended. Bowel-sounds were infrequent but of normal character.

At operation (Mr. T. Duncan) shortly after admission the clinical diagnosis was confirmed. Through a short, upper right, paramedian incision a gangrenous gall-bladder that had undergone torsion on a narrow pedicle was easily delivered into the wound. The pedicle was ligated and divided to remove the gall-bladder. The wound was closed without drainage, the operation being completed in 15 minutes. Although an intravenous infusion was used during the procedure, this was discontinued immediately postoperatively and the patient was started on oral feeding next morning. Her recovery was uneventful and she was discharged home a week after operation, her sutures being removed by her own doctor on the tenth postoperative day. The wound healed by first intention and the patient has remained well.

PATHOLOGY.—The gall-bladder was necrotic and contained several stones.

DISCUSSION

Among the possible aetiological factors in torsion of the gall-bladder in the older age-groups, loss of fat and visceroptosis have been cited (Gross, 1936), as these tend to produce a gall-bladder mesentery. Kyphosis may also be a factor by making the gall-bladder more dependent (Rais and Thulin, 1957). Both patients reported here were very thin and kyphotic. Although Ashby (1965) has postulated that a syndrome of recurrent gall-bladder torsion occurs, there was nothing in the history of the present cases to suggest previous attacks.

What initiates the torsion is debatable. It has been suggested that vigorous peristalsis in the neighbouring viscera or sudden violent body movement may be responsible (Short and Paul, 1934; Shah, 1966). The presence of gall-stones may be a contributory factor in some cases. Both the patients described in this paper had stones in the gall-bladder, and Levene (1958) noted that stones were present in 50 per cent of the reported female cases of gall-bladder torsion compared with a post-mortem incidence of 5 per cent in women of the same age-group. It is thought that stones might precipitate torsion by giving the colon more purchase on the gall-bladder (Short and Paul, 1934) or by increasing peristalsis in the gall-bladder (Levene, 1958). It is also possible that a small stone obstructing the cystic duct and causing a sudden increase in tension in the gall-bladder might lead to torsion if the gall-bladder has acquired a mesentery, by a mechanism similar to that which is sometimes seen when an acutely obstructed appendix curls upon its mesentery owing to the sudden increase in tension in the organ.

Torsion of the gall-bladder occurs primarily in elderly women and as these are increasing in number the condition will no doubt increase in frequency. It is important that it should be distinguished from acute cholecystitis, as conservative treatment in torsion of the gall-bladder would be fatal. The clinical presentation does vary, however, and Flannery and Caster (1956), in a review of 27 reported cases, found that none had been diagnosed preoperatively. The present *Case* 2 was diagnosed as torsion on the basis of the patient's age and body configuration, and the fact that the degree of guarding over the gall-bladder was out of proportion to the systemic upset to be expected in acute cholecystitis.

Since gall-bladder torsion is readily amenable to surgical treatment even in the very elderly, as is shown in this paper, a plea is made that the condition is borne in mind in the differential diagnosis of the acute abdomen in this age-group.

ADDENDUM

Just before this paper was submitted for publication the author had occasion to respond to the plea made in the last paragraph.

Case 3.—Late in the evening of 19 March, 1972, a woman aged 83 years was admitted as an emergency with a diagnosis of acute cholecystitis. She had a 24-hour history of upper abdominal pain and vomiting, the pain localizing in the right upper abdomen. Her temperature was 37·6° C. and pulse-rate 96 per minute. She had marked tenderness in the right hypochondrium with some guarding. Although the clinical picture was consistent with acute cholecystitis it was noted that she was thin and kyphotic, and, with the previous cases in mind, the possibility of torsion of the gall-bladder was considered. Because of this, laparotomy was carried out that night. A torsion of the gall-bladder was indeed present. The gall-bladder was tense and congested and had undergone torsion through one complete turn in a clockwise direction. A small gall-stone was found impacted in the cystic duct. (This finding supports the theory of aetiology postulated above.) An easy cholecystectomy was performed and the patient made an uneventful recovery.

Acknowledgements.—I wish to express my thanks to Mr. F. C. Walker for permission to report *Case* 1, and to Mr. T. Duncan for permission to report the other 2 cases.

PROBLEMS IN ACUTE HYPERPARATHYROIDISM

By F. BURCHARTH* and H. VIBE-HANSEN
DEPARTMENT OF THORACIC SURGERY, BISPEBJERG HOSPITAL, UNIVERSITY OF COPENHAGEN

SUMMARY

The diagnostic and therapeutic problems of acute hyperparathyroidism are discussed on the basis of 4 selected cases. A highly raised serum-calcium level was demonstrated in all 4 cases. Serum-calcium determinations should be undertaken in every case which presents a vague clinical picture. Primary hyperparathyroidism should be treated by operation as soon as the diagnosis has been made, before any other surgical therapy of accompanying disorders is carried out, such therapy being liable to provoke a crisis requiring immediate operation.

PRIMARY hyperparathyroidism is most commonly featured in its chronic form, which in rare cases may be complicated by a hypercalcaemic crisis. Hypercalcaemic crises have been described with increasing frequency in recent years, but the total number of cases reported remains just over 100 (Burcharth and Vibe-Hansen, 1969; Boquist, Bergdahl, and Andersson, 1971).

Recognition of this condition is very important, as failure to operate is nearly always fatal (Lemann and Donatelli, 1964; Anglem, 1966). As only a few patients with primary hyperparathyroidism develop a hypercalcaemic crisis, certain releasing factors must be required. It is recognized that mental and physical stress, e.g., surgical operation, can produce a crisis (Carlsson, Bates, and Boyce, 1960; Burcharth and Vibe-Hansen, 1969; Heimann and Nilsson, 1970; Boquist and others, 1971).

Acute hyperparathyroidism is characterized by an intensification of the symptoms of hypercalcaemia. The disease begins with vague and non-specific general symptoms, such as fatigue, anorexia, weight-loss, vomiting, and abdominal pain, and in some cases paralytic ileus. Mental symptoms, particularly depression, and in some cases psychoses, may be noticed from the outset. If the crisis is allowed to continue, progressive clouding of the consciousness is seen proceeding to stupor and coma. Left untreated the crisis will culminate in cardiovascular shock.

Four case histories are reported here, and the problems concerning diagnosis and treatment of acute hyperparathyroidism are discussed. The cases have been selected from a series of patients with primary hyperparathyroidism treated within the period 1965–71.

CASE REPORTS

Case 1.—A woman aged 56 years, over a period of 3 years had repeatedly had symptoms of renal calculi and hypertension, and intermittent attacks of fatigue, abdominal pain, pancreatitis, and mental disorders. Primary hyperparathyroidism was suspected. In confirmation the serum-calcium level was 15·5 mg. per 100 ml. Exploration of the neck disclosed two adenomas in the lower parathyroid glands, which were removed. Postoperatively the serum-calcium level fell to 10·4 mg. per 100 ml. and remained normal.

Three years later symptoms recurred, and the serum calcium had risen to 12–13 mg. per 100 ml. Exploration of the neck revealed no further adenomas. The patient then improved, and after 2 years she failed to appear for 'follow-up' examination.

Eleven years later (17 years after the first symptoms) the patient returned with pronounced hyperparathyroidism and the serum calcium was 19·6 mg. per 100 ml. Peritoneal dialysis was performed, but despite this the serum calcium rose to 24·5 mg. per 100 ml. in 48 hours. Haemodialysis in the next 24 hours reduced the serum calcium to 14·0 mg. per 100 ml. Exploration of the neck revealed an adenoma in the upper left pole of the thyroid gland which was removed. Postoperatively the serum calcium fell to 11·7–12·6 mg. per 100 ml. One month later it had risen to 20·7 mg. per 100 ml. and the patient was again undergoing a hypercalcaemic crisis.

On reoperation a fourth adenoma was found at the upper right pole of the thyroid. Histological examination showed water-clear hyperplasia. Postoperatively hypoparathyroidism developed which required prolonged treatment with vitamin D and calcium.

The serum calcium has remained normal since. The patient still has her symptoms of impaired renal function, renal calculi, and grave hypertension.

Case 2.—A woman aged 57 years was admitted with a few months' history of fatigue, nervousness, mental depression, and a weight-loss of 14 kg. The serum-thyroxin level was found to be raised to 342 nmol. per litre, which was compatible with hyperthyroidism, and the patient was treated with propyl-thio-uracil. During the patient's stay in hospital her mental symptoms became aggravated, and she became confused. The serum-calcium level (not measured before) was 18·3 mg. per 100 ml. The level fell to 14 mg. per 100 ml. after intravenous therapy with phosphate, and her condition became relatively stabilized. As other causes of the hypercalcaemia were absent exploration of the neck was performed with removal of one parathyroid adenoma and resection of the thyroid gland. The serum calcium and serum thyroxin have remained normal since, and the patient is symptom-free except for mild nervous symptoms.

Case 3.—A woman aged 65 years, with mild diabetes mellitus but otherwise previously in good health, was subjected to left thoracotomy with excision of a tuberculous process. The patient was given anti-tuberculous chemotherapy pre- and postoperatively.

The first 3 postoperative days were uneventful, but on the fourth day the patient became depressed and increasingly drowsy. The blood-sugar level had risen to 470 mg. per 100 ml., but returned to normal after the injection of insulin. The patient grew even more distant, became highly febrile, and complained of diffuse abdominal pain. On the sixth postoperative day, when all other possible causes of the patient's condition had been investigated, the serum-calcium level was measured and found to be elevated (17·8 mg. per 100 ml.).

Initially treatment was attempted with large doses of a cortisone compound intravenously, and the serum-calcium level dropped to 16·1 mg. per 100 ml. and there was some improvement in the patient's condition. On the eighth postoperative day the serum calcium rose again to 17·8 mg. per 100 ml. and the patient became comatose.

---

* Present address: Wedreborg Awle 40, 2820 Gentofte, Copenhagen, Denmark.

Acute primary hyperparathyroidism was suspected and an infusion of sodium phosphate was commenced in an attempt to prepare the patient for operation, but she died after 1 hour's treatment.

Post-mortem examination disclosed a parathyroid adenoma, 1 cm. in diameter, in the superior mediastinum. There were no adenomas in the neck. Nephrocalcinosis was also present.

Case 4.—A man aged 27 years presented with polyuria of 4 years' duration, a weight-loss of 10 kg. within the past 6 months, intermittent abdominal pain, and vomiting. Following a traffic accident he was admitted to an orthopaedic surgical unit with a fractured patella. Five days after admission the patient became nauseated and vomited several times. The serum creatinin rose from 1·9 to 5·2 mg. per 100 ml. On the tenth day anuria set in. The serum calcium, which had not been measured before, was 18·7 mg. per 100 ml. A 1·5 × 1-cm. soft tumour was palpable inferiorly on the left side of the neck. The patient was subjected to haemodialysis, and consequently his condition improved. The serum calcium fell to 13·7 mg. per 100 ml. and the serum creatinin to 4·2 mg. per 100 ml. within 12 hours.

Eleven days after his admission and 24 hours after acute hyperparathyroidism had been diagnosed an operation was performed to remove three parathyroid adenomas, two of which weighed 5 g. and one 40 g.

Postoperatively the patient developed severe pulmonary oedema, which was treated by positive-pressure ventilation. The postoperative serum calcium was 11·9 mg. per 100 ml. A few hours after the operation the patient had a cardiac arrest. Artificial respiration and external cardiac massage were administered without effect.

Post-mortem examination disclosed bilateral pneumonia and pronounced bilateral nephrocalcinosis.

DISCUSSION

A diagnosis of acute hyperparathyroidism can often be made from the clinical picture. The disease is particularly suspected if the serum calcium is about 16–17 mg. per 100 ml. or higher. In the majority of cases values above 17 mg. per 100 ml. are found (Pyrah, Hodgkinson, and Anderson, 1966; Burcharth and Vibe-Hansen, 1969). The patients described here had serum-calcium values ranging from 17·8 to 24·5 mg. per 100 ml. On the other hand, in some reported cases a crisis occurred although the values were only slightly raised (Smith, Bradshaw, and Holleman, 1963). This may be due to an increase of the ionized serum-calcium fraction owing to concomitant acidosis and hypoproteinaemia.

The present *Case* 1 had had her hyperparathyroidism controlled for some years, since the first operation, with a persistent, slightly raised serum calcium. She presented again with acute symptoms of hypercalcaemia and a high serum-calcium level. The other 3 patients had never before been suspected of having hyperparathyroidism, and the diagnosis was made at such an advanced stage that the symptoms of crisis were pronounced.

In *Case* 2 the symptoms were for a long time interpreted as due to hyperthyroidism. Aggravation of the condition and impairment of the consciousness despite treatment with propyl-thio-uracil raised a suspicion of acute hyperparathyroidism, a diagnosis which was confirmed by a serum-calcium level of 18·3 mg. per 100 ml.

A high incidence of thyroid disorders in relation to primary hyperparathyroidism has been demonstrated by several investigators (Hellstrøm and Ivemark, 1962; Burcharth, Castberg, and Vibe-Hansen, 1972). A significantly raised serum-calcium value has been measured in patients with thyrotoxicosis (Lim, Jacob, and Khoo, 1969). This is probably due to a stimulating effect of thyroxin on the parathyroid glands (Heydenreich and Bock, 1970). Furthermore, the thyroid gland is the main site of production of calcitonin.

Case 3 had not previously displayed any signs or symptoms of hyperparathyroidism. Her condition was at first interpreted as the beginning of diabetic coma. Her condition deteriorated despite control of the diabetes, and after excluding other possibilities, acute hyperparathyroidism was suspected and confirmed by a serum-calcium level of 17·8 mg. per 100 ml.

Case 4 had for some length of time had symptoms compatible with a diagnosis of primary hyperparathyroidism. The symptoms progressed excessively in a few days, and a diagnosis of acute hyperparathyroidism was again confirmed by a serum-calcium level of 18·7 mg. per 100 ml.

In *Cases* 3 and 4 the crisis was provoked by surgical intervention and injury respectively. In *Cases* 1 and 2 there were no obvious provoking factors.

Several other diseases accompanied by non-specific general symptoms may raise problems in the differential diagnosis of acute hyperparathyroidism, particularly in the earlier phases of the crisis. Hypercalcaemia may also be present in association with various other conditions, but in these the serum-calcium level rarely exceeds 16 mg. per 100 ml. (Henley, 1964). In the fulminant crisis, however, the symptoms are so pronounced and characteristic that these, together with the high serum-calcium level, exclude any other diagnosis. The fully developed crisis is a life-threatening condition and therefore an early diagnosis is of great importance. Patients with urolithiasis, thyroid disorders, non-characteristic general symptoms, non-characteristic abdominal complaints, mental disorders, hypertension, peptic ulcer, pancreatitis, and osseous changes with decalcification should always be examined for the presence of hyperparathyroidism.

Medical treatment of primary hyperparathyroidism has been attempted. The following methods are those most frequently employed: phytate by mouth to reduce the calcium absorption from the intestine, kelate- and complex-forming substances, sodium phosphate, mithramycin, calcitonin, and dialysis. None of the stated methods is capable of reducing a high serum calcium, as seen in the hypercalcaemic crisis, to normal.

Phosphate treatment was given with a limited response in *Cases* 2 and 3. Preoperative dialysis, employed in *Cases* 1 and 4, effected a transitory lowering of the serum-calcium level.

Calcitonin, whose chemical data and production in pure form have been clarified within recent years, has been considered with great expectations in the treatment of both chronic and acute hyperparathyroidism. Calcitonin depresses the bone resorption by a negative 'feed-back' mechanism. Possibly it also enhances the phosphate excretion in urine. Copp (1970) recently showed that calcitonin has strong sodiuretic and diuretic effects. Calcitonin only has a hypocalcaemic effect in osteolytic bone diseases. Copp (1970) also showed that possibly it is useful in the treatment of Paget's disease and the hypercalcaemia attending osteolytic bone metastases. However, Sørensen and Hindberg (1970) demonstrated in animal experiments that prolonged calcitonin administration causes secondary hyperparathyroidism with compensatory hypercalcaemia. Therefore, we cannot yet say with certainty whether or not calcitonin can replace the surgical treatment of primary hyperparathyroidism. It may, however, when available for clinical use, be employable for preoperative treatment in cases of acute hyperparathyroidism.

The only rational treatment of primary hyperparathyroidism consists of surgical removal of abnormally acting parathyroid tissue. Surgery must be carried out as soon as the diagnosis has been made and ought to precede the treatment of other accompanying diseases if such are present, e.g., urolithiasis, owing to the risk of provoking a hyperparathyroid crisis.

Acute hyperparathyroidism should be treated by immediate operation, even though such patients often are in a very poor state with grave fluid and electrolyte disorders. This is because conservative methods are incapable of controlling the crisis. In the presence of a crisis the patient's condition will deteriorate rapidly, and the mortality-rate will rise considerably, despite operation, with the increasing length of the crisis. Anglem (1966) found a mortality-rate of 57 per cent. The present *Cases* 3 and 4 had a fatal course which ended in cardiovascular shock.

Acute hyperparathyroidism is most commonly due to an adenoma of the 'chief-cell' type, and less frequently is due to multiple adenomas, diffuse hyperplasia, or cancer (Boquist and others, 1971). In *Cases* 2 and 3 solitary adenomas were found, in *Case* 4 multiple adenomas, and in *Case* 1 diffuse hyperplasia.

It is important to identify all four parathyroid glands during the operation. In the presence of hyperplasia the treatment consists of removal of three and a half glands. This is illustrated by *Case* 1, in which the patient had hyperplastic parathyroid tissue removed by three operations within a period of 14 years, the later two being performed with the patient in a crisis.

POSTOPERATIVE WOUND INFECTION IN COLONIC AND RECTAL SURGERY

By R. C. BURTON

UNIVERSITY OF MELBOURNE, DEPARTMENT OF SURGERY, THE ROYAL MELBOURNE HOSPITAL

Summary

There was a statistically significant association between the species of bacteria isolated from the bowel at operation, and the species subsequently isolated from a postoperative wound infection in 100 patients who underwent colonic or rectal surgery. There was also a statistically significant increase in the incidence of Gram-negative bacteriaemia in patients who developed a wound infection following such surgery. This bacteriaemia was most commonly detected before and during the operation. Its role in the aetiology of postoperative wound infection has not yet been established.

In 1969 a prospective investigation of 100 patients submitted to elective colonic and rectal surgery was carried out in the Royal Melbourne Hospital (Burton, 1972). The purpose of this paper is to report on the aetiology, incidence, and type of postoperative wound infections which occurred in these patients.

METHODS

All the patients were examined daily from the morning before the operation until the day of discharge or death. Systemic venous blood cultures were obtained from each patient on the day before operation, on the day of the operation, before, during, and after the procedure, and then once a day for 5 days, unless the date of admission, discharge, or death occurred within this period. Nineteen patients also had a single peroperative portal venous blood culture. In addition to the blood cultures peroperative swabs of the bowel lumen at the site of the operation were obtained in 92 patients.

When a postoperative infection was suspected bacteriological cultures were taken from the site in question. A postoperative wound infection was recorded when inflammation of the wound, a serosanguineous or purulent discharge, and culture of a pathogen from the discharge were all present. The infections were graded as follows:—

Grade 1: Localized minor inflammation with a serosanguineous discharge only.

Grade 2: Purulent infection with less than half of the wound involved.

Grade 3: Purulent infection with more than half of the wound involved.

RESULTS

Fifteen different operations were performed on the 56 male and 44 female patients included in the study (*Table I*).

Table I.—CORRELATION OF THE OPERATIONS PERFORMED WITH THE DEVELOPMENT OF A POSTOPERATIVE WOUND INFECTION

OPERATION	NO OF PATIENTS	NO. OF PATIENTS WITH WOUND INFECTION
Abdominoperineal resection of the rectum	16	15
Sigmoid colectomy*	16	9
Anterior resection of the rectum	14	8
Closure of colostomy	10	7
Pull-through resection of the rectum	7	2
Right hemicolectomy	6	3
Sigmoid colostomy	6	3
Transverse colostomy	6	3
Total colectomy†	5	3
Left hemicolectomy	4	1
Segmental colonic resection	3	3
Sigmoid colotomy	2	2
Hartmann's resection of the rectum	2	1
Ileotransverse anastomosis	2	0
Caecostomy	1	1
	100	61

* One patient also had a transverse colostomy performed.
† One patient had an ileorectal anastomosis, and 2 an ileostomy.

Table II.—SUMMARY OF 68 CASES OF WOUND INFECTION (61 PATIENTS)

	GRADE I	GRADE II	GRADE III	TOTAL
Abdominal	15	30	9	54
Perineal	5	6	3	14

Sixty-one patients developed a postoperative wound infection, and a total of 68 such infections, of various grades, was recorded (*Table II*). Eight patients developed an intraperitoneal abscess and 3 patients had generalized peritonitis, and in each case an abdominal wound infection was present.

Prophylactic antibiotics were administered to 48 patients, 31 of whom developed a postoperative wound infection. There is no statistically significant difference between the incidence of wound infection in this group and in the group of 52 patients who did not receive prophylaxis. The antibiotics were either given orally preoperatively in a non-absorbable form, or were administered systemically during and/or following the operation. The numbers were too small to make a valid comparison of the régimes employed; however, the lowest incidence of wound infection (5 of 13 patients) was in the patients who received penicillin G intravenously during the operation.

Thirty-one of the 42 patients who had an abdominal intestinal stoma formed or closed during their operation developed an abdominal wound infection. This incidence of wound infection is significantly greater than that in the remaining 58 patients ($P<0·05$, $\chi^2 = 4·9$). The pathogens isolated from the wound, blood, and bowel were, with the exception of 17 *Staphylococcus aureas* wound isolates, all enteric flora (*Table III*). Of the patients with wound infection, 54 had pathogens isolated from their bowel swabs and in 35 cases the species was the same as that isolated from the postoperative wound infection. This association is statistically significant ($P<0·05$, $\chi^2 = 4·7$).

Table III.—ENTERIC PATHOGENS ISOLATED FROM THE BLOOD, WOUND, AND BOWEL CULTURES

SPECIES	NO. OF ISOLATES			
	Blood	Bowel	Wound	Total
Escherichia coli	23	77	46	146
Proteus sp.	8	28	38	74
Klebsiella sp.	28	10	16	54
Enterobacter sp.	28	3	7	38
Paracolon sp	2	2	3	7
Total Enterobacteriaceae sp.	89	120	110	319
Streptococcus faecalis	14	16	13	43
Anaerobes	8	16	10	34
Pseudomonas pyocyanea	3	8	5	16
Total isolates	114	160	138	412

Table IV.—GRAM-NEGATIVE BACTERIAEMIA AND WOUND INFECTION IN 100 PATIENTS

BLOOD CULTURES	WOUND INFECTION	NO INFECTION
Positive	27	8
Negative	34	31

$\chi^2 = 5·8$, $P<0·05$.

Gram-negative bacteriaemia was significantly more common in the patients who developed a postoperative wound infection (*Table IV*). However, only 9 of the 27 patients who had positive blood cultures and a postoperative wound infection had the same species of bacteria isolated from the two sites. This association is not statistically significant.

DISCUSSION

The wound-infection rate following colonic and rectal surgery reported here is high (61 per cent). However, it is comparable to the rates reported by other authors who employed a similar definition of wound infection and kept a careful prospective surveillance for its occurrence. Everett, Brogan, and Nettleton (1969) reported an overall incidence of 58 per cent, and Jepsom, Larsen, and Thomsen (1969) an incidence of 53 per cent in their bowel-surgery cases. Many authors exclude the grade 1 wound infections from their figures, which would reduce the incidence of wound infection in this investigation to 50 per cent. This is comparable to the incidence of 46·2 per cent reported by Kippax and Thomas (1966) in the first year of their survey, and to the figure of 50 per cent reported by Hughes (1967) for the group of patients in his survey who did not receive prophylactic antibiotics.

The very high wound-infection rate in abdomino-perineal resection has been noted by other authors. If the grade 1 infections in this investigation are excluded, this incidence becomes 63 per cent, which is comparable to the figure of 53 per cent reported by Jepsom and others (1969) and also to the 58 per cent of Hughes, Hardy, Cuthbertson, and Rubbo (1970) in the group of patients in their survey who did not receive prophylactic antibiotics. These patients comprise almost one-third of those whose operations involved formation or closure of an intestinal stoma. These procedures are often associated with extensive contamination of the operative field, and therefore, as Cowling (1962) reported from the Royal Melbourne Hospital, the wound-infection rate for these operations is significantly higher.

The predominance of Gram-negative bacilli of the family Enterobacteriaceae is typical of wound infections occurring after colonic and rectal surgery (Rubbo, Hughes, Blainey, and Russell, 1965; Kippax and Thomas, 1966; Azar and Drapanas, 1968). These wound infections are assumed to be endogenous (Everett and others, 1969). The results of this investigation show a statistically significant association between the identity of the bacteria isolated from the colon or rectum at the operative site, and that of the bacteria subsequently recovered from the post-operative wound infection. This provides good evidence that these infections are caused by bacteria spilled into the wound from the bowel during the operation.

The high incidence of systemic and portal Gram-negative bacteriaemia in patients with large-bowel pathology submitted to operation has been previously reported (Eade and Brooke, 1969; Burton, 1971, 1972). Positive blood cultures are most often obtained before or during the operation, and are rarely found after the third postoperative day unless the patient develops severe sepsis (Burton, 1972). The role of Gram-negative bacteriaemia in the causation of post-operative wound infections is uncertain. Although patients who have positive blood cultures do have a statistically significantly increased incidence of postoperative wound infection, there is no statistically significant association between the identities of the bacteria isolated from the blood and the wound infection. There is, however, good experimental evidence that circulating bacteria can lodge in surgical wounds and cause a wound infection (Howe, 1969).

Since a major factor in the aetiology of postoperative wound infections following colonic or rectal surgery is contamination of the wound by enteric bacteria at the time of surgery, then, to be effective, prophylactic antibiotics should be in the tissues at this time. This principle has been proved experimentally (Burke, 1961), and the only double-blind prophylactic antibiotic trials to demonstrate a statistically significant advantage for these agents in human colonic and rectal surgery have employed peroperative systemic antibiotics (Bernard and Cole, 1964—penicillin G + methicillin + chloramphenicol; Polk and Lopez-Mayor, 1969—Cephaloridine; Hughes and others, 1970—penicillin G). Similar investigations have shown that preoperative non-absorbable antibiotics are not effective in the prophylaxis of wound infection (Gaylor, Clarke, Kudinoff, and Finegold, 1960; Everett and others, 1969). Uncontrolled, or non-double-blind trials, are not a worth-while source of evidence in this field, and as there is not yet a published double-blind trial of the use of topical antibiotics prophylactically in colonic and rectal surgery their worth is unknown. In terms of the principle outlined above they should be effective, and one double-blind trial has demonstrated a statistically significant reduction in postoperative wound infection following appendicectomy (Rickett and Jackson, 1969—ampicillin).

Acknowledgements.—I am indebted to Professor M. R. Ewing and all the honorary surgeons, and their registrars and residents, who co-operated with me and encouraged this study in the Royal Melbourne Hospital. This work was supported in part by the Victor Hurley Medical Research Fund of the Royal Melbourne Hospital.

AN EPIDEMIOLOGICAL STUDY OF REGIONAL ENTERITIS IN THE GLOUCESTER AREA

BY J. C. TRESADERN,* M. W. L. GEAR, AND A. NICOL
GLOUCESTERSHIRE ROYAL HOSPITAL

SUMMARY

An epidemiological study has been made of regional enteritis in the Gloucester area during the period from 1 Jan., 1966, to 31 Dec., 1970. There were 19 cases in an average population of 253,000, giving an average incidence of new cases of 1·5 per 100,000 per year. There was a significant peak of cases in the 15–24 age-group. The incidence in men was slightly higher than in women. There was a family history of ulcerative colitis in 2 cases. There were 3 cases of regional enteritis of the large bowel only, all occurring in women. Extensive large- and small-bowel involvement occurred predominantly in the younger patients.

ONLY two studies of regional enteritis in the United Kingdom have provided an incidence rate for a defined geographical area (Evans and Acheson, 1965; Kyle and Blair, 1965). In addition, Davis (1961) derived an approximate incidence rate based on the records of three London hospitals. In a review of regional enteritis Law (1969) stated: 'To make such data [incidence rates] even more useful, we should have incidence and prevalence rates from different parts of the country and the world.' We hope that this study will enhance the usefulness of those mentioned above.

STUDY METHODS

The design of this survey is based on that of Evans and Acheson (1965) with modifications. A 5-year period was reviewed from 1 Jan., 1966, to 31 Dec., 1970. The geographical area under review was that covered by the Gloucester, Stroud, and Forest Hospitals Group which serves eleven urban and rural districts. Population figures were determined from the *Municipal Year Book* for each year. The distribution by age and sex was obtained from the Office of Population Censuses and Surveys. The total population per year was almost static, rising from 248,000 in 1966 to 258,000 in 1970, an increase of about 4 per cent. An earlier independent study for the Hospital Management Committee had shown that of the people in the catchment area who required admittance to hospital for any reason, less than 2 per cent were referred to hospitals outside the study area.

Retrieval of Cases.—The primary source of information was the in-patient diagnostic index of the Gloucestershire Royal Hospital covering the period stated. To allow for delay either in admitting a case or in establishing the correct diagnosis the records for 1971 were also reviewed. Dyer and Dawson (1970) indicated an initial misdiagnosis rate of up to 27 per cent of cases of regional enteritis as some form of colonic disorder; accordingly, notes of all the patients who were admitted with a diagnosis of ulcerative colitis, chronic colitis, sigmoiditis, diverticulitis, proctitis, and miscellaneous bowel disorders were reviewed. From all of these sources 38 possible cases were retrieved. Inquiry of the hospital's consultant physicians and surgeons concerning their private practice produced 2 more cases.

This study was restricted to patients who were admitted to hospital at some time during their illness. This approach was dictated by the fact that there is no out-patient diagnostic index, and it would be quite impractical to review the notes of every hospital out-patient. Of all the patients with regional enteritis who were traced 80 per cent were admitted within 3 months of first presenting at an out-patients' clinic and 90 per cent within 12 months. The search of in-patients' records for 1971 also ensured as complete a retrieval of cases as possible. Discussions with the consultant staff indicated that no patient with regional enteritis was being treated or followed as an out-patient who had not already been admitted for investigation or operation.

ASSESSMENT OF CASES

Initially a total of 40 case histories was scrutinized for acceptance, the criteria for which are listed below.

Presentation.—Cases were only accepted for this series if they had presented for consultant opinion during the period studied. Ideally the date of onset of symptoms should be the point of acceptance to the series, but this date is difficult to establish. In some patients the first symptoms complained of were so vague that it was difficult to be sure that they were due to regional enteritis, even in retrospect. Other patients, particularly those with long histories, could not give an accurate date of the onset of symptoms. In contrast, the date of first presentation to a consultant is accurately known for all the patients. In fact, about 75 per cent of our series presented within 6 months of their first symptoms. A total of 15 cases was rejected from the series because they were first seen before the study period.

Residence.—Cases were rejected if the patient had not been resident in the study area for at least a year prior to presentation. Only 1 case was rejected on these grounds. All the patients in the final series had been resident in the area for at least 10 years and 75 per cent were born in the area.

Diagnostic Criteria.—The diagnostic methods used were radiology, laparotomy, and histology. According to the findings, cases were either put into one of two categories: 'definite regional enteritis' and 'probable regional enteritis', or rejected. Cases had to meet at least one of the following criteria to be included in the series:—

1. A characteristic radiological appearance seen on barium follow-through and/or barium-enema examinations.

---

* Present address: Radcliffe Infirmary, Oxford.

2. A characteristic macroscopic appearance at laparotomy.

3. Characteristic microscopic appearances in biopsies taken at laparotomy or sigmoidoscopy.

Cases were only designated as 'definite regional enteritis' when a histological diagnosis was available. If the histology report was inconclusive (usually reported as 'compatible with regional enteritis') the case was designated 'probable regional enteritis', provided that the other criteria were satisfied. All the histological material was reviewed by one of us (A. N.) with no prior knowledge of the clinical histories. One case was rejected because the clinical and laparotomy findings were not sufficiently characteristic of regional enteritis and no biopsy had been taken. Four other cases were rejected because no evidence of regional enteritis was seen on review of the histological material.

ACCEPTED CASES

The final series comprised 19 cases; 6 of these were designated 'definite regional enteritis' with typical appearances at laparotomy and on microscopy. The other 13 were classified as 'probable regional enteritis'. Of the latter category, 2 were diagnosed without laparotomy; both were severe and clinically typical with unequivocal radiological evidence of the disease. A further 2 cases in this 'probable' category were diagnosed on laparotomy appearances only, no biopsy being taken. These patients, presenting initially as suspected acute appendicitis, were probably cases of so-called 'acute' regional enteritis and have been asymptomatic since discharge from hospital. A further 'acute' case was diagnosed on the basis of radiology and laparotomy, the histology of a mesenteric node being inconclusive.

Follow-up.—Nine of the patients in the series are currently being followed up in the out-patients' clinic. Two others have only recently defaulted from follow-up. Postal questionnaires were sent to all the patients, inquiring about their present medical condition, residential history, family history, associated disorders, etc.

RESULTS

Incidence.—The average annual population for the 5-year study period was 253,000. There was a total of 19 new cases, giving an average incidence of 1·5 cases per year per 100,000 of population.

Age and Sex.—The distribution of the sexes in the general population in the study area is 49 per cent males and 51 per cent females. In our series there were 10 males and 9 females. The average incidence in each sex, therefore, was 1·61 males and 1·39 females per 100,000. The difference is not significant.

The age-group and sex distribution of the cases are shown in *Table I*. Separate incidence rates are calculated for each age-group, but not for each sex in any one age-group. The youngest patient was 12 at presentation and the oldest, 77.

As shown in *Table I* there is a peak incidence of 5·05 per 100,000 in the age-group 15–24. Compared with the adjacent age-groups this difference is statistically significant. Differences between other age-groups are not statistically significant. There is no bias in the distribution of sexes within each age-group.

Geographical Distribution.—The patients' addresses were plotted on a 3-miles-to-the-inch map of the study area. There was no grouping of the cases other than that expected on the basis of population differences. In addition, the cases occurring in the city of Gloucester were plotted on a large-scale street map of the city. Again there was no obvious grouping.

Table I.—AGE AND SEX DISTRIBUTION OF 19 CASES OF REGIONAL ENTERITIS

AGE-GROUP (yr.)	ESTIMATED POPULATION	NO. OF CASES OBSERVED			INCIDENCE PER 100,000	95 PER CENT CONFIDENCE LIMITS
		Male	Female	Total		
0–14	62,700	0	1	1	0·32	*–1·78
15–24	35,600	5	4	9	5·05	2 31–9 60
25–34	33,400	1	0	1	0 60	*–3·33
35–54	65,600	3	1	4	1 22	0·33–3·12
55–74	45,800	1	2	3	1·31	0·27–3·83
75+	9900	0	1	1	2·10	*–11·25

* The value of the lower confidence limit was so small that a detailed calculation was not recorded.

Table II.—SITES OF INVOLVEMENT IN 19 CASES OF REGIONAL ENTERITIS

SITE	SEX			PERCENTAGE OF TOTAL	NO. OF CASES	
	Male	Female	Total		Under 25 Years	Over 25 Years
Small bowel only	6	4	10	52·4	4	6
Large and small bowel	3	3	6	31·8	5	1
Large bowel only	0	3	3	15·8	1	2

Family History.— A number of surveys have shown that up to 11 per cent of patients with regional enteritis have blood relatives with either regional enteritis or ulcerative colitis (Kirsner and Spencer, 1963). Two of our 19 patients (11·5 per cent) have relatives with ulcerative colitis.

Associated Disorders.—Inquiry was made for disorders which have previously been reported to be associated with regional enteritis. Skin disorders are a common association (Dyer, Verbov, Dawson, Borrie, and Stansfeld, 1970); 1 of our patients had psoriasis of many years' standing, a second case had erythema and hyperkeratosis of the hands for some months, and a third had intermittent diffuse skin rashes for many years. An association with hepatobiliary disease has also been reported (Palmer, Kirsner, Goldgraber, and Fuentes, 1963; Dordal, Glagov, and Kirsner, 1967; Perrett, Higgins, Johnston, Massarella, Truelove, and Wright, 1971). One of our patients admitted to having had a 'liver disorder' in the past, the precise nature of which could not be ascertained.

Sites of Involvement.—The sites of involvement are shown in *Table II*. The age and sex distributions are also shown. All the patients with disease confined to the large bowel were females. Of the 6 patients with large- and small-bowel involvement, 5 were aged under 25. One aged 16 was a particularly severe case with lesions in the ileum, caecum, colon, and rectum, and a probable lesion in the jejunum. Another patient aged 12 had extensive involvement of the colon and jejunum.

Race and Mortality.—All the patients were white United Kingdom citizens. There were no deaths in this series.

Chronological Distribution.—The number of new cases occurring in each of the 5 years studied was determined. There was no distinct pattern in the distribution and so separate incidence rates for each year were not calculated. We would not expect to see any pattern in such a short study period.

DISCUSSION

The average annual incidence of regional enteritis in this series was 1·5 new cases per 100,000 population. This compares with previous reports of 0·8 in Oxford (Evans and Acheson, 1965), 1·3 in North-east Scotland (Kyle and Blair, 1965), and 1·0 (approx.) in London (Davis, 1961). Comparison may also be made with thyroid carcinoma (1·4 per 100,000) and Hodgkin's disease (2·37 per 100,000). At first sight there appears to be a regional variation in incidence, particularly between Gloucester and Oxford, which are geographically closely related. However, with a condition as uncommon as regional enteritis these differences are not significant and could represent the sampling errors inherent in such small series (34 cases in the Oxford study).

The sex distribution showed a slight male preponderance, though this was not significant.

With regard to age-specific incidence, regional enteritis is traditionally considered to affect mainly young adults (Crohn, Ginzburg, and Oppenheimer, 1932; Thayer, 1970). Monk, Mendeloff, Siegel, and Lilienfeld (1967) determined age-specific incidence rates for the disease in Baltimore, U.S.A., and concluded that there is 'no age pattern evident in regional enteritis', but the condition was studied only in persons aged 20 years or over. The present study is the first in the United Kingdom to produce age-specific incidence rates, and we found a definite and statistically significant peak in the 15–24 age-group. This appears to be superimposed on a general trend of increasing incidence with increasing age. Although this latter trend is not statistically significant, we believe it may represent the generally increasing susceptibility to disease that occurs with ageing.

Regional enteritis of the large bowel only has been found to be more common in females than in males, and it also tends to occur in an older age-group than small-bowel disease (Cornes and Stetcher, 1961). In the present series all cases of primary large-bowel disease occurred in females. Five of our 6 patients with both the large and small bowel involved were aged under 25. Two patients with jejunal involvement were aged 12 and 16 respectively. It seems, therefore, that extensive severe disease is more likely to occur in the younger patient. The relative frequency of large- and small-bowel lesions matches closely that reported by Atwell, Duthie, and Goligher (1965).

Acknowledgements.—We would like to express our thanks to all who helped in the carrying out of this survey, especially the staff of the Medical Records Department of the Gloucestershire Royal Hospital. We are indebted to Dr. Martin Vessey, of the Department of the Regius Professor of Medicine at Oxford, for his helpful advice and encouragement. We would also like to thank those consultants and general practitioners who supplied us with information.

IN BRONCHITIS early optimism confirmed by further clinical experience

“On the basis of our earlier experience,[1] we said of trimethoprim that ‘we believe it to represent a major discovery and to have far-reaching therapeutic possibilities.’ Not only have we had no subsequent reason to alter this belief, but in our view some very promising possibilities have yet to be explored.”[2]

More effective than ampicillin or tetracycline

In the reduction obtained in sputum volume and purulence SEPTRIN* has been shown to be superior to either ampicillin or tetracycline.[3,4]

Highly active against both primary and secondary invaders

"... not only are the two primary pathogens *Strep pneumoniae* and *H influenzae* sensitive, but so are secondary invaders such as klebsiella which often replace them after antibiotic treatment."[2]

"It is seldom at the completion of a clinical trial that authors are inclined to classify an antimicrobial ..., but in this case, on our results, we feel that the combination of trimethoprim plus sulphamethoxazole can only be considered excellent on the criteria originally specified, namely the elimination of the infecting microorganism."[5]
